

ENOC 2022

ENOC 2022 - Book of abstracts

10th European Nonlinear Dynamics Conference

July 17-22, 2022
Lyon, France

ORGANIZERS

Local Organizing Committee (LOC)

Claude Henri Lamarque (Chair)

Régis Dufour (Co-Chair)

Fabrice Thouverez (Co-Chair)

Louis Jézéquel (Honorary Chairman)

Sébastien Baguet (Secretary General)

Administrative support (INSAVALOR)

Muriel Personne

Secretarial support

Zahia Achoui, Cécile Demornex

Local organizing committee

Sébastien Besset

Laurent Blanc

Emmanuel Gourdon

Alain Le Bot

Lionel Manin[†]

Lyes Nechak

Joel Perret-Liaudet

Didier Rémond

Emmanuel Rigaud

Jean-Jacques Sinou

Alireza Ture Savadkoobi

[†] Lionel left us in may 2021. We would like to acknowledge his memory and his dynamic involvement in the organizing committee.

European Nonlinear Oscillations Conference Committee (ENOCC)

Gaëtan Kerschen (Chair)

University of Liege, Belgium

Katrin Ellermann

University of Graz, Austria

Alexander Fidlin

Karlsruher Institut für Technologie, Germany

Oleg Gendelman

Technion, Israel Institute of Technology, Israel

Ivana Kovačić (Co-chair)

University of Novi Sad, Faculty of Technical Sciences, Serbia

Claude-Henri Lamarque

University of Lyon, France

Stefano Lenci

Università Politecnica delle Marche, Italy

Andrei Metrikine

Delft University of Technology, The Netherlands

Ekaterina Pavlovskaja

University of Aberdeen, UK

Gabor Stepan

Budapest University of Technology and Economics, Hungary

Scope of the conference

Although the brand name ENOC is still used as the historical abbreviation, the present European Nonlinear Dynamics Conferences organized by EUROMECH aim at covering the complete field of Nonlinear Dynamics, including Multibody Dynamics and coupling to Stability, Identification, Control and (Structural) Optimization.

Presently, ENOCs are the largest, high-quality, scientific events in the broad area of nonlinear dynamics not only in Europe but on a worldwide basis. Indeed, parallel important events organized by other Societies often cover partial aspects of the whole scientific area, for being either more theoretically or more engineering oriented.

In contrast, ENOC encompasses many diverse topics ranging from dynamical systems theory to different engineering applications, and collects scholars from theoretical and applied mechanics as well as from applied mathematics and physics, within an actually cross-disciplinary framework.

The 10th European Nonlinear Dynamics Conference (ENOC 2022) is held in Lyon, France and is organized by the University of Lyon at the Lyon Convention Centre.

ENOC History

Since 1992, EUROMECH organizes European Nonlinear Oscillations Conferences through the European Nonlinear Oscillations Conference Committee (ENOCC). Actually, these events have a much longer tradition, since they are successors of the former ICNO (International Conference on Nonlinear Oscillations) series held from 1961 to 1990 in East-European countries. Starting from the 1st International Conference on Nonlinear Oscillations in Kiev, 1961, twelve ICNOs were organized till 1990. Then, starting with the 1st European Nonlinear Oscillations Conference in Hamburg, 1992, nine ENOCs were organized till 2017 (Prague, Copenhagen, Moscow, Eindhoven, St. Petersburg, Rome, Wien and Budapest).

Both the ICNO and ENOC series of conferences intend to be a meeting place for nonlinear dynamics' scientists from all over the world, where in particular "East meets West"

ENOC 2022 - Program overview

KEYNOTE LECTURES

Auditorium Lumière - 11:00-12:00

Monday, July 18, 2022

On Exact Analytical Solutions for Free and Forced Discrete and Continuous Nonlinear Oscillators

Ivana Kovačić

University of Novi Sad, Faculty of Technical Sciences, Serbia

Tuesday, July 19, 2022

On the role of nonlinear dynamics in the installation, operation and monitoring of offshore wind turbines

Andrei Metrikine

Faculty of Civil Engineering, TU Delft

Wednesday, July 20, 2022

Engineering Nonlinearity

Oleg Gendelman

Technion - Israel Institute of Technology, Haifa, Israel

Thursday, July 21, 2022

High damping metamaterials with hysteretic resonators

Walter Lacarbonara

Department of Structural and Geotechnical Engineering, Sapienza University of Rome, Italy

Friday, July 22, 2022

Computing nonlinear modes in complex continuum mechanical models

Bruno Cochelin

École Centrale de Marseille, University of Marseille, France

Mini-Symposia (MS) Co-organizers

MS-01 Reduced-Order Modeling and System Identification

Lawrence A. Bergman, University of Illinois at Urbana-Champaign, USA

Mehmet Kurt, Stanford University, USA

Keegan Moore, University of Nebraska-Lincoln, USA

MS-02 Asymptotic Methods

Jan Awrejcewicz, University of Lodz, Poland

Igor V. Andrianov, Aachen University, Germany

Leonid I. Manevitch†, Russian Academy of Sciences, Russia

Livija Cveticanin, University of Novi Sad, Serbia

† Leonid Manevich left us in the summer of 2020. We would like to pay tribute to him.

MS-03 Computational Methods

Jan Sieber, University of Exeter, UK

Harry Dankowicz, University of Illinois at Urbana-Champaign, USA

Themistoklis Sapsis, Massachusetts Institute of Technology, USA

MS-04 Experiments in Nonlinear Dynamics and Control

Hiroshi Yabuno, University of Tsukuba, Japan

Walter Lacarbonara, University of Rome, Italy

Guilhem Michon, University of Toulouse, France

MS-05 Slow-Fast Systems and Phenomena

Jon Juel Thomsen, Technical University of Denmark, Denmark

Anatoly Neishtadt, Loughborough University, UK

D. Dane Quinn, The University of Akron, USA

MS-06 Fractional Derivatives

Pierre Melchior, Bordeaux Institute of Technology, France

Dana Copot, Ghent University, Belgium

MS-07 Dynamics and Optimization of Multibody Systems

Felix L. Chernousko, IPMech RAS, Russia

József Kövecses, McGill University, Canada

Werner Schiehlen, University of Stuttgart, Germany

MS-08 Nonlinear Phenomena in Mechanical and Structural Systems

Jerzy Warmański, Lublin University of Technology, Poland

Bala Balachandran, University of Maryland, USA

Sotirios Natsiavas, Aristotle University of Thessaloniki, Greece

MS-09 Nonlinear Dynamics in Engineering Systems

Yuri Vladimirovich Mikhlin, National Technical University “Kharkov Polytechnical Institute”, Ukraine

Matthew Cartmell, The University of Strathclyde, Scotland, UK

Konstantin Vitalievich Avramov, NAS of Ukraine, Ukraine

Francesco Pellicano, University of Modena and Reggio Emilia, Italy

MS-10 Non-Smooth Dynamics

Remco Ingmar Leine, University of Stuttgart, Germany

Vincent Acary, INRIA, France

Olivier Brûls, University of Liège, Belgium

MS-11 Systems with Time Delay

Zaihua Wang, Nanjing University of Aeronautics and Astronautics, China

Tamas Insperger, Budapest University of Technology and Economics, Hungary

Gabor Orosz, University of Michigan at Ann Arbor, USA

MS-12 Micro- and Nano-Electro-Mechanical Systems

Slava Krylov, Tel Aviv University, Israel

Anil Bajaj, Purdue University, USA

E.M. Abdel-Raman, University of Waterloo, Canada

MS-13 Nonlinear Dynamics in Biological Systems

Gert van der Heijden, University College London, UK

Gergely Röst, University of Szeged, Hungary

Soheil Fatehiboroujeni, UC Merced, USA

MS-14 Nonlinear Dynamics for Engineering Design

Marco Amabili, McGill University, Canada

Stefano Lenci, Università Politecnica delle Marche, Italy

Bogdan Epureanu, University of Michigan, USA

MS-15 Energy Transfer and Harvesting in Nonlinear Systems

Alexander Vakakis, University of Illinois at Urbana-Champaign, USA
Oleg Gendelman, Technion, Israel Institute of Technology, Israel

MS-16 Random Dynamical Systems - Recent Advances and New Directions

Rachel Kuske, School of Math, Georgia Tech, USA
Daniil Yurchenko, Heriot-Watt University, UK

MS-17 Time-periodic systems

Tamas Kalmar-Nagy, Budapest University of Technology and Economics, Hungary
Thomas Pumhössel, Johannes Kepler Universität, Austria
Zoltán Dombóvári, Budapest University of Technology and Economics, Hungary

MS-18 Control and Synchronization in Nonlinear Systems

Nathan van de Wouw, Eindhoven University of Technology, The Netherlands
Bernard Brogliato, INRIA Grenoble Rhône-Alpes, France
Alexey Pavlov, Norwegian University of Science and Technology (NTNU), Norway

MS-19 Fluid-Structure Interaction

Andrei Metrikine, Delft University of Technology, The Netherlands
Oded Gottlieb, Technion - Israel Institute of Technology, Israel
Kerry Hourigan, Monash University, Australia

MS-20 Wave propagation in Mechanical Systems and Nonlinear Metamaterials

Francesco Romeo, Sapienza University of Rome, Italy
Yuli Starosvetsky, Technion, Israel Institute of Technology, Israel
Marco Lepidi, University of Genova, Italy

MS-21 Nonlinear Dynamics in Acoustics

Cyril Touzé, ENSTA ParisTech, France
Olivier Thomas, ENSAM Lille, France
Jose Antunes, Instituto Superior Técnico, University of Lisbon, Portugal
Stefan Bilbao, University of Edinburgh, UK

MS-22 Special session dedicated to L.I. Manevitch

Yuri V. Mikhlin, National Technical University «Kharkiv Polytechnic University», Ukraine
Igor V. Andrianov, Aachen University, Germany
Oleg V. Gendelman, Technion, Israel Institute of Technology, Israel

ENOC 2022 MS Sessions

Monday, July 18, 2022

13:30 - 15:30 MS-04 Experiments in Nonlinear Dynamics and Control (Rhone 3B)	11
13:30 - 15:30 MS-15 Energy Transfer and Harvesting in Nonlinear Systems (Rhone 1)	26
13:30 - 15:30 MS-07 Dynamics and Optimization of Multibody Systems (Saint Clair 2)	36

Summary. Nonlinear gear dynamic response and rattle noise induced by vibroimpacts between gear teeth are investigated using a specific experimental set-up allowing the visualization of impacts thanks to a high-speed camera. The control parameters during the experiment are the drag torque, the mean drive gear rotational speed, and the velocity fluctuation amplitude and frequency. Most of the time, an almost 1T-periodic response is observed with 2 impacts per period. A contact phase between gear teeth is observed after each impact instead of an instantaneous rebound. The number of successive tooth pairs crossing the meshing zone without any contact between gear teeth varies according to the ratio of the excitation frequency to the rotation frequency. Analytical and numerical works performed using a gear rattle model show good agreement with the experiments. Finally, the sound pressure emitted from the gear pair is measured. The acoustic power imputable to gear rattle is found to be proportional to the total kinetic energy transferred per second to the system by the successive impacts.

Introduction

Many geared systems, are subjected to such external excitations that contact losses between gear teeth may occur under some particular operating conditions (e. g. manual automotive gearbox [1], roots vacuum pump [2]). The nonlinear gear dynamic response is then characterized by impacts between the active and/or the reverse tooth flanks, leading to a broadband noise emitted from the mechanical system known as gear rattle noise. In this study, a specific experimental set-up is designed to analyse the rattle behaviour of a spur gear. Most of the key parameters governing the nonlinear dynamics are controlled during the experiments, that is to say the velocity fluctuation amplitude and frequency of the drive gear, the inertia of the output gear, the drag torque, and the gear backlash. Unlike most systems and experimental studies, the vibratory level of the drive gear is controlled independently of its mean rotational speed. Operation is performed without oil lubrication in order to allow simple modelling of the elastic and damping characteristics during impacts and easy direct visualization of the meshing zone, thanks to a high-speed camera. The occurrence of successive impacts between gear teeth obtained from video post-processing are then coupled with the gear dynamic transmission error measurement thanks to high resolution optical encoders. Finally, the sound pressure generated by successive impacts between gear teeth is also measured thanks to a microphone.

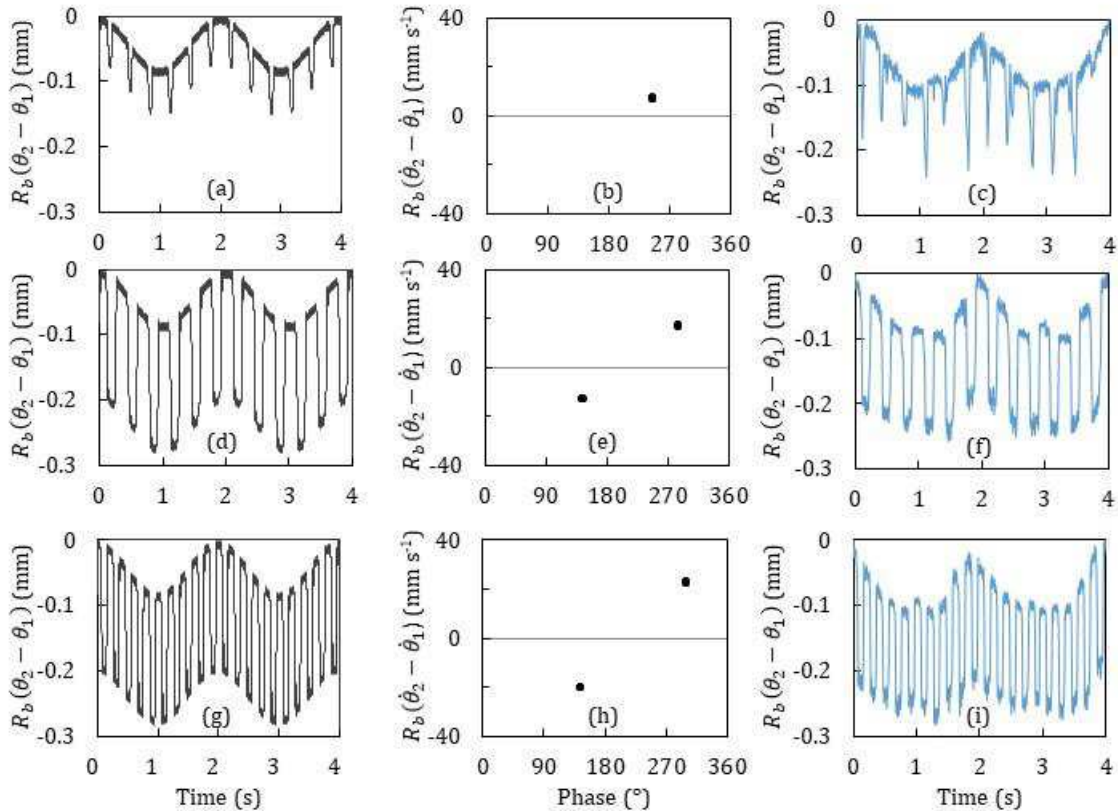

Figure 1: Impact response (numerical transmission error, Poincaré section, experimental transmission error) for several velocity fluctuation frequency and amplitude.

Nonlinear gear dynamic responses

The instantaneous drive gear velocity is:

$$\Omega(t) = \Omega_0 + \Delta\Omega \sin(\omega t) \quad (1)$$

The piloting allows increasing and decreasing sweeps of the mean rotational speed Ω_0 , the velocity fluctuation amplitude $\Delta\Omega$ and frequency ω . Parameters are controlled independently. First, the effect of velocity fluctuation amplitude $\Delta\Omega$ is analysed for a chosen excitation frequency ω . Second, the effect of the excitation frequency ω is analysed for a chosen velocity fluctuation amplitude $\Delta\Omega$. For a very low excitation, an almost permanent contact between the active flanks is observed. When the amplitude is increased, the rattle threshold is reached. Video post-processing (see figure 2) and dynamic transmission error response (see figure 1) show noticeable contact losses and impacts. First, impacts only occur between the active flanks with a low impacting velocity, because the excitation amplitude is still too low to cross the gear backlash. Larger excitation amplitude leads to successive impacts alternating between the active and the reverse flanks. The output gear crosses the gear backlash forward and backward. Each impact is followed by a persistent contact phase between the gear teeth. The free flight period and the following persistent contact phase show a duration of the same order of magnitude. Considering the period of the excitation $T = 2\pi/\omega$, the gear dynamics corresponds to a $1T$ -periodic response with 2 impacts per period. Poincaré sections show that impact phases and impacting velocities are almost constant for all the successive impacts between the active flanks, as well as for all the impacts between the reverse flanks. Visualization confirms that the number of successive tooth pairs in contact and the number of successive tooth pairs crossing the meshing zone without any contact between gear teeth vary according to the ratio of the excitation frequency to the rotation frequency.

Figure 2: Sequence of images of the contact along a period of excitation.

The gear rattle dynamics is modelled with a SDOF bouncing ball with two moving walls excited by the velocity fluctuation. After adjustment of the restitution coefficient modelling the damping characteristics during impacts, a very good agreement between experimental and numerical results is observed. A slight difference is confirmed between active flanks impacts and reverse flanks impacts for which the impacting velocity is slightly lower. The squared impacting velocity transferred to the system, shows a linear relationship with the product $\omega\Delta\Omega$. It is proportional to the impacting kinetic energy which is entirely transferred to the system, because of the persistent contact observed after the impact. Taking account of the number of impacts per second proportional to ω , the assumption that the acoustic power generated by the successive impacts is proportional to the energy transferred to the system per second i.e. parameter $\omega^2\Delta\Omega$, is validated by rattle noise measurement. For low amplitude of parameter $\omega^2\Delta\Omega$, the successive impacts are clearly audible once they occur, but the sound pressure radiated from the system is mainly due to the gear whining noise. For larger amplitude of parameter $\omega^2\Delta\Omega$, the rattle noise induced by the successive impacts becomes the main source of acoustic nuisance.

Ensemble Models for Identification of Nonlinear Systems with Stick-Slip

Ingrid Pires*, Helon Vicente Hultmann Ayala* and Hans Ingo Weber*

**Department of Mechanical Engineering, Pontifical Catholic University, Rio de Janeiro, Brazil*

Summary. The nonlinear interactions between the drilling equipment and the rock formation result in torsional, axial, and lateral oscillations in oil drilling routines. Concerning torsional oscillations, the stick-slip phenomenon is the most severe stage. This kind of self-sustained vibrations compromise the performance of mechanical systems. Accordingly, adequate mathematical models are required to analyze these vibrations. In this work, we study two different ways of combining system identification techniques. We employ time-domain data of an experimental setup to build ensemble models. Then we simulate the system and compare their effectiveness in enhancing the accuracy of model predictions and reproducing the stick-slip phenomenon.

Introduction

The nonlinear interactions between the drilling equipment and the rock formation result in torsional, axial, and lateral oscillations in oil drilling routines. The stick-slip phenomenon is the most severe stage of torsional oscillations. In these drilling processes, the phenomenon of stick-slip is the alternation of two phases: the stick phase, in which the drill bit remains stopped by the resistive torque, and the slip phase, which begins when the stored energy overcomes the resistive torque, and the bit is set in motion.

Stick-slip oscillations compromise the performance of mechanical systems [1], therefore proper mathematical descriptions are required to simulate and analyze the system. Extensive surveys on drill string modeling and dynamics can be found in [2, 3].

A common practice is to model the nonlinear interaction between the drill string and rock as dry friction. Regarding the stick-slip phenomenon, the complexity of the analysis lies in the fact that two different friction mechanisms govern the motion. During the stick phase, the static friction rules the motion, while velocity-dependent kinetic friction governs it during the slip phase [1].

Practical limitations of analytical analysis motivate the application of system identification, which comprises a set of techniques for building data-based models. The author of [4] classifies system identification techniques in white, gray, and black-box. They differ from each other by the amount of prior knowledge employed in the construction of mathematical models.

This paper explores two different methods of building ensemble models for an experimental drill string setup. The ensemble model, in this context, consists of a combination between grey and black-box approaches. The test rig used in this study uses dry friction contact to simulate the nonlinear interactions present in drilling routines. We employ time-domain data to build the ensemble models and compare their effectiveness in enhancing the accuracy of model predictions and reproducing the stick-slip phenomenon. The main contribution of this work is the investigation of the suitability of the ensemble of gray and black-box approaches for the identification of systems with friction-induced vibrations.

Experimental system

The test rig employed in this study is a horizontal apparatus composed of a DC motor connected to two solid discs by a low stiffness shaft. The shaft transmits torque and motion from the DC motor to the discs, which are free to rotate. Figure 1 displays a picture of the experimental setup.

Figure 1: Experimental test rig composed of DC motor, solid discs, and low stiffness shaft.

The rig can replicate the undesired torsional vibrations present in drilling routines. Two braking devices act on the solid

Figure 2: Measured time history of (top) disc angular velocity, ω_d ; and (bottom) motor torque, τ_m .

discs to induce friction torque, leading the system to exhibit torsional oscillations and stick-slip. Only the subsystem composed of one of the discs, the intermediary one, and the shaft connecting it to the DC motor is considered in this work.

The dynamical model

Assuming that the subsystem composed of the intermediary disc and the shaft connecting it to the DC motor behaves as a torsional pendulum and that the only resistive torque in the system is caused by the friction torque induced by the braking device, we modeled it as:

$$\begin{aligned} J_d \ddot{\theta}_d + c(\dot{\theta}_d - \dot{\theta}_m) + c_d \dot{\theta}_d + k(\theta_d - \theta_m) &= -T_f, \\ J_m \ddot{\theta}_m + c(\dot{\theta}_m - \dot{\theta}_d) + c_m \dot{\theta}_m + k(\theta_m - \theta_d) &= \tau_m, \end{aligned} \quad (1)$$

where the moments of inertia of the disc and the motor are J_d and J_m . The shaft stiffness is denoted by k and the internal damping by c . c_d and c_m are the external dampings. θ , $\dot{\theta}$, and $\ddot{\theta}$ are the angular displacement, angular velocity, and angular acceleration of the inertias, respectively. The resistive friction torque on disc D2 is denoted by T_f , and the torque transmitted to the mechanical subsystem is denoted by τ_m .

The experimental data

We utilized a LabView-based Data Acquisition System (DAQ) to measure forces, displacements, and velocities. Figure 2 shows the time histories of the disc angular velocity (top) the motor torque (bottom). The motor torque is the system input, and the disc angular velocity is the system output.

We acquired these records for a nominal angular velocity of 5.76 rad/s and an average normal contact force between pin and disc of 50 N . As we can observe in Fig. 2, this combination of nominal angular velocity and normal force leads the system to exhibit stick-slip oscillations. The signals were recorded for 270 seconds.

Methodology

This analysis employs the test rig physical description in two different ensemble models to improve the precision of the predictions. There are three approaches for system identification: white, gray, and black-box. The techniques differ from each other by the amount of prior knowledge used in the mathematical models' construction. The white-box approach applies only physical insight, the gray-box uses less physical information, and the black-box does not involve a priori knowledge. The ensemble models studied in this paper are combinations of gray and black-box components.

This study compares two different methods of building ensemble models. According to [5], one method to build an ensemble model is to use a white-box as a mean function and fit the model residuals using a black-box algorithm. Instead, in this study, we used the gray-box model as a mean function and modeled the residuals with a black-box algorithm:

$$\hat{y}_e = \overbrace{f(x, u)}^{\text{gray-box}} + \overbrace{g(\hat{e}, u)}^{\text{black-box}} \quad (2)$$

where \hat{y}_e is the predicted output of the ensemble model. \hat{y}_e is a sum of the predicted system model output $\hat{y}_m = f(x, u)$ and the predicted model residual $\hat{e} = g(\hat{e}, u)$. The predicted system output \hat{y}_m is a function of the system input u , and space states x , and the predicted error \hat{e} is a function of the system input u and itself. Another way to construct an ensemble model is to use the information encoded in a white or a gray-box model as an additional input to the black-box. Here, we used the gray-box model output as an input to the black-box as follows:

$$\hat{y}_e = \overbrace{h(e, \underbrace{f(x, u)}_{\text{gray-box}})}^{\text{black-box}} \quad (3)$$

h is a function of the model residual, e , and the output of the gray-box model $f(x, u)$. For simplicity, we name (2) Model 1 and (3) Model 2 in the analysis. Figure 3 gives a general overview of the methodology employed for the formulation of Model 1 and Model 2.

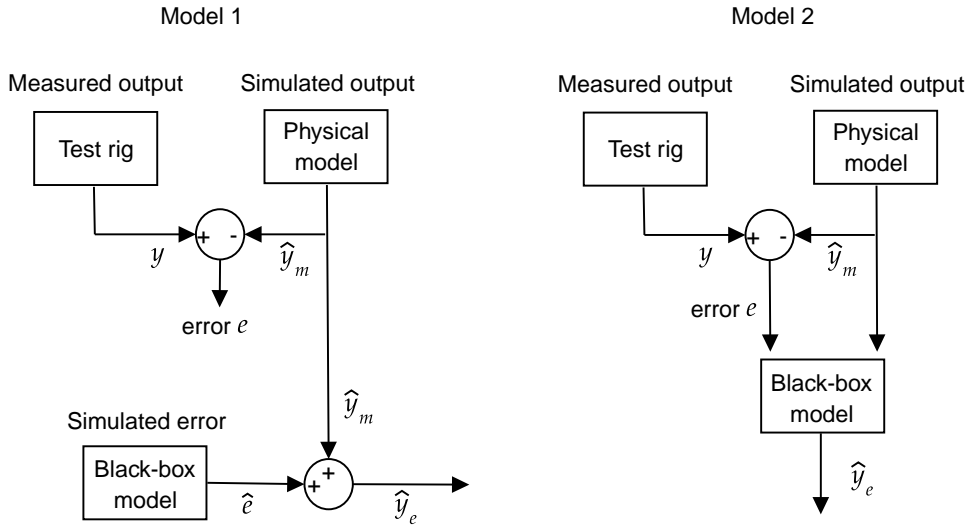

Figure 3: Methodological formulations for (right) Model 1, and (left) Model 2.

Gray-box model

Physical and semi-physical models are particular cases of gray-box models and are related to the estimation of the physical parameters of a system. To estimate the physical parameters of the test rig described by (1), we defined the following state-variables:

$$\mathbf{x} = [\delta \quad \dot{\theta}_d \quad \dot{\theta}_m]^T,$$

where $\delta = \theta_d - \theta_m$ is the angular difference. Therefore, (1) can be rewritten as a state-space system as follows:

$$\begin{aligned} \dot{\mathbf{x}} &= \begin{bmatrix} 0 & 1 & -1 \\ -k/J_d & -(c+c_d)/J_d & c/J_d \\ k/J_m & c/J_m & -(c+c_m)/J_m \end{bmatrix} \mathbf{x} + \begin{bmatrix} 0 & 0 \\ -1/J_d & 0 \\ 0 & 1/J_m \end{bmatrix} \begin{bmatrix} T_f \\ \tau_m \end{bmatrix} \\ y_m &= [0 \quad 1 \quad 0] \mathbf{x} \end{aligned} \quad (4)$$

where y_m is the output of our gray-box model. The system of (4) is nonlinear since resistive friction torque T_f is a nonlinear function of the disc angular velocity ω_d . T_f is given by:

$$T_f = F_f a, \quad (5)$$

where a is the distance between the disc center and the disc-pin contact point. F_f is the friction force.

The Coulomb friction model states that friction opposes the relative motion between contacting surfaces, and its magnitude is proportional to the normal contact force. The classical Coulomb friction model presents a velocity dependence by the sign function that introduces a discontinuity in the system of ODEs. The regularized Coulomb friction model, instead,

considers the hyperbolic tangent with the transition velocity, v_t , approximation for this study to avoid discontinuities. The following equation defines the regularized model:

$$F_f = F_C \tanh\left(\frac{v}{v_t}\right). \quad (6)$$

where F_f is the friction force, $F_C = \mu_k F_N$ is the magnitude of the Coulomb friction, v is, from the perspective of the body, the relative tangential velocity between the contacting surfaces, F_N is the normal force, and μ_k is the kinetic friction coefficient. For simplicity, we consider $T_C = F_C a$ as the resistive torque related to the kinetic Coulomb friction.

Black-box model

Black-box models are constructed without a priori information. Data acquired from experimentation is used to capture the system dynamics in this modeling. Regarding black-box, we utilized the AutoRegressive eXogenous (ARX) model and the Nonlinear AutoRegressive eXogenous (NARX) model. The ARX structure is:

$$y(k) = -(a_1 y(k-1) + a_2 y(k-2) + \dots + a_n y(k-n_y)) + (b_1 u(k) + b_2 u(k-1) + \dots + b_{n+1} u(k-n_u)), \quad (7)$$

where $y(k)$, $u(k)$ are the system output and input, respectively; and n_y and n_u are the maximum lags at the system output and input, respectively.

The NARX models are a nonlinear extension of the ARX models [6, 7]. The NARX structure is:

$$\begin{aligned} y(k) &= F(y(k-1), y(k-2), \dots, y(k-n_y), \\ &u(k-d), u(k-d-1), \dots, u(k-d-n_u)), \end{aligned} \quad (8)$$

F is some nonlinear function, and d is a time delay.

Results and Discussion

We evaluated the performance of the proposed identification methodology via simulation. First, we integrated (4) utilizing the 5th-order Runge-Kutta numerical method with a time step equal to 0,01 in Matlab. The simulations employed the experimental data for input τ_m . The data set employed for the identification is composed of experimental data from 30 to 90 seconds. And the one used for the validation analyses is composed of experimental data from 120 to 180 seconds. Table 1 gives the set of estimated parameters obtained employing the system dynamics forward simulation. Using the estimated parameter depicted in Table 1, we simulated the system and calculated the error of prediction to build the ensemble models.

Table 1: Estimated parameters values

k (Nm/rad)	0.1614
c (Ns/m)	0
c_d (Ns/m)	0
c_m (Ns/m)	0.0071
T_C (Nm)	0.2278

For Model 1, the NARX model with motor torque τ_m as input, and error e as output was built as follows:

$$e(k) = \alpha_1 e(k-1) + \alpha_2 e(k-2) + \beta_1 \tau_m(k-1) + \beta_2 \tau_m(k-2) + \gamma_1 e(k-1) \tau_m(k-1), \quad (9)$$

where α_1 , α_2 , β_1 , β_2 , and γ_1 are the parameters of the NARX model. We trained the black-box model with the recorded input and output data of the time interval from 30 to 90 seconds of the recording in Fig. 2 and validated it by employing the recorded input and output data of the time interval from 120 to 180 seconds. We constructed the ensemble model as displayed in (2).

For Model 2, the ARX model with error e and y_m as input, and ensemble model y_e as output was built as follows:

$$y_e(k) = -(a_2 e(k-2) + b_1 y_m(k-1) + b_2 y_m(k-2)) + c_1 y_e(k-1), \quad (10)$$

where a_2 , b_1 , b_2 , and c_1 are the parameters of the ARX model. We trained the black-box model with the recorded input and output data of the time interval from 30 to 90 seconds of the recording in Fig. 2 and validated it by employing the recorded input and output data of the time interval from 120 to 180 seconds. We constructed the ensemble model as displayed in (3).

Figure 4 depicts the free-run prediction obtained with Model 1 (top) and Model 2 (bottom), plotting the direct comparison of experimental and estimated time histories of the disc angular velocity for the validation set. The two ensemble models can reproduce the torsional oscillations with the stick-slip phenomenon observed in the experimental results. Figure 5 shows us one interval of the stick phase, comparing measurements and estimations for the two models.

Figure 4: Comparison of measured and predicted disc angular velocity using: (top) Model 1, and (bottom) Model 2.

Figure 5: Comparison of measured and predicted disc angular velocity, one stick phase interval, using: (top) Model 1, and (bottom) Model 2.

Figure 6 plots the histogram of the prediction errors for both Models. From the graph of Fig. 6, we can conclude that Model 2 presents the higher prediction errors. Table 2 presents the Root Mean Squared Error (RMSE) and the maximum error for the two ensemble models. From Tab. 2, we see that the ensemble Model 1 presented the lowest RMSE score and the lowest maximum error.

Table 2: RMSE and maximum error scores

	RMSE	max error
Model 1	0.0897	0.3065
Model 2	0.1514	0.4741

As we are interested in the accuracy of predictions and the reproduction of the dynamical phenomenon observed in experimental tests, we also evaluate the average duration of the stick intervals. Table 3 presents the estimated mean stick

Figure 6: Histogram of prediction errors for Model 1 and Model 2.

duration for the two ensemble models studied. The mean stick interval duration predicted with Model 1, 0.3715s, is the one that gets closer to the calculated from experimental measurements, that is 0.3770s.

Table 3: Mean stick duration

Model 1	0.3715
Model 2	0.3913

We chose the RSME, the maximum errors, and the average duration of the stick intervals to compare the model's effectiveness in enhancing the accuracy of predictions and reproducing the stick-slip phenomenon. From the results presented in Table 2 and Table 3, we can say that the ensemble Model 1 performs better in reproducing the test rig experimental data when compared to the ensemble Model 2.

Concluding Remarks

In this work, we compared two different methods of combining system identification techniques. The investigated system is a laboratory test rig that reproduces the torsional vibration of a drill string in drilling operations. We estimated the mechanical parameters and dry contact friction parameters utilizing measured data. With the estimated parameters, we built the ensemble models. Model 1 uses the gray-box model as a mean function and adds the black-box modeled residuals; Model 2 uses the information encoded in the gray-box model as an input to a black-box model.

The proposed ensemble models combine the physics-based approach and ARX or NARX formulations to capture the aspects of the dynamical response missed by the physical model alone. The hybrid formulations were proposed to increase the accuracy of the predictions without losing interpretability.

Experimental bifurcation analysis of a self-excited system exhibiting a subcritical Hopf bifurcation using control-based continuation

K.H. Lee*, D.A.W. Barton* and L. Renson[†]

* *Department of Engineering Mathematics, University of Bristol, United Kingdom*

[†] *Department of Mechanical Engineering, Imperial College London, United Kingdom*

Summary. In this paper, control based continuation (CBC) is exploited to systematically characterise in a controlled manner the LCOs of an airfoil during wind tunnel tests. Limit cycle oscillations (LCOs) are found in a wide range of engineering systems such as aircraft, valves, towed wheels and machine tools. The development of corresponding mathematical models that can accurately predict the region where LCOs exist is challenging, especially when the LCOs coexist with the stable equilibrium of the system. Experimental validation is also challenging as the LCOs that can be observed during tests can have large amplitudes. Contrary to previous applications of CBC, the present system is autonomous and the frequency of oscillation is therefore a priori unknown. A phase-plane (geometric) control approach is used to overcome this difficulty. Experimentally measured bifurcation diagrams are then exploited for parameter estimation and model validation.

Introduction

Limit cycle oscillations (LCOs) are found in a wide range of engineering systems such as aircraft, valves, towed wheels and machine tools. In those systems, LCOs emerge from a Hopf bifurcation which can either be super- or sub-critical. The latter is particularly problematic as the stable equilibrium of the system will coexist with LCOs that have potentially large amplitudes. A transition from the equilibrium to such a large-amplitude LCO could cause unacceptable oscillation amplitudes and even lead to catastrophic failures.

The development of mathematical models that can accurately capture the region where the equilibrium and the LCOs coexist is key to the proper operation and safety of those engineering systems. However, this is very difficult task as it often entails capturing complex nonlinear physical phenomena such as fluid-structure interactions (see example here below). Furthermore, parameter estimation and model validation may not be able to exploit LCO data as it would be unsafe to operate the system in this regime of motion.

In this paper, we overcome these difficulties using control-based continuation (CBC). CBC is an experimental scheme that combines feedback control with path following techniques to systematically investigate the dynamic behaviour of physical systems. CBC was applied to a wide range of mechanical experiments such as a impact oscillators, nonlinear energy harvesters, and a cantilever beam with a nonlinear mechanism at its free tip [3, 2, 4]. Here, CBC is exploited to characterise the dynamics of a two-degree-of-freedom airfoil exhibiting LCOs through a subcritical Hopf bifurcation. Testing such a system with a feedback controller provides numerous advantages compared to classical open-loop experiments. If properly designed, the controller maintains the response of the system around a prescribed operating point, avoiding untimely transitions to other, potentially dangerous behaviours. The controller also modifies the linearization of the dynamical system such that unstable responses are stable and hence observable. The unstable LCOs correspond to smaller oscillation amplitudes which can be safely measured and exploited for parameter estimation and model validation.

Application of CBC to LCOs

The fundamental idea of CBC is to find a suitable target signal for the controller such that it becomes *non-invasive* and does not modify the position in parameter space of the responses of the open-loop experiment of interest. The target signal is usually described by a finite sum of Fourier modes whose coefficients can be found iteratively. Until now, the frequency of the target signal was known a priori and identical to the frequency of the external excitation applied to the system (see, for instance, [2]). This is no longer the case here where the system is autonomous.

To overcome this difficulty and obtain the appropriate frequency for the target signal, the fundamental component of the target signal $z^*(t)$ is phase locked with the measured response of the system $z_1(t)$. This is equivalent to locking the phase between force and the response of the forced Hopf bifurcation. For simplicity, the target signal is also limited to a single Fourier mode. Assuming that the measured signal z_1 is analytic, it and its time derivative can be expressed as

$$\begin{aligned} z_1(t) &= A(t) \cos(\phi), \\ z_2(t) &= \dot{z}_1(t) = -\dot{\phi} A(t) \sin(\phi) \end{aligned} \quad (1)$$

where, $A(t)$ is the instantaneous amplitude, ϕ is the instantaneous phase of the response, $\dot{\phi}$ is the frequency of the response. The target signal can then be set as

$$z^*(t) = \hat{A} \cos(\phi) \quad \text{where} \quad \phi = \tan^{-1} \left(\frac{-z_2(t)}{\dot{\phi} z_1(t)} \right) \quad (2)$$

and \hat{A} is the unknown amplitude of the control target. The amplitude coefficient \hat{A} is found such that the controller becomes non-invasive. This is achieved by solving the zero problem $\Xi = \hat{A} - A(\hat{A})$ where A is amplitude of the measured

Figure 1: Picture of the flutter rig and CBC results of two systems. (a) Picture of the rig (b) CBC result and numerical computation of LCO of the model (system 1) (c) CBC result and numerical computation of LCO of the model (system 2). (●) is measured stable LCO, (○) is measured unstable LCO, (—) is computed LCO from the model.

response. This one-dimensional problem can be solved using Newton-like algorithms or, more simply, by testing a range of target amplitudes and taking the one for which $|\Xi_k| < \delta$, where δ is a user-defined tolerance.

Experimental results

CBC was applied to a flutter rig (Figure 1(a)) with a rigid NACA-0015 wing profile and two degrees of freedom (heave and pitch). The heave motion was measured using a laser displacement sensor and the control force was applied to the heave motion using an APS Electro-Seis Shaker. The CBC algorithm were run on a laptop computer connected to a real-time controller (RTC). The RTC consists of a BeagleBone Black on which is fitted with a custom data acquisition board [1] in which the real-time feedback controller was implemented. Measurement and actuation was performed with a sampling frequency of 5 kHz.

The bifurcation diagram obtained using CBC is presented in Figure 1 (b)-(c). LCOs measured at different wind velocities represent either unstable (○) or stable (●) LCOs of the underlying uncontrolled experiment. The location of the sub-critical Hopf bifurcation and the LCOs represent valuable information that was exploited to estimate the nonlinear parameters of the mathematical model. This models accounts for the presence of linear and nonlinear stiffnesses in heave and pitch. It also includes an unsteady representation of the aerodynamics. The bifurcation diagrams found for this model are shown in Figure 1(b)-(c) for two different configurations. The agreement between the model and the unstable responses is very good. The significant difference observed at high amplitudes between the model and the experimentally-measured stable LCOs is thought to be due to complex aerodynamic phenomena that are not included in the model.

Conclusions

Control-based continuation was exploited to characterise the limit cycle oscillations of a flutter rig in wind tunnel tests. The control target signal was phase-locked with the response of the system to find and match the frequency of oscillation. Identified LCOs were exploited to estimate parameters of a model and reproduce numerically the bifurcation diagram of the system.

Experimental Dynamics of Composite Bistable Cantilever Shells

Andrzej Mitura*, Jerzy Warminski*, Matteo Brunetti** and Francesco Romeo**

*Department of Applied Mechanics, Lublin University of Technology, Lublin, Poland

**Dipartimento di Ingegneria Strutturale e Geotecnica, Sapienza University of Rome, Rome, Italy

Summary

Bistable cantilever shells subjected to harmonic base excitation have been experimentally investigated with the aim of extending previous quasi-static studies [1] and characterizing their nonlinear dynamic behavior. The tested shells have rectangular planform and almost cylindrical shape. Their shorter edge, flattened by means of a specifically designed clamp, has been excited using an electrodynamic shaker. Sensors and dedicated interface electronics for forward and backward frequency sweeping and control have allowed the identification of the nonlinear resonance curves. Such curves describe the intrawell nonlinear dynamics around the stable equilibrium configurations of the tested shells and have clearly exhibited the expected softening behaviour. Moreover, the experimental campaign provided insights on the dynamic regimes enabling to trigger snap-through mechanisms.

Introduction

The possibility to design and manufacture bi- or multi-stable structures is interesting for both technological and scientific reasons. As an example, a bistable device consisting of a ferromagnetic cantilever elastic beam and two fixed magnets has been proposed in [2]; for such a system the bistability is the result of the interaction between the magnetic field yielded by the magnets and the beam. The authors found the occurrence of nonlinear phenomena, including chaos; in this case the bistability has been exploited to harvest energy from the beam motion. More complicated bistability or multistability systems are presented in the doctoral dissertation [3], where potential applications in aircraft and aerospace industries are suggested. A special class of cantilever composite shells exhibiting multi-stability has been presented by the authors in [1]. Finite element numerical simulations confirmed by experimental tests demonstrated the existence of two or four stable equilibrium configurations, depending on the shape of the natural stress-free configuration of the shell. While therein the research was limited to quasi-static analysis, in this contribution the aim is to perform experimental tests for characterizing the nonlinear dynamics of the multi-stable shells.

Tested composite shells and experimental setup

The manufactured shells are made of carbon-epoxy unidirectional eight-layers composite with stacking sequence [45/-45₂/45/-45/45₂/-45]. Each prototype has been manufactured using autoclave technology; we refer to [1] for all the details about the shell geometry and the constitutive properties. During the manufacturing process different moulds have been used to obtain the two shapes chosen for the prototypes. These latter have an almost cylindrical shape and differ only in length; we label A the longer shell, B the shorter. The natural stress-free configuration of A and B shells is shown in Figure 1. After flattening and clamping one of the shorter edges both shells turn out to be bi-stable, with I or C stable shape configurations (see reference [1]).

The shells are clamped into a special holder and then mounted on the electrodynamic shaker armature. The structure is then kinematically excited with the shaker controller set in sine mode with a constant acceleration of amplitude a_{shaker} . The excitation frequency $f(t)$ has been swept forward and then backward and the shell response has been measured by a piezoelectric triaxial accelerometer (a_x, a_y, a_z). Based on the measured signals, the experimental resonance characteristics have been identified.

Figure 1: Shell shape before clamping, variant A and B.

Experimental results

The experimental results for the (longer) shell A are shown in Figure 2 for I (Figure 2 a) and C stable shapes (Figure 2b), respectively (accelerometer at the free end). For the I stable shape the softening effect is clearly visible: when incrementing the excitation amplitude the resonance is shifted towards lower frequencies. In contrast, for the C stable shape the resonance shifting is not so evident.

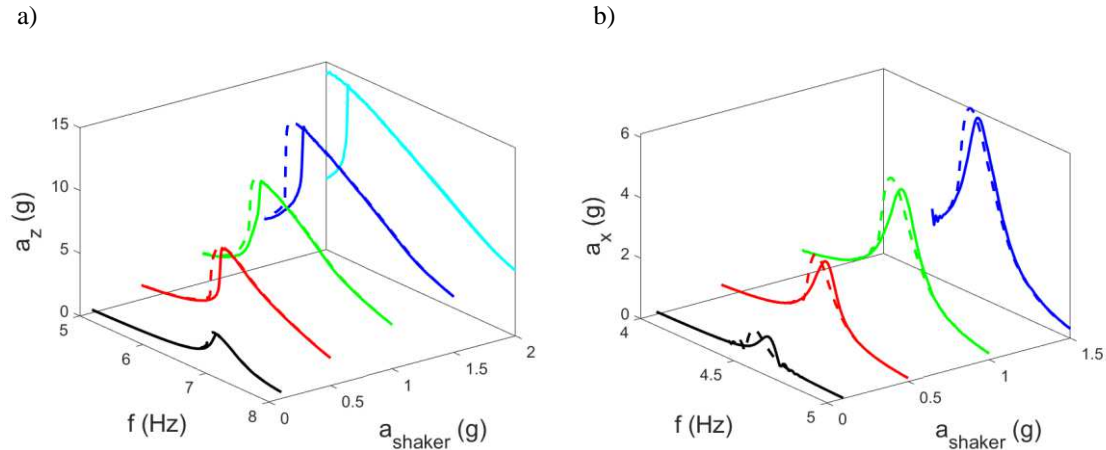

Figure 2: Resonance characteristics of A shell; a) I stable configuration, b) C stable configuration
solid line - frequency sweep forward, dashed line - frequency sweep backward

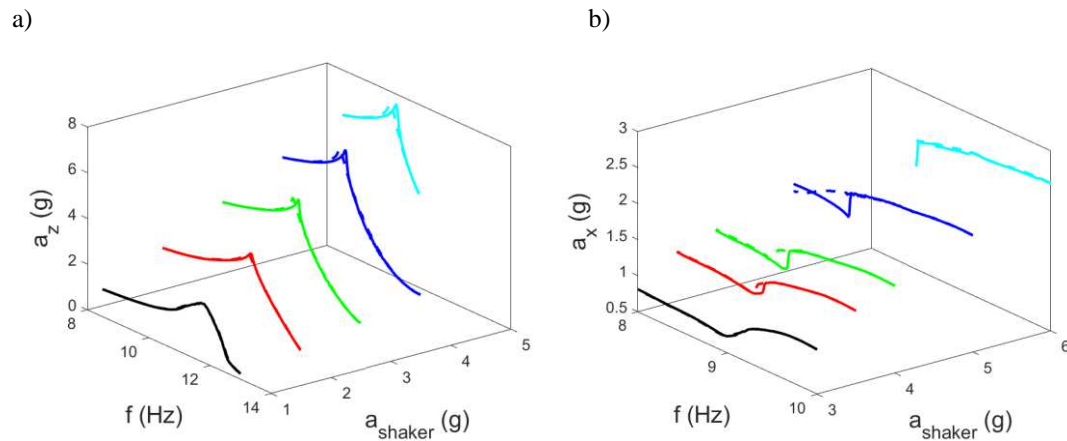

Figure 3: Resonance characteristics of B shell; a) I stable configuration, b) C stable configuration
solid line - frequency forward, dashed line - frequency backward

The experimental curves for the (shorter) shell B are shown in Figure 3 (accelerometer at the clamped end). As expected, the resonance frequencies of the shorter shell are higher than those of the longer shell. For example, the natural frequency of the I stable configuration is about 11 Hz for the shell B (Figure 3a) and about 7 Hz for the shell A (Figure 2a). In this case the softening effect is evident on both Figures 3a and 3b: for the shorter shell, as the excitation amplitude is increased, the resonance frequencies for both the I and C stable shapes are shifted towards lower values.

Conclusions

In this contribution the nonlinear dynamics of bi-stable composite shells has been experimentally investigated. The intrawell dynamics around the stable configurations has shown a softening behaviour for both the manufactured prototypes. While the snap-through phenomenon has not been found in the present experimental set-up, further on-going tests are devoted to trigger a shape jump between the I and C stable configurations. The obtained data will be used to validate numerical models as well as reduced order semi-analytical models.

Summary. We study experimentally and numerically the propagation of an air bubble through a fluid-filled, geometrically-perturbed Hele-Shaw channel; a system which supports several stable modes of steady bubble propagation. During its transient evolution, a bubble may undergo several topological changes in the form of breakup and coalescence, depending on both initial conditions and control parameters. Long-term, either a single asymmetric or symmetric bubble is recovered or else multiple bubbles remain, whose relative separation increases with time. We explore how the transient and long-term evolution is controlled by edge states available to the bubble, which may change with each new topological configuration.

Introduction

Two-phase displacement flow in a confined geometry is a fundamental problem in fluid mechanics with applications in biomechanics, geophysics and industry. A canonical example is the viscous fingering instability which occurs when air displaces a viscous fluid in a Hele-Shaw channel of width much greater than its depth. An initially flat interface evolves into a single finger of air, symmetric about the centreline of the channel [1]. When the nondimensional driving flux is above a threshold, which depends on the roughness of the channel, this finger is observed to become unstable to tip-splitting leading to the emergence of complex patterns [2]. As the steady solution is linearly stable for all computed flow rates [3], these further instabilities must arise subcritically. For both air fingers (i.e. of semi-infinite extent) and bubbles (with fixed volume), models of the system also contain alternative, weakly-unstable families of multiple-tipped symmetric solutions and asymmetric solutions in addition to the linearly stable solution branch [4].

The system can be perturbed by introducing a small depth-perturbation to the channel cross section (see figure 1a, b) (termed a ‘rail’) which discourages propagation in the centre of the channel. The perturbed system is axially uniform and can support invariant propagation modes, which are broadly similar to those in the Hele-Shaw channel of rectangular cross-section. However, their stability is altered so that multiple linearly stable steady solutions occur for the same driving parameters (figure 1c). Hence, several long-term outcomes are possible for a bubble propagated from a centred initial position. For small flow-rates the bubble will readily settle on a stable off-rail state (see figure 1c) but for larger flow-rates the bubble shape will become increasingly deformed and a large range of transient behaviour is observed, including tip-splitting, and oscillatory behaviour [5]. Our previous studies have focused on a single-bubble configuration, where we showed that the bubble evolution is guided by transient exploration of the stable manifolds of weakly unstable edge states of the system [5]. In this paper, we explore in particular the behaviour at flow rates where the propensity for bubble breakup and topological changes can have a profound effect on the governing dynamics and lead to the bubble exploring multiple topological configurations before reaching its final state.

Experiment

The experimental channel is shown schematically in figure 1a,b. An air bubble of controlled volume is injected at one end of the channel and propagated by infusing silicone oil at a constant flow rate. We impose different initial conditions corresponding to bubbles of different initial widths by allowing a controlled relaxation period prior to flow initiation. The channel aspect ratio is fixed at 40, and the rail occupies 25% of the channel width and 2.4% of its height.

Numerical model

We use a depth-averaged model for bubble propagation in this large-aspect ratio channel. This model, which qualitatively captures all observed modes of finger propagation in the constricted Hele-Shaw channel [6], was recently extended to

Figure 1: (a) Top-view of the experimental channel with an axially uniform, centred rail. (b) Cross-section of the channel. (c) Numerical bifurcation diagram depicting the steady modes of bubble propagation in terms of the bubble velocity as a function of the flow rate [5]. Stable and unstable modes are indicated by solid and dashed lines, respectively.

Figure 2: Examples of experimentally-observed transient bubble dynamics showing bubble breakup and recombination, leading to distinct outcomes (a) the compound bubble will eventually recombine to a single bubble and (b) two asymmetric bubbles which will eventually drift apart.

include bubble breakup and coalescence and to describe the motion of one or more bubbles. The use of a simplified model allows the computational effort to be concentrated on capturing the 2D interface as viewed in the experiment, enables a much wider range of computations, and also allows us to directly isolate different physical mechanisms. We solve our model equations using a finite-element method in the open-source library `oomph-lib`, and have access to steady solutions, bifurcation tracking, initial value problems, linear stability and weakly nonlinear stability analysis.

Results

An initially centred bubble may eventually reach the on-rail or off-rail single-bubble steady solutions, or else form two or more bubble fragments which drift away from each other as they propagate. These long-term outcomes can be reached via a surprisingly rich range of transient evolution scenarios, with the transient evolution depending on both control parameters and the initial bubble width. Only for the smallest flow rates does the bubble always remain simply connected throughout its evolution. Above a threshold flow rate, initially slender bubbles evolve towards on-rail steady states, while initially wide bubbles will break up into two or more separating bubbles. For example, figure 2 shows scenarios for two very similar bubbles. In each case the bubble first splits into three smaller bubbles, which then undergoes a complicated sequence of recombination and splitting, and eventually reach two different outcomes.

In order to explore the interactions between multiple bubbles and how these select the eventual fate, we concentrate on situations where the first topological change usually involves the bubble breaking into two near-equal size fragments. The subsequent evolution depends on the volume ratio selected by breakup and the relative position of each bubble, along with the driving parameters. We calculate steady solutions for the two-bubble configuration numerically using our depth-averaged model. Nearly all of these states are weakly unstable, but we find strong evidence that they act as edge states controlling whether the newly-formed bubbles remain on different sides of the rail (and hence usually separate) or whether they migrate across the rail to recombine.

Conclusion

This system exhibits rich transient evolutions, some of which involving bubble breakup into two or more bubbles, and can be followed by other topological reorganisations of the system. The problem is amenable to experiments and numerical simulations using a simplified model. We provide evidence that the dynamics of both single and multiple bubble systems are organised by weakly unstable solutions or “edge states”, and can calculate these using our simplified model. As the flow rate increases, transient bubble shapes are increasingly deformed and the number of breakups and recombinations undergone by the bubble increases. We suspect that this increase in complexity is due to a subcritical transition to disorder above a threshold that depends on the roughness of the occlusion, reminiscent of the transition to turbulence in shear flow.

Summary. This abstract presents the design of a new nonlinear vibration absorber that aims to attenuate the vibration of an elastic structure near its resonance frequency. This absorber is formed by connecting the elastic structure via a piezoelectric patch to an electrical shunt circuit consisting of a resonant shunt (R-L circuit), combined in series with a quadratic voltage component. The 2DOF reduced order model showed that, for suitable tuning, a 2:1 internal resonance could be generated leading to a creation of an anti-resonance in the response of the elastic structure at the resonance frequency of the mode to be attenuated. The anti-resonance amplitude is shown to remain constant after a threshold excitation level giving this absorber an advantage over the linear absorbers.

Nonlinear Piezoelectric Shunt Absorber Design

The shunt absorber is designed by connecting an electric shunt circuit, consisting of a resistor R and an inductor L in series with a quadratic nonlinear voltage component, to an elastic structure through a piezoelectric patch, as shown in Fig. 1. The quadratic nonlinear term is set to be proportional to the square of the voltage across the piezoelectric patch V_p by a gain equals to β . By introducing this quadratic non-linearity in the shunt circuit and by tuning the electrical resonance

Figure 1: Nonlinear shunt circuit schematic

frequency to be at one half of the resonance frequency of the structure mode to be attenuated, a 2:1 internal resonance would occur. Such an internal resonance, when forcing above a threshold level, leads to an energy transfer from the mode to be attenuated to an electrical mode at the first sub-harmonic frequency. As a result, a kind of anti-resonance at the resonance frequency of the structure is created and the amplitude of the anti-resonance is shown to be independent of the excitation level, leading to a saturation phenomenon [1, 2].

Reduced Order Model and Numerical Results

The main equations governing an elastic system subjected to harmonic excitation and connected to a nonlinear resonant shunt circuit through a piezoelectric patch as shown in Fig. 1, are: (see [3])

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{D}\dot{\mathbf{u}} + \mathbf{K}\mathbf{u} + \mathbf{K}_c V_p = \mathbf{F} \cos(\Omega t), \quad (1a)$$

$$C_p V_p - Q - \mathbf{K}_c \mathbf{u} = 0, \quad (1b)$$

$$V_p + L\ddot{Q} + R\dot{Q} + \beta V_p^2 = 0, \quad (1c)$$

where \mathbf{M} , \mathbf{K} , and \mathbf{D} are the mass, stiffness, and damping matrices respectively. \mathbf{K}_c is the electro-mechanical coupling coefficients vector, C_p is the piezoelectric patch capacitance, and \mathbf{F} is the excitation force vector. A reduced order model is constructed by performing two modal expansions. The first one is obtained by expanding the displacement vector denoted by \mathbf{u} on the basis of the N linear modes. This would lead to a linearly coupled 2DOF system in terms of the charge Q and the modal displacement q_i , by truncating the displacement at the i -th mode to be attenuated. Then, a second modal expansion is done, on a basis of two modes to obtain the following fully quadratic differential system:

$$\ddot{x}_1 + 2\mu_1 \dot{x}_1 + \omega_1^2 x_1 + \Lambda_1 x_1^2 + \Lambda_2 x_1 x_2 + \Lambda_3 x_2^2 = f_1 \cos \Omega t, \quad (2a)$$

$$\ddot{x}_2 + 2\mu_2 \dot{x}_2 + \omega_2^2 x_2 + \Lambda_4 x_1^2 + \Lambda_5 x_1 x_2 + \Lambda_6 x_2^2 = f_2 \cos \Omega t. \quad (2b)$$

Eq. (2) is solved using the Multiple Scales Method (MSM) to have a closed form solutions that are used to study the effect of each design parameter on the response, so an optimized parameters selection could be established to achieve the highest attenuation. In addition, the Harmonic Balance Method (HBM), coupled with a numerical continuation procedure based on the Asymptotic Numeric Method (ANM) [4, 5], is used for results validation. Then, the results could be transferred back to the physical coordinates, which are plotted in Fig. (2). It can be observed that the stable solution of q_i stems from the principal resonance curve through a branching point bifurcation, reaching a minimum at the resonance frequency.

Figure 2: Numerical Results of the amplitudes of q_i (left) and Q (right) based on HBM. Solid line for stable solution and dotted line for unstable solution.

Experimental Setup and Results

Experimental tests are conducted on a cantilever beam to attenuate the first bending mode by connecting the nonlinear shunt circuit through a piezoelectric patch glued at the beam bottom. The excitation is done on the beam tip by inducing a current in a coil-magnet system, as shown in Fig. 3. The nonlinear shunt circuit consisted of an Antoniou synthetic inductor, to achieve a high inductance value, in series with a multiplier circuit composed of a set of Op-Amps and a signal

Figure 3: Experiment Setup

Figure 4: Experimental Results

multiplier, to generate the quadratic voltage behaviour. The time signal of the velocity is measured also at the beam tip using a laser vibrometer, and the voltage across the piezoelectric patch is measured using a voltage probe, which is then fed back to the input of the multiplier circuit. The harmonics amplitude could be extracted from the time signal, and the experimental results are shown in Fig. 4, which clearly validate the numerical results in Fig. 2.

Conclusions

In this study, a semi-passive nonlinear piezoelectric shunt absorber is designed for the first time to attenuate the vibration level using the 2:1 internal resonance features. A 2DOF reduced order model has been constructed, in which the numerical and experimental results appeared to be in full accordance. In addition, when connecting the absorber to a cantilever beam, a high attenuation is achieved near the resonance frequency of the first bending mode.

A numerical study on passive suppression of vortex-induced vibration (VIV) using an elastic rotative non-linear vibration absorber

Guilherme Rosa Franzini

Offshore Mechanics Laboratory, Escola Politécnica, University of São Paulo, Brazil

Summary. The focus of this contribution is to present a numerical study on passive suppression of the vortex-induced vibration phenomenon (VIV) using an elastic rotative non-linear vibration absorber (ERNVA). The cylinder (structure to be controlled) is constrained to oscillate only in the cross-wise direction (i.e., the direction orthogonal to the direction of incoming flow). The hydrodynamic loads are modeled using a wake-oscillator model. Curves showing the efficiency of the device are presented and discussed.

Introduction

Vortex-induced vibration (VIV) is a particular flow-induced vibration phenomenon particularly important on risers' dynamics. Phenomenological aspects of the phenomenon can be found in the surveys [1] and [2]. Its self-excited and self-limited character plays a role in the structural lifespan due to fatigue. Hence, VIV suppression is of interest for both industrial and academic communities.

A number of studies focusing on VIV suppression can be found in the literature. For the sake of conciseness of this extended abstract, focus is placed on investigations using rotative non-linear vibration absorbers (RNVAs) or non-linear energy sinks (RNES). A rotative NVA is composed of a rigid arm fitted with a tip-mass, linked to the main structure by means of a linear dashpot in which energy is dissipated.

References [3, 4] bring numerical studies focusing on the behavior of a cylinder fitted with a RNVA subjected to VIV. In both papers, the cylinder was constrained to oscillate in the cross-wise direction and the forces applied by the fluid to the solid are computed using computational fluid dynamics (CFD) techniques. In these references, the authors point out the existence of strongly modulated responses for the cylinder and a decrease in the cylinder response. [5] also deals with the passive suppression of VIV using a RNVA, but using reduced-order models based on wake-oscillators for calculating the hydrodynamic load. The latter reference numerically investigates the cases in which the cylinder is constrained to oscillate in one or two directions of the horizontal plane. Due to the lower computational cost compared to the CFD, [5] presents maps showing the sensitivity of the response with respect to the RNVA parameters.

This paper extends the work presented in [5]. Instead of considering a rigid arm, an elastic linear spring allows motion of the suppressor mass in the radial direction. This type of suppressor is herein defined as elastic non-linear vibration absorber (ERNVA). At least to the author's knowledge, this is the first application of such device for VIV suppression.

Mathematical model and results

Consider the problem sketched in Fig. 1. The rigid cylinder has mass M , length L , diameter D and is immersed in a fluid of specific mass ρ and characterized by an uniform free-stream velocity U_∞ . The cylinder is assembled onto a viscoelastic support of stiffness k_y and damping constant c_y and its cross-wise displacement is Y . The ERNVA is composed of a point mass m_N placed at the tip of an elastic arm of axial stiffness and damping constant of constant k_r and c_r respectively. The elastic arm is hinged to the cylinder by means of a dashpot of constant c_θ . The instantaneous radial position of the point mass is $r_0 + r(t)$, r_0 being the unstretched length of the arm. Two reference frequencies can be defined, namely $\omega_{n,y} = 2\pi f_{n,y} = \sqrt{k_y/(M + m_N + m_a)}$ (m_a is the potential added mass) and $\omega_r = \sqrt{k_r/m_N}$. Now, consider the dimensionless quantities defined in Eq. 1.

Figure 1: Schematic representation of the problem. The cylinder is constrained to oscillate in the cross-wise direction.

$$y = \frac{Y}{D}, \eta = \frac{r}{D}, \tau = \omega_{n,y} t, \hat{r} = \frac{r_0}{D}, \hat{m} = \frac{m_N}{M + m_N}, \zeta_r = \frac{c_r}{2m_N \omega_r}, \zeta_y = \frac{c_y}{2(M + m_N + m_a) \omega_{n,y}}, \hat{\omega} = \frac{\omega_r}{\omega_{n,y}}$$

$$U_r = \frac{U_\infty}{f_{n,y} D}, m^* = 4 \frac{(M + m_N)}{\rho \pi D^2 L}, C_a = 4 \frac{m_a}{\rho \pi D^2 L} \quad (1)$$

In addition to the above quantities, the mathematical model also depends on the Strouhal number St , the amplitude of the lift coefficient obtained for a fixed cylinder \hat{C}_L and the mean drag coefficient (also for a fixed cylinder) C_D . Following the wake-oscillator model proposed in [6], the loads due to the fluid-structure interaction can be obtained by coupling a van der Pol equation to the structural oscillator by means of empirically calibrated parameters, namely A_y and ϵ_y . Using this approach, the mathematical model is governed by the following dimensionless mathematical model:

$$\ddot{y} + 2\zeta_y \dot{y} + y = \frac{1}{2\pi^3} \frac{U_r^2}{(m^* + C_a)} \sqrt{1 + \left(\frac{2\pi \dot{y}}{U_r}\right)^2} \left(\frac{q_y}{\dot{q}_y} \hat{C}_L - C_D \frac{2\pi \dot{y}}{U_r}\right) = \varepsilon \left[2 \sin \theta \dot{\eta} \dot{\theta} - \ddot{\eta} \cos \theta + (\hat{r} + \eta) \frac{d}{d\tau} (\dot{\theta} \sin \theta) \right] \quad (2)$$

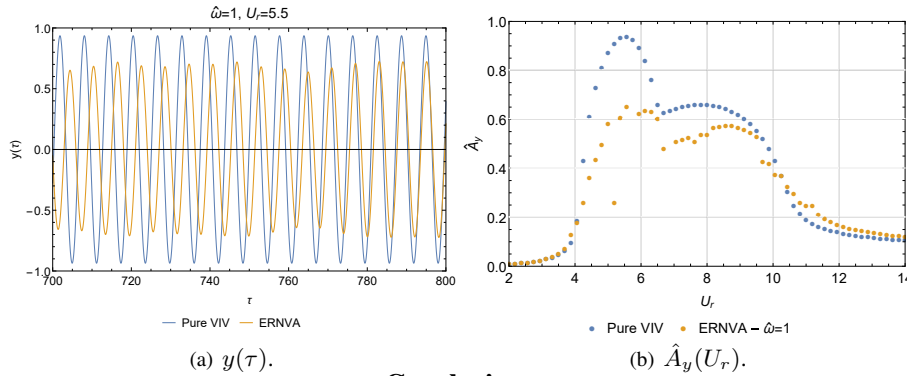

$$(\hat{r} + \eta)^2 \ddot{\theta} + (2\zeta_\theta \dot{\theta}^2 + 2(\hat{r} + \eta) \dot{\eta}) \dot{\theta} = (r + \eta) \ddot{y} \sin \theta \quad (3)$$

$$\ddot{\eta} + 2\zeta_r \dot{\eta} + (\hat{\omega}^2 - \dot{\theta}^2) \eta = \hat{r} \dot{\theta}^2 - \ddot{y} \cos \theta \quad (4)$$

$$\ddot{q}_y + \epsilon_y St U_r (q_y^2 - 1) \dot{q}_y + (St U_r)^2 q_y = A_y \ddot{y} \quad (5)$$

where $\varepsilon = (\hat{m} m^*) / (m^* + C_a)$. Equations 2 - 5 are numerically integrated using the Mathematica[®] NDSolve function during $\tau_{max} = 1000$. For the sake of limitation on the number of pages of this extended abstract, just one set of parameters is tested. The chosen parameters for the cylinder and the ERNVA are $m^* = 2.6$, $\zeta_y = 0.0001$, $\zeta_r = \zeta_\theta = 0.10$, $\hat{\omega} = 1$, $\hat{r} = 0.5$ and $\hat{m} = 0.07$. The investigated reduced velocity is $U_r = 5.5$, a favorable scenario for VIV. Only two non-trivial initial conditions are considered, namely, $\theta(0) = \pi/6$ and $q_y(0) = 0.10$.

Fig. 2(a) shows two displacement time-histories $y(\tau)$, one of them being labeled as “Pure VIV” and corresponding to the condition in which no suppressor is attached to the cylinder. From this figure, one clearly notice that the presence of the ERNVA decreased the characteristic oscillation amplitude from $\hat{A}_y \approx 0.94$ (“Pure VIV” case) to $\hat{A}_y \approx 0.65$, a reduction close to 33%. The complete curve of characteristic oscillation amplitude as a function of reduced velocity is depicted in Fig. 2(b), which shows that the ERNVA is able to suppress VIV for a certain range of reduced velocities corresponding to the lock-in.

Conclusions

This extended abstract presented a numerical investigation on passive suppression of VIV using an elastic rotative non-linear vibration absorber (ERNVA). Considering the ERNVA mass equal to 7% of the total oscillating mass, it was found that a decrease in the characteristic oscillation amplitude has been achieved, specially close to $U_r = 5.5$. In the full paper and at the conference, more comprehensive studies will be presented.

Broadband vibration energy harvesting based on a weakly coupled nonlinear periodic system

Kaouthar Aouali, Najib Kacem and Nouredine Bouhaddi

Univ. Bourgogne Franche-Comté, FEMTO-ST Institute, CNRS/UFC/ENSMM/UTBM, Department of Applied Mechanics, 25000 Besançon, France

Summary. In this work, a broadband vibration energy harvester based on a weakly coupled nonlinear periodic N-Dofs system is proposed. In order to enlarge the frequency bandwidth of the harvester, the multimodal property induced by the system periodicity and the nonlinear hardening and softening behaviors are functionalized.

Over the past decades, many efforts have been made to harvest energy from ambient vibrations. Various techniques for vibration energy harvesting (VEH) based on different energy conversion mechanisms have been achieved and proved their potential to enhance the output performances of the harvesters. Although the conversion's mechanisms are various and the development of harvesters is continuous, VEHs still have limitations. In fact, most devices have a narrow operating bandwidth. Consequently, their implementation is limited in real-life applications where energy prevails over a wider bandwidth. To overcome this limitation, several approaches have been proposed namely the adoption of multimodal configurations and the introduction of nonlinearity.

In the following, we are interested in the enhancement of the performances of a vibrating energy harvester based on electromagnetic transduction. The present work investigates the benefits of the multimodal approach and the introduction of the nonlinearity. The multimodal approach involves operating multiple modes in a periodic N-Dofs discrete system. This technique proves its potential to enlarge the frequency bandwidth [1,2,3]. Concerning the nonlinearity, it is used also to extend the frequency bandwidth and diverse works have shown the remarkable improvement of the bandwidth while using this method [4,5,6]. In this work, we functionalized simultaneously the nonlinear softening and hardening behaviors of different Dofs.

Numerical simulations on 5 and 10-Dofs systems have been performed to highlight the benefits of the proposed approach.

Determination of performance parameters of nonlinear galloping energy harvesters using Jacobi elliptic functions

Filip Sarbinowski*, Roman Starosta *

**Institute of Applied Mechanics, Poznan University of Technology, Poznan, Poland*

Summary. In the work, through analytical considerations, the peak efficiency of three different variants of galloping energy harvester was defined. For this purpose, the authorial method based on elliptic harmonic balance was employed, consisting of comparison of impossible to analyze, accurate high order solutions, and simplified solutions of a linearized model. Research has shown that the peak efficiency of the hardening and bistable devices is greater by 17% and 30% respectively in regards to the linear device, while application of softening stiffness always leads to a loss of efficiency.

Introduction

In the era of the idea of the Internet of Things, the desire of scientists, engineers, medics, and even not-professionals is to continuously measure countless physical phenomena that occur both in our surroundings and at great distances beyond direct human reach. This increases the requirements for measuring devices and thus for their power supply – if access to the operating device is limited, it may not be possible to route the power cables or periodically exchange the batteries. The solution to this problem may be the application of autonomous devices - equipped with their generator harvesting ambient energy. An example of such a generator is the galloping energy harvester (GEH) - the device that allows to harvest the energy of vibrations induced by the flow.

In its simplest version, the GEH can be considered as a body (resonator) mounted on the elastic element, coupled to the piezoelectric (Fig. 1.), described by the mathematical model (1) – (2). If an appropriately shaped body is used, the geometry of which is represented by the coefficients a_1 and a_3 , at a certain flow velocity, called the critical velocity, negative damping will be induced in the system and thus stability of the system will be lost.

Figure 1: Model of the aeroelastic energy harvester

$$m \ddot{z}(t) + S(z(t)) - \theta v(t) = -\frac{1}{2} \rho h \left(a_1 U \dot{z}(t) + a_3 \frac{\dot{z}(t)^3}{U} \right) \quad (1)$$

$$C_p \dot{v}(t) + \frac{v(t)}{R} + \theta \dot{z}(t) = 0 \quad (2)$$

where: m – mass of the body, $S(z(t)) = k z(t)$ – restoring force, $z(t)$ – displacement, $\dot{}$ and $\ddot{}$ – first and second time derivative, h – characteristic length of the body, ρ – fluid density, U – flow velocity, a_1 , a_3 – experimentally determined coefficients, $v(t)$ – voltage, θ – piezoelectric coefficient, R – circuit resistance, C_p – circuit equivalent capacity.

The efficiency of the device

One of the most important parameters describing energy generators is peak efficiency η_{peak} . In [1], the maximum efficiency was derived for the simplified linear GEH model, in which the harvested was defined as structural damping. In work [2], we confirm the validity of the obtained results also for the full electromechanical model. These results indicate that the peak efficiency of such a device depends only on the geometry of the resonator and has a form:

$$\eta_{peak} = -\frac{a_1^2}{6 a_3} \quad (3)$$

The natural path of exploring this matter are studies of the possibilities offered by the application of a system with different types of non-linear stiffness characteristics. Although there already studies that compare different GEH variants, e.g. [3], but none of them have defined the efficiency of the devices.

Our earlier studies proved that the analytically formulated limit cycle of the model of the device can be obtained through the harmonic balance assuming some form of the model solution. In the case of devices with a more complex structure, the solutions obtained with this method are, however, too complicated to draw appropriate conclusions from them. Preliminary studies indicate that an excellent alternative may be the elliptic harmonics balance method, where the solution of the model is assumed in the form of elliptic Jacobi functions. Because of that, in the paper, we propose a method of solving this problem based on a comparison of a linearized, easy-to-analyze solution and a very precise one, obtained with elliptic harmonic balance method. The analytical forms of both solutions are very similar, and the value of the factors by which they differ can be strictly defined at extreme points.

Results and conclusions

Employing the elliptic harmonics balance, the expressions describing the efficiency of various variants of devices were obtained as a function of the flow velocity in the form of $\eta_N = \eta_L \Psi$, where $\eta_L = \eta_L(U)$ is the efficiency of linear device and $\Psi = \Psi(m)$ (Fig. 2) is the coefficient that describes the impact of nonlinearity on the efficiency of the device in function of the modulus of elliptic function m . Depending on the nature of the nonlinearity, the value modulus is bounded in the following ranges: for hardening stiffness $0 < m < 0.5$, for softening stiffness $0 < m < 1$ and for bistable system $0.5 < m < 1$, it is therefore, possible to strictly determine the value of the Ψ coefficient at extreme

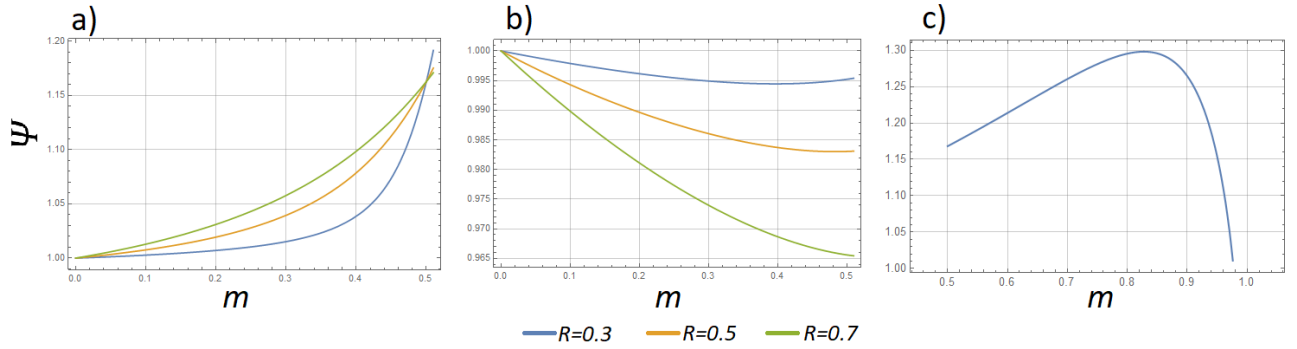

Figure 2: Ψ values as a function of m for different R values and different stiffness variants: a) hardening, b) softening, c) bistable

Based on the above information, it can be concluded that: a) the function $\Psi(m)$ for the system with hardening stiffness depends on the values of the system parameters, but for the $m = 0.5$ it always has the same, maximum value $\Psi(0.5) \approx 1.17$, b) maximum value of $\Psi(m)$ for the system with softening stiffness is reached for $m = 0$ and $\Psi(0) = 1$ therefore, the softening stiffness will lead to a decrease in peak efficiency, c) regardless of the system parameters, the peak value of $\Psi(m)$ for the bistable system is $\Psi(0.83) \approx 1.30$.

Summary. This work studies a problem of passive mitigation by means of one nonlinear energy sink (NES) of a dynamic instability arising from two unstable modes of a primary structure. For that, a phenomenological friction model with four-degrees-of-freedom (DOF) having two unstable modes (the primary structure) is coupled to a NES. We investigate analytically, using an asymptotic analysis, the response regimes resulting from the interaction between the two unstable linear modes of the primary structure and the NES. The analytical results are compared and complemented by direct numerical simulations of the coupled system. In each situation, a good agreement is observed which allows us to validate the presented asymptotic analysis.

Introduction

In the context of passive control of dynamic instabilities, the Nonlinear Energy Sinks (NESs) are now well-known means. For example, NES have been used to suppress aeroelastic instability [1], regenerative chatter in machine tool vibrations [2], helicopter ground resonance instability [3] or friction-induced vibrations due to mode coupling instability [4]. The NES operate on the basis of Targeted Energy Transfer (TET) concept. In general, a NES consists of a light mass, an essentially nonlinear spring (here cubic) and a viscous linear damper. Because of its essentially nonlinear stiffness, a NES can adjust its frequency to that of the primary system and therefore engage in resonance over a large frequency range. Whether for a system under impulsive, harmonic or broadband frequency excitation or whether for an auto-oscillating system, TET results from nonlinear mode bifurcations. In general, the phenomenon of TET can be described as a 1:1 resonance capture [5].

In this work a friction system is considered as a primary system, it consists in a simple four-DOF (two linearly coupled well-known Hult n's models, see Fig. 1) [6]. The model has two unstable modes, i.e. the associated eigenvalues have positive real parts with also the same order of magnitude. Moreover, the imaginary parts (the frequencies) are chosen to be incommensurable. We study the mitigation by means of a single NES of the friction-induced vibrations resulting of the presence of two unstable modes and having therefore two frequency components. Moreover, because the system (without NES) is linear, it undergoes, when it is unstable, an exponential growth of its amplitude.

Preliminary numerical simulations of the coupled system show that the single NES is effectively capable to interact with the two unstable modes and mitigate the double instability. Inter alia, the mitigation may be performed through periodic regimes (see Fig. 2(a) where ϵ is a small parameter related to the mass ratio between the NES and the primary structure) or Strongly Modulated Responses (SMR, see Fig. 2(b)).

In order to understand these interactions and the mitigation processes, based on the procedure presented by the authors [7], an analytical framework is presented. The obtained results are compared and completed by direct numerical integration of the coupled system. The method and the major results of the study are summarized below.

Figure 1: The phenomenological system under study.

Figure 2: Possible mitigation responses obtained from direct numerical integration of the coupled system.

Method and results

The analytical method begins with the so-called biorthogonal transformation to diagonalize the primary friction system. Then, the resulting diagonalized system is reduced keeping only the two unstable modes and ignoring the two stable modes. Afterwards, the slow-flow motion of the system is obtained using the complexification-averaging (CA-X) method within the assumption of two simultaneous 1:1-1:1 resonances to the natural frequencies of the two unstable modes. The slow-flow, which also depends on the small parameter ϵ , is analyzed in the framework of the Geometric Singular Perturbation Theory (GSPT) [8] in which it is defined as a $(4, 2)$ -fast-slow system. Each of the two slow variables characterizes one of the two unstable modes of the primary system whereas the four fast variables describe the NES motion (amplitude and phase of each of the two frequency component).

The Critical Manifold (CM) of the slow-flow is obtained, it is a two-dimensional parametric surface (with respect to two of the four fast variables) which evolves in the six-dimensional variable space. The shape of the CM and its stability properties allow us to contemplate some mitigated responses, in agreement with the preliminary numerical simulations. Indeed, the critical manifold appears as the union between a normally hyperbolic attracting domain with four closed normally hyperbolic saddle type domains.

First, equilibrium positions of the slow-flow are deduced from the knowledge of the CM. A stable equilibrium position (which is on the attractive part of the CM) characterizes a mitigation regime through a periodic response of the initial system if one of the frequency component is completely suppressed, otherwise the response is quasi-periodic with two frequency components. Secondly, because two of the normally hyperbolic saddle type domains meet the attracting part at fold curves, mitigation regimes through Sustained relaxation oscillations of the slow-flow - i.e SMR for the initial system - are possible. Contrary to the case with only one unstable mode, because of the two-dimensional CM, multiple SMR scenarios are possible with different levels of complexity. Fig. 2(b) show an example of a "complex" SMR.

The analysis also suggests that the system may have simultaneous stable attractors (two stable equilibrium positions, one stable equilibrium position with stable sustained relaxation oscillations ...).

Numerical simulations valid the possibility of a competition between two stable attractors and allowing us to study their basins of attractions. In each considered situation, a good agreement has been observed between theoretical results and numerical simulations which validates the proposed asymptotic analysis.

To conclude, this study confirms that a NES is able to mitigate simultaneously two unstable modes.

Application of the ODE Integration Methods for Multibody Systems With and Without Redundant Constraints

Marcin Pękal* and Marek Wojtyra*

**Institute of Aeronautics and Applied Mechanics, Faculty of Power and Aeronautical Engineering, Warsaw University of Technology, Warsaw, Poland*

Summary. The multibody approach is commonly used in analyzing complex mechanical systems. Simulation of multibody systems (MBSs) may be a challenging task. Some problems are present for both overconstrained and non-overconstrained MBSs. The other difficulties concern only overconstrained MBSs. Various formulations and numerical solution approaches may be used to simulate MBSs. Some of them allow us to transform the DAEs into ODEs and have different computational properties, especially in the presence of redundant constraints. These methods are investigated in this paper. The numerical methods were compared with respect to the integration method used. The following methods are considered: the Zero Eigenvalue Method, the Pseudo Upper Triangular Decomposition method (two forms—with the Householder Transformation and the Gauss Decomposition), the Schur Decomposition Method, the SVD Method, the QR Decomposition Method, the Direct Integration Method, the Coordinate Partitioning Method, the Udwadia-Kalaba Formulation, the Least-squares Block Solution (two forms), the Udwadia-Phohomsiri Formulation, and the Wang Huston Formulation. For these methods, both the non-stiff ODE solvers (ode45, ode23, ode113) and stiff solvers (ode15s, ode23t, ode23tb, ode23s) of MATLAB® were considered. The methods were tested on two exemplary MBSs described in absolute coordinates—overconstrained and non-overconstrained robotic manipulators.

Introduction and motivation

The method of multibody systems (MBSs) may be used in many areas, e.g., to describe robots, mechanisms, machines, and vehicles. It may also be used for less common applications, e.g., molecular modeling, biomechanical systems, or modeling of contact or impact. The analysis of MBSs may cause some problems.

During simulations of MBSs, various numerical difficulties may occur. One source of the problems may be related to the type of equations to solve. Usually, the MBSs are described by differential-algebraic equations (DAEs). In this set, the algebraic equations describe the constraint equations that represent loop closing kinematic pairs—in the case of relative joint coordinates—or all kinematic pairs—in the case of absolute coordinates.

The DAEs are usually more challenging to solve than ordinary differential equations (ODEs). Depending on the multibody formulation employed, DAEs may have a different index, which determines the computational complexity of the equations. Large DAEs may also be challenging to integrate. Some methods allow us to transform the DAEs into ODEs. These methods are investigated in this paper.

A significant group of MBSs is the group of systems with redundant constraints. The introduction of redundant constraints into the structure of the system is usually the result of a conscious decision of the designer, made after considering the advantages (e.g., greater strength) and disadvantages (e.g., the requirement of greater accuracy of manufacturing of the bodies and the introduction of assembly stresses) of such systems.

Redundant constraints cause further problems in the simulation of the system. In the case of overconstrained MBSs, additional numerical issues result from the fact that the Jacobian/constraint matrix of the considered MBS is rank-deficient. These problems may be reduced by using the appropriate methods to analyze overconstrained MBSs (see, e.g., [2, 1, 5, 6]). Some publications compare selected ODE approaches that are applicable to simulate multibody systems with or without redundant constraints, e.g., [4, 2, 1, 6, 5]. However, a limited number of integration methods were tested in these publications. Hence, a natural question arises: **will the obtained results regarding the relative effectiveness of these methods be the same when other integration schemes are used, and will all integration algorithms give the results at all?** This paper presents the preliminary results of research conducted in this research field.

Numerical methods

In this paper, selected approaches used for the simulation of the MBSs are considered. These methods allow for the integration of the DAEs by using methods for ODEs. The following methods are used: the Zero Eigenvalue Method [4, 6, 2, 1], the Pseudo Upper Triangular Decomposition method (two forms—with the Householder Transformation and the Gauss Decomposition) [4, 6, 2, 1], the Schur Decomposition Method [4, 6, 2, 1], the SVD Method [4, 6, 2, 1], the QR Decomposition Method [4, 6, 2, 1], the Direct Integration Method [5], the Coordinate Partitioning Method [4, 6, 2, 1], the Udwadia-Kalaba Formulation [4, 5, 2, 1], the Least-squares Block Solution (two forms) [5, 2, 1], the Udwadia-Phohomsiri Formulation [5, 2, 1], and the Wang Huston Formulation [6, 2, 1].

Several integration schemes were considered for these methods, i.e., the non-stiff ODE solvers (ode45, ode23, ode113) and stiff solvers (ode15s, ode23t, ode23tb, ode23s) of MATLAB®. The ode45 is the Runge-Kutta method based on the Dormand-Prince (4,5) pair [7], which is frequently the first-choice method [3]. The ode23 is the Runge-Kutta method based on the Bosacki-Shampine (2,3) pair [7]. The ode113 is an application of the Adams-Bashforth-Moulton approach [7]. The ode15s is quasi-constant step size NDFs/BDFs method [7]. The ode23t is trapezoidal rule method [8]. The ode23tb is the Runge-Kutta method with a trapezoidal rule and second-order BDF (TR-BDF2 method) [3]. The ode23s is modified Rosenbrock code [7].

Examples and results

Two MBSs described by absolute coordinates are studied—redundantly constrained and non-redundantly constrained robotic manipulators (see Fig. 1). Both the systems are spatial. The non-overconstrained manipulator was created by removing the redundant body no. 7 of the other MBS. The Euler angles (zxz) are used for the orientation description of the systems to allow us to consider the numerical methods that do not work in the case of a singular mass matrix.

The manipulators are built from the bodies of the same parameters, i.e., length $l = 0.5\text{ m}$, mass $m = 5\text{ kg}$, and moments of inertia $J_x = 0.025\text{ kgm}^2$, $J_y = J_z = 0.12\text{ kgm}^2$. Revolute joints connect the bodies. The gravity acts in the negative direction of axis z_0 , and its acceleration $|g| = 9.80665\text{ m/s}^2$. During the simulations, the manipulators were loaded with forces.

Figure 1: Considered robotic manipulators—overconstrained (on the left) and non-overconstrained (on the right)

The 10-second simulations of motion were performed for selected error tolerance values. MATLAB® run in single-thread mode during the calculations to obtain more reliable time results (which are not disturbed by the time needed to exchange data between multiple threads).

Conclusions

It turns out that the efficiency of the methods depends not only on the selected integration method but also on the structure of MBS. The non-stiff ODE solvers gave results for both the overconstrained and non-overconstrained manipulators. In contrast, the stiff solvers had trouble getting a solution, especially (but not only) in the case of the redundantly constrained manipulator. In addition, not all the methods had produced results in a reasonable time. Some simulations were interrupted when no result was obtained within approximately 15 minutes. It should be emphasized that the obtained results cannot be considered valid for all MBSs. However, based on this work, it can be supposed which of the studied simulation methods will be better for the other systems. This work also provides a reasonable basis for further research in numerical methods for MBSs.

A rockfall simulation scheme which preserves the stability properties of rotating rocks

Remco Leine*, Giuseppe Capobianco*, Perry Bartelt†, Guang Lu†

**Institute for Nonlinear Mechanics, University of Stuttgart, Germany*

†*WSL Institute for Snow and Avalanche Research SLF, Davos Dorf, Switzerland*

Summary. The stability properties of a freely rotating rigid body are governed by the intermediate axis theorem, i.e. rotation around the major and minor principal axes is stable whereas rotation around the intermediate axis is unstable. The stability of the principal axes is of importance for the prediction of rockfall. Current numerical schemes for 3D rockfall simulation, however, are not able to correctly represent these stability properties. In this paper we give a proof using Lyapunov functions of an extended intermediate axis theorem, which not only involves the angular momentum equations but also the orientation of the body. Inspired by the stability proof, we present an novel scheme which respects the stability properties of a freely rotating body and which can be incorporated in numerical schemes for the simulation of rigid bodies with frictional unilateral constraints.

Introduction

A full 3D simulation technique for rockfall dynamics, taking rock shape into account and using the state-of-the-art methods of multibody dynamics and nonsmooth contact dynamics, has been developed in [3]. The rockfall simulation technique is based on the nonsmooth contact dynamics method with hard contact laws. The rock is modeled as an arbitrary convex polyhedron and the terrain model is based on a high resolution digital elevation model. The developed numerical methods have been implemented in the code RAMMS::ROCKFALL, which is being actively used in the natural hazards research community, and is to date the only 3D code which takes rockshape into account [2].

Field observations of natural rockfall events as well as high precision measurements with instrumented experimental rocks [1] have shown that platy disk-shaped rocks have the tendency to roll and bump down the slope around their major principal axis¹. Simulations with the present implementation of RAMMS::ROCKFALL, however, fail to represent the observed rolling phenomenon.

The intermediate axis theorem is a result of the Euler equations describing the movement of a rigid body with three distinct principal moments of inertia. The theorem describes the following effect: rotation of a rigid body around its minor and major principal axes is stable, while rotation around its intermediate principal axis is unstable. The classical intermediate axis theorem, however, only involves the Euler equations for the three components of the angular velocity. In this paper, we describe the dynamics of a freely rotating body in state-space form using as states the three angular velocity components and an arbitrary parametrization of the orientation of the body with respect to the inertial frame. Using the method of Lyapunov functions we rigorously prove an extended version of the intermediate axis theorem in the full state-space.

In this paper we will show that the present scheme, which is fully explicit during flight phases of the rock, does not respect the intermediate axis theorem. Furthermore, we will present an alternative implicit scheme which correctly describes the stability properties of a freely rotating body.

Equations of motion of a free spinning body

Let \mathcal{V} be the Euclidean vector space. To describe the orientation of the rock, we will use a body-fixed frame $K = (\vec{e}_x^K, \vec{e}_y^K, \vec{e}_z^K)$ as well as an inertial frame $I = (\vec{e}_x^I, \vec{e}_y^I, \vec{e}_z^I)$. An arbitrary vector $\vec{a} \in \mathcal{V}$ can be expressed in the K -frame through the tuple ${}_K\vec{a} \in \mathbb{R}^3$, which is related to its representation ${}_I\vec{a}$ in the inertial frame through

$$\vec{a} = \mathbf{A}_{IK} {}_K\vec{a}, \quad (1)$$

where $\mathbf{A}_{IK} = ({}_I\vec{e}_x^K \quad {}_I\vec{e}_y^K \quad {}_I\vec{e}_z^K) \in \text{SO}(3)$ is the transformation matrix describing the orientation of the rock. Let ${}_K\vec{\Omega}$ denote the angular velocity of the body expressed in the body-fixed frame K . The spin of the body is defined by

$$\vec{N}_S = \Theta_S \vec{\Omega} \quad (2)$$

where Θ_S is the inertia tensor. The inertia tensor takes a constant form in the body-fixed frame, which we choose to be aligned along the principal axes of inertia, such that

$$\Theta := {}_K\Theta_S = \begin{pmatrix} A & 0 & 0 \\ 0 & B & 0 \\ 0 & 0 & C \end{pmatrix} \quad (3)$$

where $A, B, C > 0$ are the principal moments of inertia around the minor, intermediate and major axis respectively. We will denote $\Theta := {}_K\Theta_S$ as inertia matrix to have a short-hand notation. During flight, the rotational motion of the rock is decoupled from the translational motion and fully described by the spin invariance $\dot{\vec{N}}_S = \vec{0}$, yielding

$${}_K\dot{\vec{N}}_S + {}_K\vec{\Omega} \times {}_K\vec{N}_S = \vec{0} \quad (4)$$

¹<https://youtu.be/oWkTfTGeAEo>

in the body-fixed frame, which lead to the Euler equations for a freely rotating rigid body

$$\Theta \dot{\omega} + \omega \times (\Theta \omega) = 0. \quad (5)$$

Herein, we used the short-hand notation $\omega = {}_K \vec{\Omega}$. The evolution of the orientation of the body is described by

$$\dot{A}_{IK} = A_{IK} \tilde{\omega}, \quad (6)$$

where $\tilde{\omega}$ is the skew-symmetric matrix such that $\tilde{\omega}c = \omega \times c$ for all $c \in \mathbb{R}^3$. The orientation of the body may be freely parameterized using for instance unit-quaternions $q \in \mathbb{R}^4$ or axis-angle notation (n, χ) . The matrix differential equation (6) results in a set of ordinary differential equations for the chosen parametrization. If a quaternion $q = (p_0, p^T)^T$ representation is used then the rotation matrix is parametrized as

$$A_{IK} = I + \frac{2}{p_0^2 + p^T p} (\tilde{p} \tilde{p} + p_0 \tilde{p}) \quad (7)$$

resulting in

$$\dot{q} = F(q) \omega \quad (8)$$

with

$$F(q) = \frac{1}{2\|q\|} \begin{pmatrix} p^T \\ \tilde{p} + p_0 I \end{pmatrix}. \quad (9)$$

Invariants of motion of the Euler equations

The body has the rotational kinetic energy

$$T = \frac{1}{2} \omega^T \Theta \omega \quad (10)$$

being a constant of motion as, using (5),

$$\frac{d}{dt} T = \omega^T \Theta \dot{\omega} = -\omega^T (\omega \times (\Theta \omega)) = 0. \quad (11)$$

A second invariant follows from the spin

$${}_I \vec{N}_S = A_{IK} \Theta \omega, \quad (12)$$

which is constant in the inertial frame, i.e.

$$\frac{d}{dt} ({}_I \vec{N}_S) = \dot{A}_{IK} \Theta \omega + A_{IK} \Theta \dot{\omega} = A_{IK} (\omega \times (\Theta \omega)) - A_{IK} (\omega \times (\Theta \omega)) = 0. \quad (13)$$

When expressed in the body fixed frame, the spin ${}_K \vec{N}_S$ is not constant but keeps a constant magnitude

$$\frac{d}{dt} \|{}_K \vec{N}_S\|^2 = \frac{d}{dt} ({}_K \vec{N}_S^T {}_K \vec{N}_S) = 2(\Theta \omega)^T \Theta \dot{\omega} = -2(\Theta \omega)^T (\omega \times (\Theta \omega)) = 0. \quad (14)$$

Stationary motion

A rigid body may undergo a stationary motion for which its angular velocity is constant, i.e. $\dot{\omega} = 0$. We will denote such a stationary motion in state-space as $(A_{IK\star}(t), \omega_\star)$. From the Euler equations (5) we infer that stationary motion is only possible if the term $\omega \times (\Theta \omega)$ vanishes. Stationary motion therefore implies that ω_\star is in an eigendirection of Θ , resulting in three stationary directions of motion ${}_K \vec{e}_x^K, {}_K \vec{e}_y^K, {}_K \vec{e}_z^K$. Without loss of generality, let $\omega_\star = \Omega e_\star$, where $e_\star = e_3 = [0 \ 0 \ 1]^T$ agrees with ${}_K \vec{e}_z^K$. The vector e_\star may be complemented by $e_1 = [1 \ 0 \ 0]^T$ and $e_2 = [0 \ 1 \ 0]^T$ to form an orthonormal basis. The evolution of the orientation of the body during stationary motion

$$A_{IK\star}(t) = A_{IK\star}(0) e^{\tilde{\omega}_\star t} \quad (15)$$

follows from the closed form solution of the matrix differential equation (6). Without loss of generality, we set $A_{IK\star}(0) = I$. From

$${}_I \vec{e}_z^{K\star}(t) = A_{IK\star}(t) e_3 = e^{\tilde{\omega}_\star t} e_\star = e_\star = {}_I \vec{e}_z^I \quad (16)$$

it follows that $\vec{e}_z^{K\star} = \vec{e}_z^I$ for all t . The stationary motion $(A_{IK\star}(t), \omega_\star)$ itself cannot be stable, irrespective of the principal axis which is considered, because a small error $\Delta\Omega$ in the magnitude of the angular velocity $\omega = (\Omega + \Delta\Omega) e_\star$ will cause $A_{IK}(t)$ to diverge from $A_{IK\star}(t)$. Hence, instead of the stationary motion we need to study the stability of the axis of rotation, or, more precisely, of a manifold in state-space related to that. Hereto, we consider the distance between the axes

of rotation $\vec{e}_z^{K*} = \vec{e}_z^I$ of the stationary motion and \vec{e}_z^K of an arbitrary motion, which we express in the K -frame using the quantity

$$\mathbf{d}(t) = {}_K\vec{e}_z^{K*} - {}_K\vec{e}_z^K = {}_K\vec{e}_z^I - {}_K\vec{e}_z^K = \mathbf{A}_{KI}(t)\mathbf{e}_* - \mathbf{e}_*. \quad (17)$$

Furthermore, to parametrize the transformation matrix $\mathbf{A}_{IK}(t)$, we also introduce the time-dependent quantities

$$\mathbf{h}_1(t) = \mathbf{A}_{KI}(t)\mathbf{e}_1 - \mathbf{e}_1, \quad (18)$$

$$\mathbf{h}_2(t) = \mathbf{A}_{KI}(t)\mathbf{e}_2 - \mathbf{e}_2. \quad (19)$$

The transformation matrix may therefore be expressed as

$$\begin{aligned} \mathbf{A}_{IK}^T(t) &= \mathbf{I} + [\mathbf{h}_1(t) \quad \mathbf{h}_2(t) \quad \mathbf{d}(t)] [\mathbf{e}_1 \quad \mathbf{e}_2 \quad \mathbf{e}_*]^{-1} \\ &= \mathbf{I} + [\mathbf{h}_1(t) \quad \mathbf{h}_2(t) \quad \mathbf{d}(t)]. \end{aligned} \quad (20)$$

Furthermore, we introduce the quantity

$$\boldsymbol{\alpha}(t) = \boldsymbol{\omega}(t) - \boldsymbol{\omega}_* \quad (21)$$

to express the difference in rotation speed, which is being governed by the Euler equations (5)

$$\boldsymbol{\Theta}\dot{\boldsymbol{\alpha}} + (\boldsymbol{\omega}_* + \boldsymbol{\alpha}) \times (\boldsymbol{\Theta}(\boldsymbol{\omega}_* + \boldsymbol{\alpha})) = \mathbf{0}. \quad (22)$$

Having introduced the quantities \mathbf{d} and $\boldsymbol{\alpha}$, we can define the manifold of stationary rotation in a straightforward way

$$\mathcal{M} = \{(\mathbf{A}_{IK}, \boldsymbol{\omega}) \in \text{SO}(3) \times \mathbb{R}^3 \mid \mathbf{d} = \mathbf{0}, \boldsymbol{\alpha} = \mathbf{0}\}. \quad (23)$$

The dynamics of the distance to the axis of stationary rotation is given by

$$\begin{aligned} \dot{\mathbf{d}}(t) &= \dot{\mathbf{A}}_{KI}(t)\mathbf{e}_* = (\mathbf{A}_{IK}(t)\tilde{\boldsymbol{\omega}}(t))^T \mathbf{e}_* \\ &= -\tilde{\boldsymbol{\omega}}(t)\mathbf{A}_{KI}(t)\mathbf{e}_* \\ &= -(\tilde{\boldsymbol{\omega}}_* + \tilde{\boldsymbol{\alpha}}(t))(\mathbf{d}(t) + \mathbf{e}_*) \\ &= -\tilde{\boldsymbol{\omega}}_*\mathbf{d}(t) - \tilde{\boldsymbol{\alpha}}(t)(\mathbf{d}(t) + \mathbf{e}_*) \end{aligned} \quad (24)$$

being only dependent on \mathbf{d} and $\boldsymbol{\alpha}$. It holds that $\dot{\mathbf{d}}(t) = \mathbf{0}$ if $\mathbf{d} = \boldsymbol{\alpha} = \mathbf{0}$ and $\dot{\boldsymbol{\alpha}}(t) = \mathbf{0}$ if $\boldsymbol{\alpha} = \mathbf{0}$. Hence, the manifold \mathcal{M} of stationary rotation is invariant. The differential equations (24) and (22) can be gathered using $\mathbf{y}(t) = (\mathbf{d}^T \quad \boldsymbol{\alpha}^T)^T$ in the system of ordinary differential equations

$$\dot{\mathbf{y}}(t) = \mathbf{f}(\mathbf{y}(t)), \quad (25)$$

which is time-autonomous. The stability of the axis of rotation now bears down to the stability of the invariant manifold \mathcal{M} , i.e. the stability of the equilibrium $\mathbf{y}^* = \mathbf{0}$ of system (25). The stability properties of stationary rotation in the 6-dimensional state-space \mathbf{y} will be referred as the extended intermediate axis theorem.

Extended intermediate axis theorem

Stability of rotation around the major principal axis

We consider motion in the vicinity of the stationary rotation $\boldsymbol{\omega}_* = \Omega\mathbf{e}_*$, $\Omega > 0$, and $C \geq \max(A, B)$ such that \mathbf{e}_* is the major principal axis of inertia. Herein, the $K*$ -frame is the body fixed frame of stationary motion, whereas we will reserve the K -frame for the body fixed frame of an arbitrary motion in the vicinity of the stationary motion. The frames are related through $\mathbf{A}_{KK*} = \mathbf{A}_{KI}\mathbf{A}_{IK*} = \mathbf{A}_{IK}^T\mathbf{A}_{IK*}$ and it therefore holds that

$$\mathbf{A}_{KK*}\mathbf{e}_* = \mathbf{A}_{KI}\mathbf{A}_{IK*}\mathbf{e}_* = \mathbf{A}_{KI}\mathbf{e}_* = \mathbf{d} + \mathbf{e}_*. \quad (26)$$

In order to set up a Lyapunov function, we consider the function

$$\bar{V}(\mathbf{d}, \boldsymbol{\alpha}) = \|\mathbf{I}\vec{\mathbf{N}}_S - \mathbf{I}\vec{\mathbf{N}}_{S*}\|^2 = \|\mathbf{K}\vec{\mathbf{N}}_S - \mathbf{K}\vec{\mathbf{N}}_{S*}\|^2. \quad (27)$$

The spin $\vec{\mathbf{N}}_{S*}$ can be easily expressed in the $K*$ -frame as ${}_{K*}\vec{\mathbf{N}}_{S*} = \boldsymbol{\Theta}\boldsymbol{\omega}_* = C\Omega\mathbf{e}_*$, which can be cast in the K -frame through

$${}_K\vec{\mathbf{N}}_{S*} = \mathbf{A}_{KK*}{}_{K*}\vec{\mathbf{N}}_{S*} = C\Omega\mathbf{A}_{KK*}\mathbf{e}_* = C\Omega(\mathbf{d} + \mathbf{e}_*). \quad (28)$$

Using ${}_K\vec{\mathbf{N}}_S = \boldsymbol{\Theta}\boldsymbol{\omega} = \boldsymbol{\Theta}(\boldsymbol{\alpha} + \boldsymbol{\omega}_*) = \boldsymbol{\Theta}\boldsymbol{\alpha} + C\Omega\mathbf{e}_*$ we arrive at

$$\bar{V}(\mathbf{d}, \boldsymbol{\alpha}) = \|\boldsymbol{\Theta}\boldsymbol{\alpha} - C\Omega\mathbf{d}\|^2 = (A\alpha_x - C\Omega d_x)^2 + (B\alpha_y - C\Omega d_y)^2 + (C\alpha_z - C\Omega d_z)^2. \quad (29)$$

Furthermore, we introduce the function

$$\hat{V}(\boldsymbol{\alpha}) = 2C T(\boldsymbol{\omega}) - \|\vec{\mathbf{N}}_S(\boldsymbol{\omega})\|^2 + \frac{1}{\Omega^2}(2 T(\boldsymbol{\omega}) - 2 T(\boldsymbol{\omega}_*))^2, \quad (30)$$

which can be expressed as

$$\begin{aligned}
 \hat{V}(\alpha) &= C\omega^T \Theta \omega - \omega^T \Theta^2 \omega + \frac{1}{\Omega^2} (\omega^T \Theta \omega - \omega_\star^T \Theta \omega_\star)^2 \\
 &= (\alpha + \omega_\star)^T (C\Theta - \Theta^2) (\alpha + \omega_\star) + \frac{1}{\Omega^2} ((\alpha + \omega_\star)^T \Theta (\alpha + \omega_\star) - \omega_\star^T \Theta \omega_\star)^2 \\
 &= \alpha^T (C\Theta - \Theta^2) \alpha + \frac{1}{\Omega^2} (\alpha^T \Theta \alpha + 2C\omega_\star^T \alpha)^2 \\
 &= A(C - A)\alpha_x^2 + B(C - B)\alpha_y^2 + \frac{1}{\Omega^2} (A\alpha_x^2 + B\alpha_y^2 + C\alpha_z^2 + 2C\Omega\alpha_z)^2
 \end{aligned} \tag{31}$$

To prove stability of the trivial equilibrium of (25) for $C \geq \max(A, B)$, we consider the Lyapunov candidate function

$$V(\mathbf{y}) = \bar{V}(\mathbf{d}, \alpha) + \hat{V}(\alpha), \tag{32}$$

which purely consists of the invariants of motion $\vec{N}_S = \text{const.}$ and $T(\omega) = \text{const.}$ and is therefore constant, i.e. $\dot{V} = 0$ along solutions of the system. The (local) positive definiteness of V remains to be investigated in the following.

First, we show that $\hat{V}(\alpha)$ is a local positive definite function in α . We infer that $\hat{V}(\alpha) \geq 0$ for arbitrary $\alpha \in \mathbb{R}^3$ as it is a sum of squares with positive coefficients for $C \geq \max(A, B)$. Moreover, the points where $\hat{V}(\alpha) = 0$ are characterized by $\alpha_x = 0$, $\alpha_y = 0$ and $\alpha_z(\alpha_z + 2\Omega) = 0$. This implies that \hat{V} vanishes at the origin and at the point $\alpha = (0 \ 0 \ -2\Omega)^T$ and is strictly positive for all other $\alpha \in \mathbb{R}^3$, proving that $\hat{V}(\alpha)$ is locally positive definite.

As V is the sum of $\bar{V}(\mathbf{d}, \alpha) \geq 0$ and $\hat{V}(\alpha) \geq 0$, it may only vanish if $\bar{V}(\mathbf{d}, \alpha)$ and $\hat{V}(\alpha)$ vanish simultaneously. From the local positive definiteness of $\hat{V}(\alpha)$ it is clear that, in the neighborhood of the origin, V may only vanish for $\alpha = 0$. Now we consider $\bar{V}(\mathbf{d}, \alpha)$ and note that $\bar{V}(\mathbf{d}, 0) = C^2 \Omega^2 \|\mathbf{d}\|^2$ can only vanish if $\mathbf{d} = 0$. This proves local positive definiteness of V and, thereby, that rotation around the major principal axis is stable. This result may be viewed as an *extended* intermediate axis theorem, as it not only proves that the angular velocity ω remains close to ω_\star (i.e. the classical intermediate axis theorem), but also proves that \mathbf{d} remains small, i.e. the orientation of the axis of rotation is stable.

Stability of rotation around the minor principal axis

We now consider the stability of stationary rotation around the minor principal axis by setting again $\omega_\star = \Omega e_\star$, $\Omega > 0$ with $e_\star = e_3$ but assuming $C \leq \min(A, B)$. The proof of the stability of stationary rotation around the minor principal axis is completely analogous to the proof for the major principal axis.

We consider again the Lyapunov candidate function of the form

$$V(\mathbf{y}) = \bar{V}(\mathbf{d}, \alpha) + \hat{V}(\alpha), \tag{33}$$

where the function

$$\bar{V}(\mathbf{d}, \alpha) = \|\Theta \alpha - C\Omega \mathbf{d}\|^2 = (A\alpha_x - C\Omega d_x)^2 + (B\alpha_y - C\Omega d_y)^2 + (C\alpha_z - C\Omega d_z)^2 \tag{34}$$

is defined as before, but $\hat{V}(\alpha)$ is chosen as

$$\begin{aligned}
 \hat{V}(\alpha) &= -C\omega^T \Theta \omega + \omega^T \Theta^2 \omega + \frac{1}{\Omega^2} (\omega^T \Theta \omega - \omega_\star^T \Theta \omega_\star)^2 \\
 &= A(A - C)\alpha_x^2 + B(B - C)\alpha_y^2 + \frac{1}{\Omega^2} (A\alpha_x^2 + B\alpha_y^2 + C\alpha_z^2 + 2C\Omega\alpha_z)^2
 \end{aligned} \tag{35}$$

The Lyapunov function is constant along solutions and is locally positive definite for $C \leq \min(A, B)$, proving stability of rotation around the minor principal axis.

Fully explicit scheme

We briefly discuss the fully explicit scheme (or pseudo-implicit scheme) which is currently implemented in RAMMS:rockfall. Let ω^k denote the angular velocity of the rock at time instant t^k . The present scheme calculates the angular velocity ω^{k+1} at time instant $t^{k+1} = t^k + \Delta t$ (in the absence of contact with the terrain) through

$$\Theta(\omega^{k+1} - \omega^k) + \frac{\Delta t}{2} G(\omega^k)(\omega^{k+1} + \omega^k) = 0, \tag{36}$$

where $G(\omega) = \Theta \tilde{\omega} + \tilde{\omega} \Theta$, resulting the explicit velocity update

$$\omega^{k+1} = \left(\Theta + \frac{\Delta t}{2} G(\omega^k) \right)^{-1} \left(\Theta - \frac{\Delta t}{2} G(\omega^k) \right) \omega^k = \omega^k - \left(\Theta + \frac{\Delta t}{2} G(\omega^k) \right)^{-1} G(\omega^k) \omega^k, \tag{37}$$

where the last step is a simplification explained in [5]. The rotation matrix is parametrized using a quaternion \mathbf{q}^k with a midpoint update rule

$$\mathbf{q}_{\text{pre}}^{k+1} = \mathbf{q}^{k+\frac{1}{2}} + \frac{\Delta t}{2} \mathbf{F}(\mathbf{q}^{k+\frac{1}{2}}) \boldsymbol{\omega}^{k+1}, \quad \mathbf{q}^{k+1} = \frac{\mathbf{q}_{\text{pre}}^{k+1}}{\|\mathbf{q}_{\text{pre}}^{k+1}\|}, \quad (38)$$

where $\mathbf{q}^{k+\frac{1}{2}} = \mathbf{q}^k + \frac{\Delta t}{2} \boldsymbol{\omega}^k$.

The rationale behind the explicit scheme is that it preserves the kinetic energy. The change in kinetic energy over the time step is

$$\begin{aligned} T(\boldsymbol{\omega}^{k+1}) - T(\boldsymbol{\omega}^k) &= \frac{1}{2} (\boldsymbol{\omega}^{k+1})^T \boldsymbol{\Theta} \boldsymbol{\omega}^{k+1} - \frac{1}{2} (\boldsymbol{\omega}^k)^T \boldsymbol{\Theta} \boldsymbol{\omega}^k \\ &= \frac{1}{2} (\boldsymbol{\omega}^{k+1} + \boldsymbol{\omega}^k)^T \boldsymbol{\Theta} (\boldsymbol{\omega}^{k+1} - \boldsymbol{\omega}^k). \end{aligned} \quad (39)$$

Substitution of the explicit scheme (36) yields

$$T(\boldsymbol{\omega}^{k+1}) - T(\boldsymbol{\omega}^k) = -\frac{\Delta t}{4} (\boldsymbol{\omega}^{k+1} + \boldsymbol{\omega}^k)^T \mathbf{G}(\boldsymbol{\omega}^k) (\boldsymbol{\omega}^{k+1} + \boldsymbol{\omega}^k) = 0 \quad (40)$$

due to the skew-symmetry of $\mathbf{G}(\boldsymbol{\omega})$ which shows that the kinetic energy is conserved. A stationary solution $\boldsymbol{\omega}_* = \boldsymbol{\omega}^k = \boldsymbol{\omega}^{k+1}$ of the scheme respects

$$\mathbf{G}(\boldsymbol{\omega}_*) \boldsymbol{\omega}_* = \boldsymbol{\omega}_* \times (\boldsymbol{\Theta} \boldsymbol{\omega}_*) = 0, \quad (41)$$

and corresponds to a stationary rotation of the Euler equations around principal axes.

Let $\boldsymbol{\alpha}^k$ be the perturbation of the angular velocity with respect to the stationary rotation $\boldsymbol{\omega}_* = \Omega \mathbf{e}_*$ around the principal axis $\mathbf{e}_* = \mathbf{e}_3$. The perturbation dynamics is obtained using $\boldsymbol{\omega}^k = \boldsymbol{\omega}_* + \boldsymbol{\alpha}^k$ as

$$\boldsymbol{\Theta}(\boldsymbol{\alpha}^{k+1} - \boldsymbol{\alpha}^k) + \frac{\Delta t}{2} \mathbf{G}(\boldsymbol{\omega}_*)(\boldsymbol{\alpha}^{k+1} + \boldsymbol{\alpha}^k) + \frac{\Delta t}{2} \mathbf{G}(\boldsymbol{\alpha}^k)(\boldsymbol{\alpha}^{k+1} + \boldsymbol{\alpha}^k) + \Delta t \mathbf{G}(\boldsymbol{\alpha}^k) \boldsymbol{\omega}_* = 0, \quad (42)$$

where the linearity of \mathbf{G} and (41) have been used. For small perturbations we can neglect higher order terms in $\boldsymbol{\alpha}^k$ giving the linearized perturbation dynamics

$$\begin{aligned} \mathbf{0} &= \boldsymbol{\Theta}(\boldsymbol{\alpha}^{k+1} - \boldsymbol{\alpha}^k) + \frac{\Delta t}{2} \mathbf{G}(\boldsymbol{\omega}_*)(\boldsymbol{\alpha}^{k+1} + \boldsymbol{\alpha}^k) + \Delta t \mathbf{G}(\boldsymbol{\alpha}^k) \boldsymbol{\omega}_* \\ &= \left[\boldsymbol{\Theta} + \frac{\Delta t}{2} \mathbf{G}(\boldsymbol{\omega}_*) \right] (\boldsymbol{\alpha}^{k+1} - \boldsymbol{\alpha}^k) + \Delta t (\mathbf{G}(\boldsymbol{\alpha}^k) \boldsymbol{\omega}_* + \mathbf{G}(\boldsymbol{\omega}_*) \boldsymbol{\alpha}^k). \end{aligned} \quad (43)$$

The linearized perturbation dynamics can be solved for $\boldsymbol{\alpha}^{k+1}$ explicitly. Hereto, the second term is reformulated as

$$\begin{aligned} \mathbf{G}(\boldsymbol{\alpha}^k) \boldsymbol{\omega}_* + \mathbf{G}(\boldsymbol{\omega}_*) \boldsymbol{\alpha}^k &= \boldsymbol{\Theta} \tilde{\boldsymbol{\alpha}}^k \boldsymbol{\omega}_* + \tilde{\boldsymbol{\alpha}}^k \boldsymbol{\Theta} \boldsymbol{\omega}_* + \boldsymbol{\Theta} \tilde{\boldsymbol{\omega}}_* \boldsymbol{\alpha}^k + \tilde{\boldsymbol{\omega}}_* \boldsymbol{\Theta} \boldsymbol{\alpha}^k \\ &= \tilde{\boldsymbol{\alpha}}^k \boldsymbol{\Theta} \boldsymbol{\omega}_* + \tilde{\boldsymbol{\omega}}_* \boldsymbol{\Theta} \boldsymbol{\alpha}^k \\ &= \boldsymbol{\alpha}^k \times (\boldsymbol{\Theta} \boldsymbol{\omega}_*) + \boldsymbol{\omega}_* \times (\boldsymbol{\Theta} \boldsymbol{\alpha}^k) \\ &=: \mathbf{A} \boldsymbol{\alpha}^k, \end{aligned} \quad (44)$$

where $\mathbf{A} = -(\widetilde{\boldsymbol{\Theta} \boldsymbol{\omega}_*}) + \tilde{\boldsymbol{\omega}}_* \boldsymbol{\Theta}$. Next, the matrix $\mathbf{B} = \boldsymbol{\Theta} + \frac{\Delta t}{2} \mathbf{G}(\boldsymbol{\omega}_*)$ in (43) has the inverse

$$\mathbf{B}^{-1} = \frac{1}{\det \mathbf{B}} \begin{pmatrix} BC & \frac{\Delta t}{2} \Omega C(A+B) & 0 \\ -\frac{\Delta t}{2} \Omega C(A+B) & AC & 0 \\ 0 & 0 & \frac{\det \mathbf{B}}{C} \end{pmatrix}, \quad (45)$$

where the determinant of \mathbf{B} is given by $\det \mathbf{B} = ABC + \frac{\Delta t^2}{4} C(A+B)^2$. Hence, the linearized perturbation dynamics can be given in the explicit form

$$\boldsymbol{\alpha}^{k+1} = (\mathbf{I} - \Delta t \mathbf{B}^{-1} \mathbf{A}) \boldsymbol{\alpha}^k = \mathbf{D} \boldsymbol{\alpha}^k, \quad (46)$$

in which the matrix \mathbf{D} has the non-zero components

$$\begin{aligned} D_{11} &= 1 - \frac{\Delta t^2}{2 \det \mathbf{B}} \Omega^2 C(A+B)(A-C), & D_{12} &= -\frac{\Delta t}{\det \mathbf{B}} \Omega AC(A-C), \\ D_{21} &= -\frac{\Delta t}{\det \mathbf{B}} \Omega BC(C-B) & D_{22} &= 1 + \frac{\Delta t^2}{2 \det \mathbf{B}} \Omega^2 C(A+B)(C-B), \\ D_{33} &= 1. \end{aligned} \quad (47)$$

The stability of rotation around the major principal axis is determined through the eigenvalues of \mathbf{D} , being the roots of the characteristic polynomial

$$\begin{aligned}\det(\lambda \mathbf{I} - \mathbf{D}) &= (\lambda - 1) [(\lambda - D_{11})(\lambda - D_{22}) - D_{12}D_{21}] \\ &= (\lambda - 1) [\lambda^2 - (D_{11} + D_{22})\lambda + (D_{11}D_{22} - D_{12}D_{21})]\end{aligned}\quad (48)$$

given by

$$\lambda_{1/2} = \frac{b \pm \sqrt{b^2 - 4c}}{2} \quad \text{and} \quad \lambda_3 = 1. \quad (49)$$

Herein, the parameters $b = D_{11} + D_{22}$ and $c = D_{11}D_{22} - D_{12}D_{21}$ can be calculated as

$$b = 2 - \frac{\Delta t^2 \Omega^2}{2 \det \mathbf{B}} C(A + B)(A + B - 2C), \quad c = 1 + \frac{\Delta t^2 \Omega^2}{2 \det \mathbf{B}} C((A + B)(A + B - 2C) - 2(A - C)(C - B)).$$

The eigenvalues $\lambda_{1/2}$ in (49) take the form

$$\lambda_{1/2} = 1 - \frac{d}{2} \pm \frac{\sqrt{d^2 + 4e}}{2} \quad (50)$$

with

$$d = \frac{\Delta t^2}{2 \det \mathbf{B}} \Omega^2 C(A + B)(A + B - 2C), \quad e = \frac{\Delta t^2}{\det \mathbf{B}} \Omega^2 C(A - C)(C - B) \quad (51)$$

For rotation around the major principal axis it holds that $C \geq \max(A, B)$ from which follows that $d < 0$. Therefore, at least one of the eigenvalues has a magnitude larger than unity which proves instability of rotation around the major principal axis, contrary to the intermediate axis theorem. Hence, the explicit scheme cannot correctly represent the stability properties of a freely rotating body.

A stability preserving implicit scheme

Here, we propose an alternative scheme for rockfall simulation with RAMMS:rockfall which preserves the stability properties of the principal axes of rotation in accordance with the intermediate axis theorem. The alternative scheme consists of two parts:

1. as update rule for the angular velocity, we use the implicit scheme proposed by [5]
2. as update rule for the orientation parametrization, we propose a novel scheme which preserves the spin.

The implicit scheme for the angular velocity calculates $\boldsymbol{\omega}^{k+1}$ at time instant $t^{k+1} = t^k + \Delta t$ during a flight phase as

$$\boldsymbol{\Theta}(\boldsymbol{\omega}^{k+1} - \boldsymbol{\omega}^k) + \Delta t \boldsymbol{\omega}^{k+\frac{1}{2}} \times (\boldsymbol{\Theta} \boldsymbol{\omega}^{k+\frac{1}{2}}) = 0 \quad \text{with} \quad \boldsymbol{\omega}^{k+\frac{1}{2}} = \frac{1}{2}(\boldsymbol{\omega}^k + \boldsymbol{\omega}^{k+1}). \quad (52)$$

Substitution of the scheme (52) in the kinetic energy expression (39) yields

$$T(\boldsymbol{\omega}^{k+1}) - T(\boldsymbol{\omega}^k) = -\frac{\Delta t}{2} (\boldsymbol{\omega}^{k+\frac{1}{2}})^T \left[\boldsymbol{\omega}^{k+\frac{1}{2}} \times (\boldsymbol{\Theta} \boldsymbol{\omega}^{k+\frac{1}{2}}) \right] = 0. \quad (53)$$

showing that the kinetic energy is preserved by the implicit scheme. The magnitude of the spin $\|\vec{\mathbf{N}}_S\| = \|\mathbf{K} \vec{\mathbf{N}}_S\| = \|\boldsymbol{\Theta} \boldsymbol{\omega}\|$, defined by (12), is only dependent on the angular velocity. The implicit scheme for the angular velocity also conserves the magnitude of the spin as follows from

$$\begin{aligned}\|\vec{\mathbf{N}}_S^{k+1}\|^2 - \|\vec{\mathbf{N}}_S^k\|^2 &= (\boldsymbol{\Theta} \boldsymbol{\omega}^{k+1})^T \boldsymbol{\Theta} \boldsymbol{\omega}^{k+1} - (\boldsymbol{\Theta} \boldsymbol{\omega}^k)^T \boldsymbol{\Theta} \boldsymbol{\omega}^k \\ &= (\boldsymbol{\Theta} \boldsymbol{\omega}^{k+\frac{1}{2}})^T \boldsymbol{\Theta} (\boldsymbol{\omega}^{k+1} - \boldsymbol{\omega}^k) \\ &\stackrel{(52)}{=} -\Delta t (\boldsymbol{\Theta} \boldsymbol{\omega}^{k+\frac{1}{2}})^T \left[\boldsymbol{\omega}^{k+\frac{1}{2}} \times (\boldsymbol{\Theta} \boldsymbol{\omega}^{k+\frac{1}{2}}) \right] = 0.\end{aligned}\quad (54)$$

We now propose an update rule for the orientation parametrization. The update of the orientation \mathbf{A}_{IK}^{k+1} is chosen such that the spin remains constant, i.e.

$${}_I \vec{\mathbf{N}}_S^{k+1} = {}_I \vec{\mathbf{N}}_S^k, \quad (55)$$

and such that the kinematic equation is correctly approximated in the sense that

$$\lim_{\Delta t \downarrow 0} \frac{\mathbf{A}_{IK}^{k+1} - \mathbf{A}_{IK}^k}{\Delta t} = \dot{\mathbf{A}}_{IK}(t^k) \quad (56)$$

where $\dot{A}_{IK} = A_{IK}(t)\tilde{\omega}$. We choose an update of the form

$$A_{IK}^{k+1} = A_{IK}^k e^{\tilde{\omega}^{k+\frac{1}{2}} \Delta t} B(\omega^k, \omega^{k+1}) \quad (57)$$

where the matrix B depends on ω^k and ω^{k+1} and needs to fulfill $B^T B = I$ to ensure that $(A_{IK}^{k+1})^T A_{IK}^{k+1} = I$. Furthermore, we demand that $B(x, x) = I$ for all x such that

$$\lim_{\Delta t \downarrow 0} B(\omega^k, \omega^{k+1}) = B(\omega^k, \omega^k) = I \quad (58)$$

from which follows the kinematic consistency (56).

To ensure the conservation of spin we demand

$$A_{IK}^{k+1} \Theta \omega^{k+1} = A_{IK}^k \Theta \omega^k \quad (59)$$

which, after substitution of the update rule, gives

$$A_{IK}^k e^{\tilde{\omega}^{k+\frac{1}{2}} \Delta t} B(\omega^k, \omega^{k+1}) \Theta \omega^{k+1} = A_{IK}^k \Theta \omega^k. \quad (60)$$

The matrix B will now be chosen such that

$$e^{\tilde{\omega}^{k+\frac{1}{2}} \Delta t} B(\omega^k, \omega^{k+1}) \Theta \omega^{k+1} = \Theta \omega^k \quad (61)$$

and therefore

$$B(\omega^k, \omega^{k+1}) \Theta \omega^{k+1} = e^{-\tilde{\omega}^{k+\frac{1}{2}} \Delta t} \Theta \omega^k \quad (62)$$

from which we see that it is indeed only dependent on ω^k and ω^{k+1} . The matrix B is a pure rotation.

Using Rodrigues formula, every pure rotation R around the unit vector k with rotation angle θ can be represented as

$$R = I + \sin \theta K + (1 - \cos \theta) K^2 \quad (63)$$

where $K = \tilde{k}$. If k and θ are chosen as

$$k = \frac{b \times c}{\|b \times c\|}, \quad \cos \theta = \frac{b \cdot c}{\|b\| \|c\|} \quad (64)$$

then it holds that $Rb = c$ if $\|b\| = \|c\|$. Furthermore, it holds that $R \rightarrow I$ for $b \rightarrow c$.

Hence, we choose $B = I + \sin \theta K + (1 - \cos \theta) K^2$ with

$$k = \frac{\Theta \omega^{k+1} \times (e^{-\tilde{\omega}^{k+\frac{1}{2}} \Delta t} \Theta \omega^k)}{\|\Theta \omega^{k+1} \times (e^{-\tilde{\omega}^{k+\frac{1}{2}} \Delta t} \Theta \omega^k)\|}, \quad \cos \theta = \frac{\Theta \omega^{k+1} \cdot (e^{-\tilde{\omega}^{k+\frac{1}{2}} \Delta t} \Theta \omega^k)}{\|\Theta \omega^{k+1}\| \|\Theta \omega^k\|}. \quad (65)$$

To prove that the proposed scheme has the desired stability properties of the principal axes of rotation, we use the Lyapunov functions $V(y^k)$ for the major and minor principal axes as presented before. As the proposed scheme conserves the kinetic energy and the spin by construction it holds that $V(y^{k+1}) = V(y^k)$, whereas positive definiteness has already been shown. The proposed scheme therefore preserves the stability properties of the principal axes of rotation in accordance with the extended intermediate axis theorem.

Numerical results

We compare the explicit and the implicit scheme on a numerical example. We consider a cuboid of mass $m = 1$ kg with length $a = 3$ m, width $b = 2$ m and height $c = 1$ m in the \vec{e}_x^K , \vec{e}_y^K and \vec{e}_z^K direction, respectively. The principal moments of inertia are therefore $A = \frac{m}{12}(b^2 + c^2)$, $B = \frac{m}{12}(a^2 + c^2)$ and $C = \frac{m}{12}(a^2 + b^2)$ such that $A < B < C$. Rotation in the neighborhood of stationary rotation $\omega_* = \Omega e_*$ around the major principal axis $e_* = e_3$ is considered. As initial conditions we choose $A_{IK}(0) = I$ and $\omega = (\omega_x \ \omega_y \ \omega_z)^T = (10^{-3} \ 10^{-3} \ 10)^T$ rad/s. We simulate 20 s using a time-step of $\Delta t = 0.01$ s using the explicit and implicit scheme. The results of both schemes are shown in Figures 1 and 2. The body initially rotates in the vicinity of the major principal axis with angular velocity $\omega_z = \Omega = 10$ rad/s, which is stable as follows from the extended intermediate axis theorem. However, in the numerical solution of the explicit scheme, the body deviates from stationary rotation around the major principal axis (approximately at $t = 10$ s) and tends to stable rotation around the minor principal axis with angular speed $\omega_x = -\sqrt{\frac{C}{A}}\Omega$. If a smaller time-step is taken in the explicit scheme, then the change of axis will be slower and will take place at a later point in time. The solution of the implicit scheme remains very close to the major principal axis, both in angular velocity and in the distance $d(t) = {}_K \vec{e}_z^{K*} - {}_K \vec{e}_z^K$ and is therefore much more accurate.

Simulation results with RAMMS::ROCKFALL

In rockfall events the rotation of platy disk-shaped rocks around their major principal axis is a remarkable phenomenon which has been recently precisely measured in experiments [1]. In order to capture these rock dynamics, we have fully implemented the newly proposed implicit scheme into RAMMS::ROCKFALL and have performed simulations in both idealized and actual rockfall environments. As a control group, the original explicit scheme employed in the current RAMMS::ROCKFALL version has been utilized to obtain rockfall simulations under the same boundary conditions.

The first group of simulations was performed with a disk-shaped rock going downward an idealized inclined slope of 40° . The rock has a uniformly distributed mass of 1000 kg and has a geometry size of 1.16, 1.14 and 0.35 m along its three principal axes, respectively (see Tab. 3). In total 300 simulations were performed with only changing the initial rock orientation. The same initial rock orientation set and time step (0.002 s) was employed for both the explicit and the implicit scheme [4]. Fig. 3 compares for both numerical schemes the kinetic rock energy using the statistic mode of RAMMS::ROCKFALL (first row). The trajectory mode (second row) shows for a single simulation the development of rock rotations along its principal axes. The implicit scheme tends to give significantly lower and much more homogeneous values of the kinetic energy. Furthermore, it takes a much shorter distance for rocks calculated with the implicit scheme to enter the mode rotating around their major principal axes, which remains stable until the rock reaches the horizontal deposition zone. Tab. 1 compares the corresponding mean and standard deviation values obtained for the both numerical schemes. The second group of simulations was performed with a so-called EOTA-shaped rock (see Tab. 3) which was used in rockfall experiments with instrumented rocks at Chant Sura in Davos, Switzerland [1]. The rock mass is 780 kg, homogeneously distributed in a rigid body of 0.93, 0.93 and 0.47 m along the three principal axes. Also 300 simulations

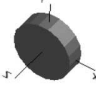

Table 1: Comparison of 300 rocks behavior on an idealized slope for the explicit and the implicit schemes.

Parameter	Explicit		Implicit	
	Mean	Standard Deviation	Mean	Standard Deviation
kinetic energy (kJ)	127.95	107.25	78.13	43.08
translational velocity (m/s)	13.35	6.29	10.59	3.48
rotational velocity (rot/s)	3.01	1.39	2.47	0.77
jump height (m)	1.23	1.24	0.87	0.84

Table 2: Comparison of 300 rocks behavior at Chant Sura for the explicit and the implicit schemes.

Parameter	Explicit		Implicit	
	Mean	Standard Deviation	Mean	Standard Deviation
kinetic energy (kJ)	64.60	46.50	76.48	47.79
translational velocity (m/s)	10.74	4.58	11.64	4.45
rotational velocity (rot/s)	2.71	1.10	2.98	1.03
jump height (m)	1.07	0.85	1.10	0.84

Table 3: Comparison of the computational time for the explicit and the implicit schemes (300-rock simulation).

Simulation case		Explicit	Implicit
idealized slope (ramp)		47 s	57 s
actual slope (Chant Sura)		9 s	15 s

were carried out here, setting the same initial rock orientations and time step (0.002 s) for both the explicit and the implicit schemes. The implicit scheme gives a more concentrated run-out zone for the rocks, see the first row in Fig. 4 and the distribution of rock kinetic energy looks “smoother” when compared with the explicit scheme. Most interestingly, the implicit scheme captures well the fast rotation of the flat rock during the entire trajectory while the explicit scheme cannot reproduce the rock’s stable rotation around its major principal axis. Tab. 2 lists the mean and standard deviation values for both the numerical schemes. Finally, Tab. 3 displays the computational time recorded for the 300-rock simulations under the explicit and the implicit schemes. The implicit scheme is a bit slower in comparison to the explicit scheme, which is expected as the updating of rock rotations requires more computational effort. However, the former does respect the stability properties of rotating 3D objects, which is a key improvement for RAMMS::ROCKFALL. Future simulations will be carefully validated against the real rockfall events and experiments. It is anticipated that for extremely long rolling phases of platy rocks the differences between the explicit and the implicit schemes could be even larger.

Conclusions

In this paper an extended intermediate axis theorem has been proven using Lyapunov functions. Using the same Lyapunov functions, we have given a rigorous proof that the implicit scheme presented in [5] respects the extended intermediate axis theorem. The computational cost per time-step is larger for the implicit scheme than the explicit scheme, as Newton iterations are needed to solve the implicit equations. However, numerical simulations show that the implicit scheme is far more accurate as it respects both the energy conservation and the invariance of the spin. The implicit scheme therefore allows to take larger time-steps without excessive error, making it a suitable scheme for 3D rockfall simulation. Numerical simulations with RAMMS::ROCKFALL using the newly developed implicit scheme show that for the downward motion of a platy rock on an actual slope the rotation around the major principal axis is stable, even in the presence of intermediate collisions and contact phases with the slope. This is in correspondence with data from field experiments.

A Three-Dimensional and Nonlinear Virtual Test Car

Georg Rill*

**Department of Mechanical Engineering, OTH Regensburg, Germany*

Summary. Virtual testing procedures have become a standard in vehicle dynamics. The increasing complexity of driver assistance systems demand for more and more virtual tests, which are supposed to produce reliable results even in the limit range. As a consequence, simplified vehicle models, like the classical bicycle model or 4-wheel vehicle models, have to be replaced by a fully three-dimensional and nonlinear vehicle model, which also encompasses the details of the suspension systems. This paper presents a passenger car model, where the chassis, the four knuckles, and the four wheels are described by rigid bodies, the suspension system is modeled by the generic design kinematics, and the TMeasy tire model provides the tire forces and torques in all driving situations.

Keywords: Virtual Test Car (VTC), Design Kinematics, TMeasy, Equations of Motion, Transient Response

Introduction

The multibody approach has become a standard in vehicle dynamics [1]. General multibody software packages, like Adams/Car [2], ReCurDyn [3], or SIMPACK [4] make it possible to assemble vehicle models of different complexities. Commercial products, like CarSim [5], CarMaker [6], or DYNA4 [7] provide ready to use vehicle models, which are real-time capable and may be used in Hardware-in-the-Loop (HIL) test rigs, in driving simulators, or for all kind of virtual driving tests including parameter optimization or autonomous drive. A basic multibody model of a standard passenger car is usually supplemented by a handling tire model, like Pacejka [8] or TMeasy [9], and it is extensible by subsystems for the steering system and the drive train [10]. Sophisticated model approaches combined with an efficient and robust solver provide an excellent runtime performance [11]. Nevertheless, simplified and rather crude three-dimensional vehicle models are still applied in the context of lap-time optimization [12] and autonomous driving [13]. However, this reduces such investigations to the level of basic studies, because the impact of the suspension properties and the road roughness on vehicle dynamics is not taken into account. This paper demonstrates, that a virtual test car (VTC), properly modeled by a three-dimensional and nonlinear multibody system, is able to achieve a much faster-than-real-time performance even on standard personal computers, although it includes the nonlinear suspension kinematics and the wheel/tire dynamics.

The VTC-Model

Model Structure

A virtual test car, valid for typical passenger cars in all driving situations, is represented by a three-dimensional multibody model which consists at least of the chassis, four knuckles, and four wheels, Figure 1. The virtual test car (VTC) is

Figure 1: Multibody model structure of a passenger car

operated with the TMeasy tire model, which represents a handling model, where the tire acts as a massless force element. The suspension kinematics allows each knuckle to perform relative to the chassis a hub motion h and a steer motion s . This generic model approach makes it possible to investigate the influence of different suspension designs, including all-wheel steering, on the handling and dynamics of a vehicle. The steer motions of passenger car front wheels are typically coupled by a rack and pinion steering system and the rear suspension often incorporates no active steer motions at all. Each of the four wheels, consisting of the rim and the tire, rotates with the angle φ about a knuckle-fixed axis, defined by the unit vector e_{yW} . The generalized coordinates $x_V, y_V, z_V, \psi_V, \theta_V$, and ϕ_V describe the momentary position and orientation of the vehicle-fixed, within the VTC model also chassis-fixed, reference frame V with respect to an earth-fixed frame 0. The points C and K denote the gravity centers of the chassis and the knuckle. In practice, the wheels of passenger cars are sufficiently balanced. Then, the wheel center W will be located on the wheel rotation axis and is fixed to the knuckle as a consequence.

The multibody system, providing the basis of three-dimensional passenger car model, has up to $f = 6 + 4 * 2 + 4 = 18$ degrees of freedom if each of the four knuckles is modeled with a hub and a steer motion. The total number of degrees of freedom is reduced to $f = 16$ if the rear wheels are not actively steered. More complex but still real-time capable vehicle models including the drive train, the steering system, and dynamic force elements are described in [11] and [14]. Appropriate road models provide the road height z and the friction coefficient μ as a function of the contact point coordinates x and y [15].

Reference Frame and Nontrivial Generalized Velocities

The momentary position and orientation of the chassis-fixed or vehicle-fixed reference frame V is provided by the position vector $r_{0V,0}$ and the rotation matrix A_{0V} defined in the VTC model as

$$r_{0V,0} = \begin{bmatrix} x_V \\ y_V \\ z_V \end{bmatrix} \quad \text{and} \quad A_{0V} = \begin{bmatrix} \cos \psi_V & -\sin \psi_V & 0 \\ \sin \psi_V & \cos \psi_V & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \cos \theta_V & 0 & \sin \theta_V \\ 0 & 1 & 0 \\ -\sin \theta_V & 0 & \cos \theta_V \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos \phi_V & -\sin \phi_V \\ 0 & \sin \phi_V & \cos \phi_V \end{bmatrix} \quad (1)$$

where x_V , y_V , z_V , ϕ_V , θ_V , and ψ_V serve as generalized coordinates. The comma separated index 0 indicates that the components of the vector r_{0V} pointing from 0 to V are expressed in the earth-fixed reference frame 0.

The components of the velocity vector v_{0V} and the angular velocity vector ω_{0V} can both be expressed in the vehicle-fixed frame. The set of kinematical differential equations

$$\begin{bmatrix} \dot{x}_V \\ \dot{y}_V \\ \dot{z}_V \end{bmatrix} = A_{0V}^T \underbrace{\begin{bmatrix} v_x \\ v_y \\ v_z \end{bmatrix}}_{v_{0V,V}} \quad \text{and} \quad \begin{bmatrix} \dot{\phi}_V \\ \dot{\theta}_V \\ \dot{\psi}_V \end{bmatrix} = \frac{1}{\cos \theta} \begin{bmatrix} \cos \theta & \sin \phi \sin \theta & \cos \phi \sin \theta \\ 0 & \cos \phi \cos \theta & -\sin \phi \cos \theta \\ 0 & \sin \phi & \cos \phi \end{bmatrix} \underbrace{\begin{bmatrix} \omega_x \\ \omega_y \\ \omega_z \end{bmatrix}}_{\omega_{0V,V}} \quad (2)$$

provides then the time derivatives of the generalized coordinates \dot{x}_V , \dot{y}_V , \dot{z}_V , $\dot{\phi}_V$, $\dot{\theta}_V$, $\dot{\psi}_V$ as a function of the generalized velocities v_x , v_y , v_z , and ω_x , ω_y , ω_z . As shown in [16] this particular choice of nontrivial generalized velocities reduces the complexity of the equations of motion significantly.

Relative Kinematics

The vehicle model, shown in Figure 1, consists of $n = 9$ rigid bodies: the chassis, four knuckles, and four wheels. The absolute position and orientation of an arbitrary body j is defined by

$$r_{0j,0} = r_{0V,0} + A_{0V} r_{Vj,V} \quad \text{and} \quad A_{0j} = A_{0V} A_{Vj} \quad (3)$$

where $r_{0V,0}$ and A_{0V} are defined by (1) and $r_{Vj,V}$ and A_{Vj} describe the position and orientation of body j relative to the vehicle-fixed reference frame V .

The vector of the absolute body velocity v_{0j} can be expressed in the vehicle-fixed frame

$$v_{0j,V} = v_{0V,V} + A_{0V}^T \frac{d}{dt} (A_{0V} r_{Vj,V}) = v_{0V,V} + \omega_{0V,V} \times r_{Vj,V} + \dot{r}_{Vj,V} \quad (4)$$

where according to (2) the components of the vectors $v_{0V,V}$ and $\omega_{0V,V}$ are entirely defined by the nontrivial generalized velocities v_x , v_y , v_z , ω_x , ω_y , ω_z . The movements of body j relative to the vehicle-fixed frame V can be characterized by a certain set of generalized coordinates, which may be collected in the vector y_j . Then, the vector $r_{Vj,V}$ describing the momentary position of body j relative to V depends on this set of generalized coordinates, $r_{Vj,V} = r_{Vj,V}(y_j)$ and its time derivative with respect to frame V results in

$$\dot{r}_{Vj,V} = \frac{d}{dt} r_{Vj,V}(y_j) = \frac{\partial r_{Vj,V}}{\partial y_j} \dot{y}_j = t_{j,V}(y_j) \dot{y}_j \quad (5)$$

where the term $t_{j,V}$ represents the partial velocity of the body j motions. Similarly, the vector of the absolute body angular velocity, expressed in the vehicle-fixed frame V , reads as

$$\omega_{0j,V} = \omega_{0V,V} + \omega_{Vj,V} = \omega_{0V,V} + d_{j,V}(y_j) \dot{y}_j \quad (6)$$

where the term $d_{j,V}$ describes the partial angular velocity of the body j motions.

The absolute acceleration and the absolute angular acceleration of body j , both expressed in the vehicle-fixed frame V , are at first provided by

$$\begin{aligned} a_{0j,V} &= A_{0V}^T \frac{d}{dt} (A_{0V} v_{0j,V}) = \omega_{0V,V} \times v_{0j,V} + \dot{v}_{0V,V} + \tilde{r}_{Vj,V}^T \dot{\omega}_{0V,V} + \omega_{0V,V} \times \dot{r}_{Vj,V} + \ddot{r}_{Vj,V} \\ \alpha_{0j,V} &= A_{0V}^T \frac{d}{dt} (A_{0V} \omega_{0j,V}) = \omega_{0V,V} \times \omega_{0j,V} + \dot{\omega}_{0V,V} + \dot{\omega}_{Vj,V} \end{aligned} \quad (7)$$

where the cross product $\dot{\omega}_{0V,V} \times r_{Vj,V}$ was transferred via $\dot{\omega} \times r = -r \times \dot{\omega} = -\tilde{r}\dot{\omega} = \tilde{r}^T\dot{\omega}$ to the multiplication of a transposed skew-symmetric matrix with a vector. The velocity $v_{0V,V}$ and the angular velocity $\omega_{0V,V}$ depend entirely on the generalized velocities. The relative velocity $\dot{r}_{Vj,V}$ and the relative angular velocity $\omega_{Vj,V}$ are provided in (5) and (6). Their time derivatives result in

$$\ddot{r}_{Vj,V} = t_{j,V}(y_j) \ddot{y}_j + \dot{t}_{j,V}(y_j) \dot{y}_j \quad \text{and} \quad \dot{\omega}_{Vj,V} = d_{j,V}(y_j) \ddot{y}_j + \dot{d}_{j,V}(y_j) \dot{y}_j \quad (8)$$

The trivial choice $z_j = \dot{y}_j$ of generalized velocities is always possible. Then (7) reads as

$$\begin{aligned} a_{0j,V} &= [I_{3 \times 3} \quad \tilde{r}_{Vj,V}^T \quad \dots t_{j,V} \dots] \dot{z} + \omega_{0V,V} \times (v_{0j,V} + \dot{r}_{Vj,V}) + \dot{t}_{j,V} \dot{y}_j = \frac{\partial v_{0j,V}}{\partial z} \dot{z} + a_{0j,V}^R \\ \alpha_{0j,V} &= [0_{3 \times 3} \quad I_{3 \times 3} \quad \dots d_{j,V} \dots] \dot{z} + \omega_{0V,V} \times \omega_{0j,V} + \dot{d}_{j,V} \dot{y}_j = \frac{\partial \omega_{0j,V}}{\partial z} \dot{z} + \alpha_{0j,V}^R \end{aligned} \quad (9)$$

where the vector

$$z = [v_x \ v_y \ v_z \ \omega_x \ \omega_y \ \omega_z \ \dot{y}_1 \ \dots \ \dot{y}_n]^T \quad (10)$$

collects the generalized velocities of the vehicle model. The symbols $I_{3 \times 3}$ and $0_{3 \times 3}$ represent 3×3 matrices of identity and zeros. The $3 \times f$ matrices $\partial v_{0j,V}/\partial z_j$ and $\partial \omega_{0j,V}/\partial z_j$, where f denotes the number of degrees of freedom, represent the partial velocities and partial angular velocities of the absolute body j motion. The symbols $a_{0j,V}^R$ and $\alpha_{0j,V}^R$ abbreviate the remaining acceleration and the remaining angular acceleration terms, which do not explicitly depend on the time derivatives of the generalized velocities.

Passenger car suspensions force the knuckles to perform rather complex nonlinear but smooth motions relative to the chassis or the vehicle-fixed reference frame V respectively. In addition, the damper elements in a vehicle suspension systems reduce the relative velocities \dot{y}_j to moderate values. As a consequence, the terms $\dot{t}_{j,V} \dot{y}_j$ and $\dot{d}_{j,V} \dot{y}_j$ can be neglected compared to the other terms in the remaining acceleration and the remaining angular acceleration which results in a non-perfect multibody model, but safes a significant amount on computation effort and still provides an acceptable accuracy [17].

Chassis

The first body, the chassis, represents a special case, because the vehicle-fixed reference V frame is fixed to the chassis. As a consequence, the position vector $r_{V1,V} = r_{VC,V}$ is constant and the rotation matrix is simply defined by the 3×3 matrix of identity, $A_{V1} = A_{VC} = I_{3 \times 3}$. Then

$$\frac{\partial v_{0C,V}}{\partial z} = [I_{3 \times 3} \quad \tilde{r}_{VC,V}^T \quad 0_{3 \times f_r}] \quad \text{and} \quad \frac{\partial \omega_{0C,V}}{\partial z} = [0_{3 \times 3} \quad I_{3 \times 3} \quad 0_{3 \times f_r}] \quad (11)$$

provide the partial velocities and the partial angular velocities of the chassis, where $f_r = f - 6$ denotes the degrees of freedom of the motions relative to the chassis.

Generic Suspension

The kinematics of standard suspension systems, like the double wishbone, the MacPherson, or the multi-link suspension, can be solved online or approximated by lookup tables or more efficiently by smooth two-dimensional functions [18]. Regardless of the type of an independent suspension the position and orientation of the knuckle fixed reference frame K relative to the chassis or vehicle-fixed frame V can be described by a position vector and a rotation matrix

$$r_{VW,V} = r_{VW,D} + \begin{bmatrix} \xi \\ \eta \\ \zeta \end{bmatrix} \quad \text{and} \quad A_{VK} = A_\gamma A_\alpha A_\beta \quad (12)$$

where $r_{VW,D}$ describes the design position of the wheel center W, which on a balanced wheel is located on the wheel rotation axis and hence fixed to the knuckle. The rotation matrix is composed of three elementary rotations, where γ describes the steer motion, α the wheel camber, and β the pitch motion of the knuckle.

In particular at kinematic and compliance (KnC) tests, the wheel center W is used as a reference point to monitor and measure the knuckle/wheel movements. The coordinates $\xi = \xi(h, s)$, $\eta = \eta(h, s)$, $\zeta = \zeta(h, s)$ as well as the rotation angles $\alpha = \alpha(h, s)$, $\beta = \beta(h, s)$, $\gamma = \gamma(h, s)$ depend on the hub and steer motions h and s . In general, the hub motion can be described by the vertical displacement of the wheel center, $\zeta = h$. A least square approximation of measured or computed KnC tests delivers the design kinematic parameters, which for a typical double wishbone suspension on the left front wheel are listed in Table 1. It provides column by column the parameter sets required for the two-dimensional design kinematic functions $f = f(h, s)$, where h and s represent the hub and the steer motion. The columns hold for the constraint knuckle motions $\xi = \xi(h, s)$ to $\gamma = \gamma(h, s)$, the spring and damper displacements $u_S = u_S(h, s)$ and $u_D = u_D(h, s)$, as well as the vertical movement $z_{arb} = z_{arb}(h, s)$ of the anti-roll bar attachment point. Each parameter set consists of the range limits (dh, ds), the initial inclinations (dfdh0, dfds0), as well as the four center (fp0, f0p, f0n, fn0) and the four corner points (fpp, fpn, fnp, fnn) as defined in [18].

The Matlab function provided in the following Listing computes the kinematics of a generic suspension modeled by the design kinematics. It provides the orientation of the knuckle-fixed reference frame, the momentary position of the wheel center which serves as a reference point for the knuckle motion, as well as the corresponding partial velocity and partial angular velocity. The 3×1 -vector u_{fe} collects the displacements of the spring u_S , the damper u_D , and the vertical movement z_{arb} of the anti-roll bar. The 3×2 -matrix $du_{fe}dyf$ contains the changes of u_{fe} with respect to the hub and steer motions collected in the 2×1 -vector $y_k = [h; s]$. They are used within the VTC environment to compute the contribution of the suspension forces to the vector of generalized forces directly via the virtual power. The additional 5×1 output vector ao collects the constraint motions resulting from the Matlab function `dk_fun`, which evaluates the two-dimensional functions as described in [18].

end

```

The generic suspension model provides the position of the wheel center $r_{wv} \rightarrow r_{VW,V}$ and the orientation of the knuckle $avk \rightarrow A_{VK}$ relative to the vehicle-fixed reference frame V as well as the 3×2 -matrices $dkv \rightarrow d_{K,V}$ and $twv \rightarrow t_{W,V}$ which provide the partial angular velocities of the knuckle and the partial velocity of the wheel center. The velocity of the wheel center and the angular velocity of the wheel are then determined by

$$v_{0W,V} = v_{0V,V} + \omega_{0V,V} \times r_{VW,V} + t_{W,V} \begin{bmatrix} \dot{h} \\ \dot{s} \end{bmatrix} \quad \text{and} \quad \omega_{0W,V} = \omega_{0V,V} + d_{K,V} \begin{bmatrix} \dot{h} \\ \dot{s} \end{bmatrix} + e_{yW,V} \dot{\varphi} \quad (13)$$

where $e_{yW,V} = A_{VK} e_{yW,D}$ provides the knuckle-fixed wheel rotation axis and $\omega_{KW,V} = e_{yW,V} \dot{\varphi}$ describes the angular velocity of the wheel rotation relative to the knuckle. The momentary position of the knuckle center K and its partial velocities are defined by

$$r_{VK,V} = r_{VW,V} + A_{VK} r_{WK,D} = r_{VW,V} + r_{WK,V} \quad \text{and} \quad t_{K,V} = t_{W,V} + d_{K,V} \times r_{WK,V} \quad (14)$$

where $r_{WK,D}$ denotes the design position of the knuckle center K relative to the wheel center W .

Equations of Motion

The state of a generic VTC model, as proposed here, is defined by $f = 18$ generalized coordinates and $f = 18$ generalized velocities collected in the vectors

$$\begin{aligned} y &= [x_V \ y_V \ z_V \ \phi_V \ \theta_V \ \psi_V \ h_1 \ s_1 \ h_2 \ u_2 \ h_3 \ u_3 \ h_4 \ u_4 \ \varphi_1 \ \varphi_2 \ \varphi_3 \ \varphi_4]^T \\ z &= [v_x \ v_y \ v_z \ \omega_x \ \omega_y \ \omega_z \ \dot{h}_1 \ \dot{s}_1 \ \dot{h}_2 \ \dot{u}_2 \ \dot{h}_3 \ \dot{u}_3 \ \dot{h}_4 \ \dot{u}_4 \ \dot{\varphi}_1 \ \dot{\varphi}_2 \ \dot{\varphi}_3 \ \dot{\varphi}_4]^T \end{aligned} \quad (15)$$

Jourdain's principle of virtual power delivers the equations of motion as a set of two first order nonlinear systems of differential equations

$$\dot{y} = K(y) z \quad \text{and} \quad M(y) \dot{z} = q(y, z, u, w) \quad (16)$$

where the vectors u and w collect all model inputs and additional dynamic states, required for dynamic tire and dynamic suspension forces. A kinematic matrix K which does not coincide with the matrix of identity, makes it possible to define non-trivial generalized velocities, as done here in (2) for the overall vehicle motions. The elements of the mass matrix M and the vector of generalized forces and torques q applied to the vehicle are generated for the $n = 9$ bodies of the VTC model via

$$M = \sum_{j=1}^n \left\{ \left(\frac{\partial v_{0j,V}}{\partial z} \right)^T m_j \frac{\partial v_{0j,V}}{\partial z} + \left(\frac{\partial \omega_{0j,V}}{\partial z} \right)^T \Theta_{j,V} \frac{\partial \omega_{0j,V}}{\partial z} \right\} \quad (17)$$

$$q = \sum_{j=1}^n \left\{ \left(\frac{\partial v_{0j,V}}{\partial z} \right)^T [F_{j,V}^a - m_j a_{0j,V}^R] + \left(\frac{\partial \omega_{0j,V}}{\partial z} \right)^T [T_{j,V}^a - \Theta_{j,V} \alpha_{0j,V}^R - \omega_{0j,V} \times \Theta_{j,V} \omega_{0j,V}] \right\} \quad (18)$$

where m_j and $\Theta_{j,V}$ describe the mass and inertia of body j , $F_{j,V}^a$ and $T_{j,V}^a$ represent the resulting vectors of the forces and torques applied to body j . Equations (6) and (9) provide the angular velocities $\omega_{0j,V}$, the partial velocities $\partial v_{0j,V} / \partial z$, the partial angular velocities $\partial \omega_{0j,V} / \partial z$, as well as the remaining acceleration $a_{0j,V}^R$ and the remaining angular acceleration $\alpha_{0j,V}^R$. The partial velocities of the front right knuckle (K2) and the front right wheel (W2) are, for example, defined by

$$\begin{aligned} \frac{\partial v_{0K2,V}}{\partial z} &= [I_{3 \times 3} \quad \tilde{r}_{VK2,V}^T \quad 0_{3 \times 2} \quad t_{K2,V} \quad 0_{3 \times 2} \quad 0_{3 \times 2} \quad 0_{3 \times 1} \quad 0_{3 \times 1} \quad 0_{3 \times 1} \quad 0_{3 \times 1}] \\ \frac{\partial \omega_{0K2,V}}{\partial z} &= [0_{3 \times 3} \quad I_{3 \times 3} \quad 0_{3 \times 2} \quad d_{K2,V} \quad 0_{3 \times 2} \quad 0_{3 \times 2} \quad 0_{3 \times 1} \quad 0_{3 \times 1} \quad 0_{3 \times 1} \quad 0_{3 \times 1}] \end{aligned} \quad (19)$$

$$\begin{aligned} \frac{\partial v_{0W2,V}}{\partial z} &= [I_{3 \times 3} \quad \tilde{r}_{VW2,V}^T \quad 0_{3 \times 2} \quad t_{W2,V} \quad 0_{3 \times 2} \quad 0_{3 \times 2} \quad 0_{3 \times 1} \quad 0_{3 \times 1} \quad 0_{3 \times 1} \quad 0_{3 \times 1}] \\ \frac{\partial \omega_{0W2,V}}{\partial z} &= [0_{3 \times 3} \quad I_{3 \times 3} \quad 0_{3 \times 2} \quad d_{W2,V} \quad 0_{3 \times 2} \quad 0_{3 \times 2} \quad 0_{3 \times 1} \quad e_{yW2,V} \quad 0_{3 \times 1} \quad 0_{3 \times 1}] \end{aligned} \quad (20)$$

The TMeasy model [9] provides the tire forces $F_{T1,0}$ to $F_{T4,0}$ and the torques $T_{T1,0}$ to $T_{T4,0}$ applied to the four wheel centers. In particular, the slip based longitudinal and lateral tire forces strongly depend on the velocity state v_{0W} and ω_{0W} of the wheel. The velocity state of the wheel depends, according to (13), on the velocity state of the vehicle ($v_{0V,V}$ and $\omega_{0V,V}$) and on the kinematical properties of the suspension systems represented by the symbols $t_{W,V}$, $d_{K,V}$, and $e_{yW,V}$, which describe the partial velocity of the wheel center, the partial angular velocity of the knuckle, and the position of the wheel rotation axis. Hence, neglecting the suspension kinematics partly or completely, as done in simplified vehicle models, inevitably results in poorly modeled tire forces and tire torques.

The vehicle dynamics represented by (16) is driven by the vector of generalized forces and torques. The contribution of front right tire, part of the front right knuckle (K2) and wheel (W2) combination, to the vector of generalized forces and torques is, for example, provided by

$$\begin{aligned} \text{overall vehicle: } q_{1:6} &= q_{1:6} + \begin{bmatrix} F_{T2,V} \\ T_{T2,V} + r_{VW2,V} \times F_{T2,V}^T \end{bmatrix} \\ \text{hub and steer motions front right: } q_{9:10} &= q_{9:10} + t_{W2,V}^T F_{T2,V} + d_{K2,V}^T T_{T2,V} \\ \text{wheel rotation front right: } q_{16} &= q_{16} + e_{yW,V}^T T_{T2,V} \end{aligned} \quad (21)$$

The relations $F_{T2,V} = A_{0V}^T F_{T2,0}$ and $T_{T2,V} = A_{0V}^T T_{T2,0}$ transform the resulting tire force vector and the resulting tire torque vector from the earth-fixed into the vehicle-fixed frame. The amount of contribution depends on the partial velocity of the wheel center $t_{W2,V}$, the partial angular velocity of the knuckle $d_{K2,V}$, and the wheel rotation axis $e_{yW,V}$. Tire forces, which support and guide the vehicle, may change very quickly and can increase to considerable values, in particular in critical driving situations. That is why, even rather small changes in the kinematical suspension properties, represented by the symbols $t_{W,V}$, $d_{K,V}$, and $e_{yW,V}$, result in significant contributions to the vector of generalized force and torques. Which magnifies the error in neglecting the specific properties of the suspension kinematics.

Example: Braking in a Turn

The numerical solution of differential equations, like the ones in (16), is discussed in [19]. A straightforward implementation of the virtual test car (VTC) entirely realized in MATLAB provides an easy to use simulation environment including plotting and animation facilities, Figure 2. As typical for standard passenger cars on dry road, the left plot in Figure 2

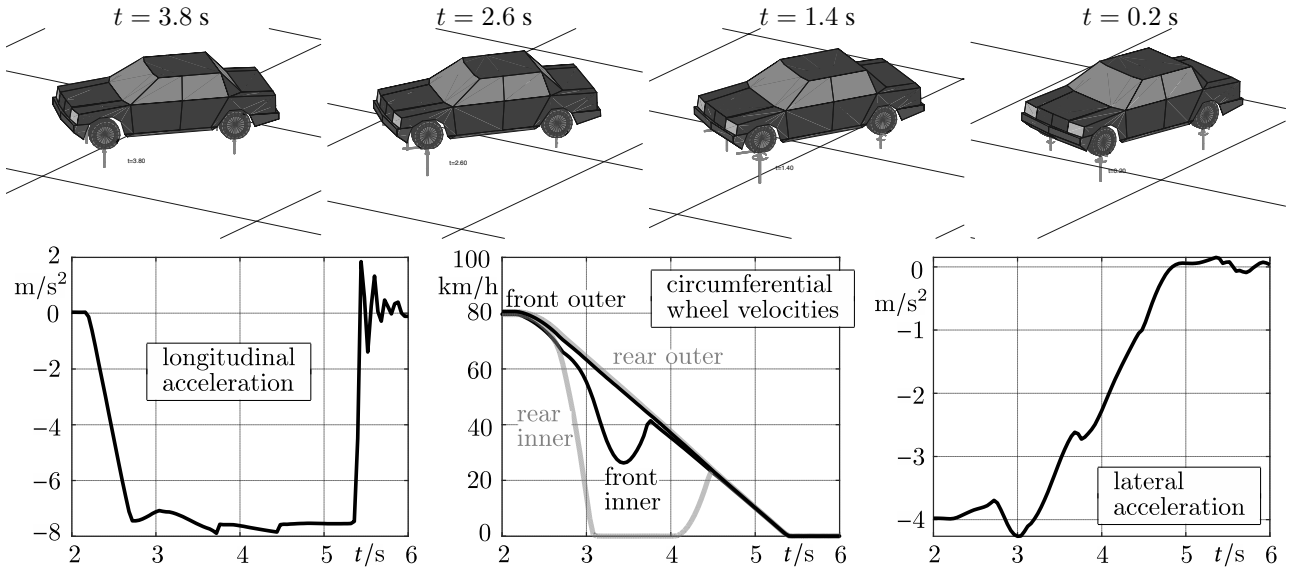

Figure 2: Emergency braking in a turn without ABS of a typical midsize passenger car illustrated by animation screenshots and plots.

indicates a maximum deceleration of approximately 8 m/s^2 . The wheel load transfer from inner to outer during cornering and from rear to front when braking causes the inner rear wheel to lock in the time interval $t \approx 3 \text{ s}$ to $t \approx 4 \text{ s}$, center plot in Figure 2. The VTC model handles wheel lock without any problems and the TMeasy tire model provides a smooth transition to stand still in addition.

The numerical integration in the time interval $2 \leq t \leq 6 \text{ s}$ performed with the standard MATLAB solver ode45, an explicit Runge-Kutta formula of order 4 and 5 with step size control, took a 2,7 GHz Quad-Core Intel Core i7 just 4.72 seconds. This is already close to real-time performance $(6 - 2)/4.72 = 0.85$ even in the comparatively slow MATLAB interpretation mode.

Influence of the Suspension Kinematics on the Vehicle Dynamics

From a Standard to a Simplified Suspension Kinematics

Table 1 provides the design kinematics parameter matrix for the front left suspension of a typical passenger car. The initial inclinations $d\alpha/dh = +0.44734 \text{ rad/m}$, $d\beta/dh = -0.32329 \text{ rad/m}$, and $d\gamma/dh = +0.11453 \text{ rad/m}$ indicate that the knuckle performs significant rotations induced by the hub motion. As typical for front axle suspensions, the first, second, and third rotation produces a partial camber compensation, counteracts the brake pitch, and generates a slight self-steering effect. The axis of the knuckle-fixed coordinate system are parallel to the corresponding axis of the vehicle-fixed reference frame. That is why, the design kinematics takes $f_{00}=f(0,0)=0$ for granted. Then, center points with different absolute values at vanishing steering angles ($s=0$), like $f_{p0_\alpha} = \alpha(+dh, 0) = +0.05305 \text{ rad}$ and $f_{n0_\alpha} = \alpha(-dh, 0) = -0.02389 \text{ rad}$ specify a nonlinear behavior, which in general is not a simple side effect but a well design feature of the suspension kinematics. The design kinematics approach makes it easy to tune or design the suspension kinematics. Replacing the first row in the parameter matrix of Table 1 by

$$+0.00000 \quad +0.00000 \quad +0.00000 \quad +0.00000 \quad +0.00000 \quad +0.08096 \quad +0.08096 \quad +0.08096 \quad dh$$

just switches off the influence of the hub motion h on the constraint motions ξ , η , α , β , and γ by leaving the force element displacements u_S , u_D , and z_{arb} unchanged. Simple 4-wheel vehicle models just take the steer motions into consideration by neglecting the vertical suspension motions in addition, thus providing a far worse approximation.

Transient Vehicle Response

The DIN ISO directive 7401 lists the step steer input as one of the standard open loop maneuvers to reveal insight into the transient response of vehicles. In practice, an ideal step input is not possible. The VTC environment realizes the steer input s at the front and optionally at the rear axle via the rack displacements. Table 2 provides the time history of the

Table 2: Define step steer input within the VTC environment via lookup tables

0.0000	0.5000	0.6000	6.0000	time sample points τ_{Si} in s
0.0000	0.0000	-0.0050	-0.0050	steer input front left $\varrho_1(t_{Si})$ in m
0.0000	0.0000	-0.0050	-0.0050	steer input front right $\varrho_2(t_{Si})$ in m

steer inputs at the front axle which correspond here to the rack displacement $\varrho_1 = \varrho_2 = \varrho$ of a standard rack and pinion steering system. The rear wheels are not steered in this example $\varrho_3 = \varrho_4 = 0$. The steering forces applied to the knuckles 1 to 4 are defined by

$$F_{Si} = c_{Si} (\varrho_i - s_i) + d_{Si} (\dot{\varrho}_i - \dot{s}_i), \quad i = 1(1)4 \quad (22)$$

The constants c_{Si} , d_{Si} summarize the stiffness and damping properties of the tie rods and the steering lever. The time histories of the steer inputs deliver also their time derivatives $\dot{\varrho}_1$ to $\dot{\varrho}_4$. The steer motions of the knuckles s_1 to s_4 and their derivatives \dot{s}_1 to \dot{s}_4 are part of the vectors of generalized coordinates y and generalized velocities z as defined in (15).

Table 2 approximates the step by a continuous ramp, where the rack is moved in the time interval $0.5 \leq \tau_S \leq 0.6 \text{ s}$ from its center position $s_1 = s_2 = 0$ to the right $s_1 = s_2 = -5 \text{ mm}$ and then ($\tau_S > 0.6 \text{ s}$) kept constant. This input generates the wheel steering angles displayed as dotted black and dotted grey lines in plot (a) of Figure 3.

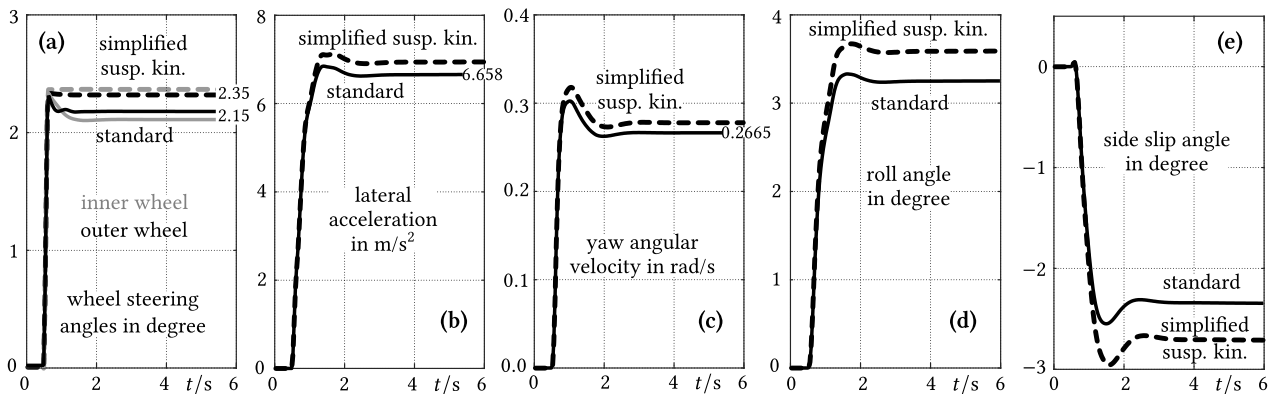

Figure 3: VTC step steer results, where solid and broken lines characterize vehicles with standard and simplified suspension kinematics

The VTC model represents here a fullsize passenger car with a wheel base of $a = 2.9 \text{ m}$, a track width of $s \approx 1.5 \text{ m}$, and wheel loads of $F_{z1} = F_{z2} = 5.39 \text{ kN}$ and $F_{z3} = F_{z4} = 5.06 \text{ kN}$ at the front and rear. The steady state values of the lateral acceleration $a_y = v^2/R = 6.658 \text{ m/s}^2$ and the yaw angular velocity $\dot{\psi} = v/R = 0.2665 \text{ rad/s}$ deliver a cornering radius of $R = 94 \text{ m}$ and a vehicle velocity of $v = 25 \text{ m/s}$ in this example. A PI-controller keeps the vehicle velocity constant during the whole maneuver by generating appropriate drive torques applied to the rear wheels.

The plots in Figure 3 compare the results of the VTC model with standard double wishbone suspensions at the front and the rear to a VTC model where the influence of the hub motion on the constraint suspension motions is completely switched off. As a consequence, the wheel steering angles of the simplified VTC model, represented by the dotted gray and dotted black lines in plot (a) of Figure 3, correspond perfectly to the step or more precisely to the ramp steer input. The nonlinear suspension kinematics of the front wheels incorporates a roll steering which reduces the steering angles with increasing body roll. That is why the steering angles drop down in the average from 2.35 to 2.15 degree when the roll angle, solid line in plot (c) of Figure 3, increases from 0 to 3.25 degree. This roll steer effect is a well designed feature of the suspension kinematics. It automatically reduces the impact of the steer input at fast cornering but keeps the maneuverability in the lower lateral acceleration range.

For a fair comparison of the standard vehicle to a vehicle with simplified kinematics the steer input of the standard vehicle is increased such that both VTC models end up in the same lateral acceleration. The results are displayed in Figure 4, where the steering wheel angles, plotted on the left, are zoomed to the interesting range from 2.0 to 2.5 degrees. In general, the kinematics of passenger car steering linkages is designed according to the Ackermann geometry which results in larger steering angles at the curve inner wheel compared to the curve outer wheel. The roll steering effect of the VTC model with the standard suspension kinematics even counteracts the Ackermann geometry, solid black and grey lines in the left plot of Figure 4. This is a smart suspension design, because during fast cornering the outer wheels are much more loaded than the inner ones and hence the steering angle of the outer wheel is the one that counts.

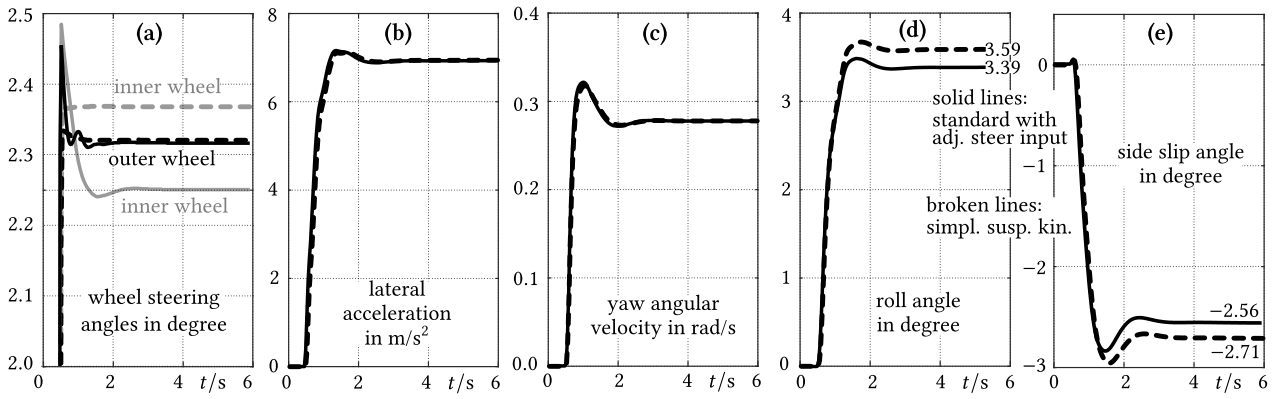

Figure 4: VTC step steer results with simplified and standard suspension kinematics with adjusted steer input

Both VTC models end up now in the same lateral acceleration and the same yaw angular velocity, plots (b) and (c) in Figure 4. But, the time histories of the roll angle and the side slip angle still differ in their steady state values, plots (d) and (e) in Figure 4.

Standard Versus Simplified Kinematics

In practice, the suspension kinematics of a passenger car is carefully designed to meet certain requests arising from the longitudinal and lateral dynamics [20]. The Figures 5 and 6 show the three-dimensional motions of the front left knuckle for the VTC model with the simplified suspension kinematics and for the VTC model with the standard suspension kinematics.

At real passenger car suspension systems a steer motion causes the knuckle to rotate about the inclined kingpin axis which in addition has a longitudinal and lateral offset to the wheel center. That is why, the centers 1 and 2 of the steered front wheels perform longitudinal ξ and lateral η motions as well as elementary rotations α , β , γ about the x -, y -, and z -axis which in case of the simplified suspension entirely depend on the steer input s , Figure 5. The vertical displacements of the wheel centers are unconstrained and described by the hub motion $\zeta = h$. Bump stops in the suspension systems restrict the jounce motions ($h > 0$) at the curve outer wheels 2 and 4, upper right plot in Figures 5 and 6. The plots in Figure 6 reveal the complexity of standard passenger car suspension systems. The distinct longitudinal motions ξ of the wheel center 3 and the distinct pitch rotations β of the knuckle 3 indicate for example the ability of the rear suspension to reduce a brake pitch. The lateral motions η and the rotations α about the x -axis provide the roll support and a partial camber compensation. The former brings down the roll angle from 3.59 to 3.39 degrees, plot (d) of Figure 4. The roll support and the camber compensation at the front and rear wheels, which are carefully coordinated to each other, reduce further on the side slip angle from -2.71 to -2.56 degrees, plot (e) of Figure 4.

The steering forces $F_S = [F_{S1} F_{S2} F_{S3} F_{S4}]^T$ and the driving torques $T_D = [T_{D1} T_{D2} T_{D3} T_{D4}]^T$ as well as the braking torques $T_B = [T_{B1} T_{B2} T_{B3} T_{B4}]^T$ define the inputs of the VTC model. The steering forces are directly applied to the knuckles. Each of the driving torques acts between the chassis and the corresponding wheel at conventional drive trains or between knuckle and wheel in case of wheel motors. The braking torques specify the maximum torques usually defined by the braking pressures distributed to the wheels. An enhanced dry friction model, as described in [20], generates the individual braking torque acting between knuckle and wheel. All inputs may be defined as simple feed forward time

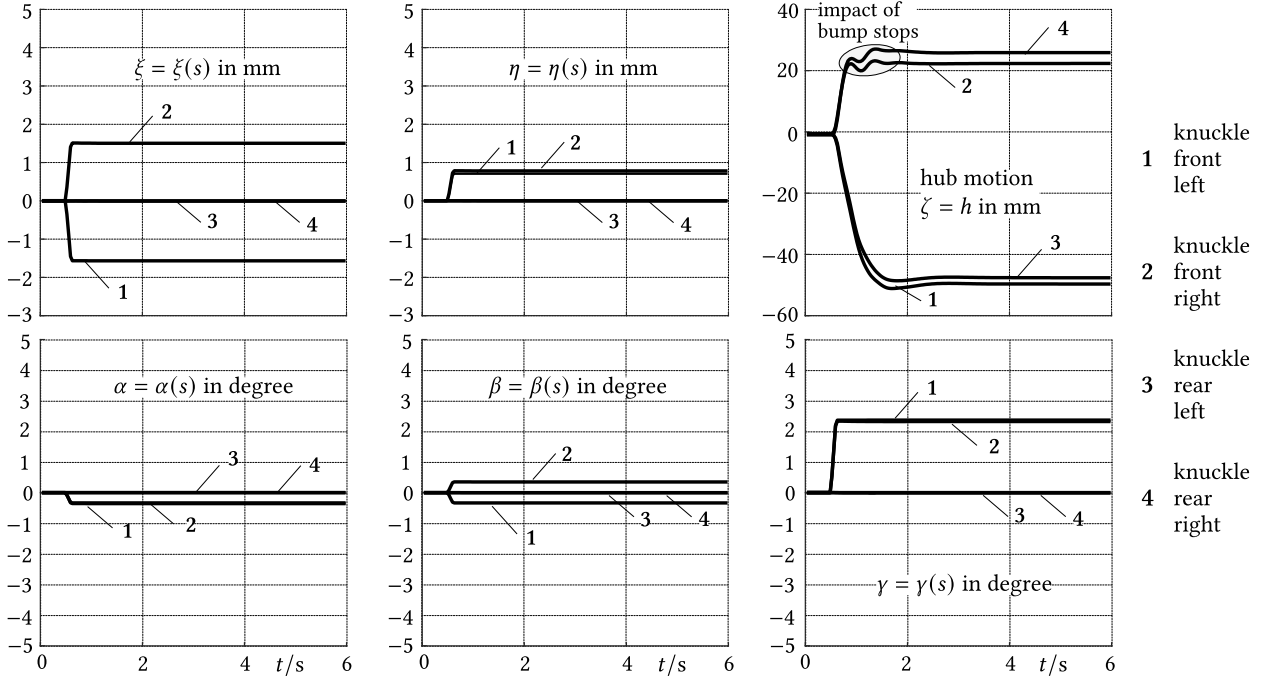

Figure 5: Simplified suspension kinematics neglecting hub influence

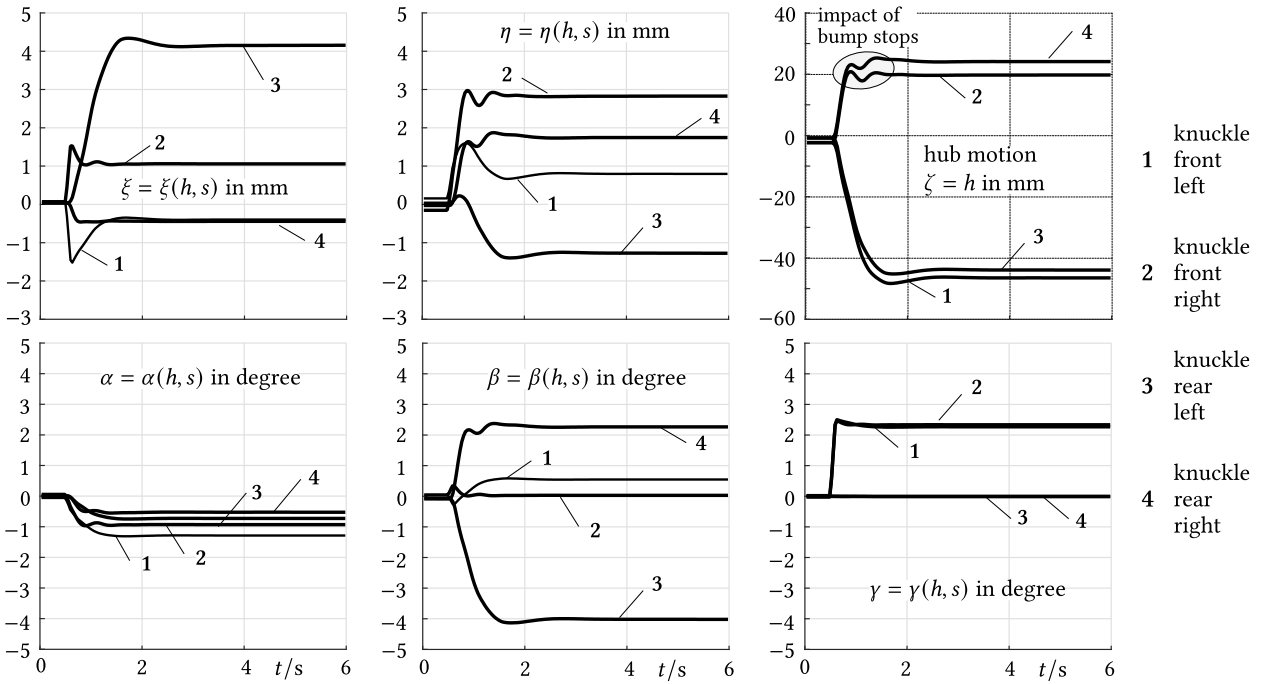

Figure 6: Standard suspension kinematics with adjusted step steer input

histories or provided by external controllers or by the output of additional subsystems. Hence, the VTC environment is able to simulate vehicles with all kind of steering, driving and braking modes.

Jourdain's principle combined with non-trivial generalized velocities and the idea of a non-perfect multibody system approach result in equations of motion of minimal complexity. A partial implicit solver, as described in [21], provides an extremely fast numerical solution of sufficient accuracy and stability.

Consequences

Human drivers and automated drivers too are very sensitive to the roll angle and to the side slip angle, in particular. Hence, a vehicle model which neglects some or all properties of the suspension kinematics is not able to reproduce the dynamics of a real passenger car with reliable accuracy. Virtual tests to investigate the dynamics and the stability of vehicles as well as the development and further improvement of driver assistance systems require at least vehicle models which incorporate the nonlinearities of the suspension kinematics. Otherwise just basic studies will be possible, which of course may serve as starting points for further and reliable investigations.

Conclusion

Simplified vehicle models, like the classical bicycle model, 4-wheel vehicle models, or even three-dimensional vehicle models neglecting the specific kinematical properties of the suspension systems, are not able to reproduce the dynamics of vehicles properly. Such models are restricted to basic studies. The VTC environment takes the three-dimensional motions of the chassis, four knuckles, and four wheels into account. The generic design kinematics suspension model is able to describe the nonlinear properties of standard passenger car suspension systems with sufficient accuracy and with a minimum of computation effort. The VTC model operated with the TMeasy tire model is valid in any driving situation. A straightforward implementation of the virtual test car (VTC) entirely realized in MATLAB provides an easy to use simulation environment including plotting and animation facilities. A VTC implementation coded in C achieves on a standard personal computer with a 2,7 GHz Quad-Core Intel Core i7 a real-time factor (real-time/cpu-time) of 160 which is magnitudes faster than real-time. Thus making the Virtual Test Car to an ideal platform for modern simulation tasks.

Abscissa minimization for self-stability of bicycles and nonholonomic acceleration when riding out of the saddle

Oleg Kirillov*

**Northumbria University, NE1 8ST Newcastle upon Tyne, UK*

Summary. The model of a two-mass-skate (TMS) bicycle is reconsidered from the point of view of optimization of its self-stability, i.e. asymptotic stability of its vertical position in a uniform straight motion with respect to small perturbations of its leaning and steering angles. The critical Froude number for the onset of the self-stability is found explicitly. Minimization of the spectral abscissa is then performed yielding a new scaling law that links together the geometric and the mass parameters of the TMS bicycle. The scaling law fits well the relations between the geometric and mass parameters of a recent experimental realization of the TMS bicycle. Modification of the TMS model by including into it a mass moving periodically in the direction perpendicular to the frame of the bicycle is discussed as a step to understand nonholonomic acceleration of bicycles when riding out of the saddle.

Self-stability of bicycles and its optimization

The bicycle is easy to ride, but surprisingly difficult to model. Refinement of the mathematical model of a bicycle has continued over the last 150 years with contributions from Rankine, Boussinesq, Whipple, Klein, Sommerfeld, Appel, Synge and many others [1, 2, 3]. The canonical, nowadays commonly-accepted model goes back to the 1899 work by Whipple [1, 4, 5]. The Whipple bike is a system consisting of four rigid bodies with knife-edge wheels making it non-holonomic, i.e., requiring for its description more configuration coordinates than the number of its admissible velocities.

Self-stability of a riderless bicycle is a well-known empirical phenomenon that can be easily reproduced in an experiment with the majority of known practical designs of bicycles. Namely, a bicycle in its uniform motion along a straight path keeps the vertical position of the plane of its frame under small perturbations if its forward speed is high enough. Moreover, perturbations of its leaning and steering angles die out, so that one can say about asymptotic self-stability of the vertical position of the bicycle. The fact of the asymptotic self-stability has been theoretically supported already by Whipple [1]. The self-stability has a number of important practical implications. For instance, the bicycle designs that do not present the self-stability are difficult for a person to ride; in other words, more stable bikes handle better. Hence, deeper understanding of the passive stabilization can provide new principles for the design of more safe and rideable bicycles, including compact and foldable models. Furthermore, it is expected to play a crucial part in formulating principles of the design of energy-efficient wheeled and bipedal robots [6].

However, the theoretical explanation of the self-stability has been highly debated throughout the history of bicycle dynamics to such an extent that a recent news feature article in *Nature* described this as “the bicycle problem that nearly broke mathematics” [7]. The reason as to why “simple questions about self-stabilization of bicycles do not have straightforward answers” [8] lies in the symbolical complexity of the Whipple model that contains 7 degrees of freedom and depends on 25 physical and design parameters [2]. In recent numerical simulations [1, 4, 5], self-stabilization has been observed for some benchmark designs of the Whipple bike. These results suggested further simplification of the model yielding a reduced model of a bicycle with vanishing radii of the wheels (which are replaced by skate blades), known as the two-mass-skate (TMS) bicycle [3, 9, 10]. Despite the self-stable TMS bike having been successfully realized in recent laboratory experiments [3], its self-stability still awaits a theoretical explanation. In this lecture we find explicitly the critical Froude number for the onset of self-stability of the TMS bicycle and will show how minimization of the spectral abscissa [11, 12] allows one to find hidden symmetries in the model, suggesting further reduction of the parameter space and, finally, providing explicit relations between the parameters of stability-optimized TMS bikes [13, 14].

Nonholonomic acceleration due to honking or riding out of the saddle

Honking means cycling out of the saddle. Cyclists use this way of riding to accelerate. In this process, the body of the cyclist moves rhythmically side to side with respect to the plane of the bicycle, while the frame of the bicycle rocks or sways with respect to the vertical position. It is known, however, that the commonly accepted modern bicycle models, stemming from the Whipple model of 1899, are non-holonomic and conservative. On one hand, this implies the conservation of energy, and on the other, non-conservation of the phase volume, which results in the possibility of the asymptotic stability of a straight vertical position of a bicycle that is riding along a straight path if the forward velocity is high enough, which is a well-known empirical fact [2, 3]. A natural question is: where the energy of dying leaning and steering motions flows? Actually, the energy in the lean and steer oscillations is transferred via a nonlinear coupling to the forward speed rather than being dissipated, as it was shown in numerical simulations in [2]. This effect suggests a method of acceleration of the bicycle due to periodic movements of a mass in the direction perpendicular to the plane of the frame of the bicycle. It can therefore be conjectured that when cycling out of the saddle, the periodical movement of the cyclist’s mass pumps energy into the forward motion leading to the desired acceleration.

Recently, acceleration due to a periodic motion of an internal mass has been theoretically discovered in a non-holonomic

Chaplygin sleigh model [15, 16] and linked to the mechanism of acceleration of particles moving between periodically oscillating walls in the Fermi-Ulam model [17]. In the present talk we will discuss the ways of extending the model of a TMS bicycle to take into account a periodically moving mass for investigation of the nonholonomic Fermi-like acceleration during cycling out of the saddle.

†Institute of Mechanics, Lomonosov Moscow State University, Moscow, Russia

Summary. The paper aim is to define an original walking for a 2D biped with a trunk, two identical legs with knees and massless feet. This walking is composed of a ballistic single-support phase and a distributed in time double-support phase. The ballistic movement in single support is defined by solving a boundary value problem with initial and final biped configurations and velocity conditions. These conditions ensure that at the beginning of the single support the toe of the rear leg rises without touching the ground again and at the landing of the heel there is no impact. In the double-support phase, the orientation of the two feet and other generalized coordinates which are used to define the configuration of the biped, are chosen as Bezier functions of time. The torques and ground reaction forces resulting from this double-support phase are determined by solving for the biped the inverse dynamic problem.

Statement of the problem

The walking motion

We design biped periodic walking, which consist of distributed in time single- and double-support phases. Ballistic single-support motion is designed. During this motion the torques in all joints are zeroes except the torque in the ankle-joint of the stance leg. The torque in the ankle-joint of the stance leg is applied in order to keep its foot in the equilibrium. During double-support motion the torques are applied in all the six joints; during this time both feet rotate: foot of the rear leg - around its toe, foot of the front leg - around its heel. To explain our statement of the problem more clearly, we show Fig. 1 with several stick-figures, which results from our numerical investigations.

Figure 1: a) Initial configuration of biped in single support. b) Intermediate configuration in single support. c) Final configuration in single support — initial one in double support. d) Intermediate configuration in double support. e) Final configuration in double support — initial one in the next single-support motion.

Mathematical model and design of the walking

The absolute orientation of the shins and thighs are defined with angles q_1, q_2, q_3, q_4 (see Fig. 2). The orientation of the trunk is defined by angle q_5 . Cartesian hip-joint coordinates are x and y . The orientation of both feet are described by angles q_{p1} and q_{p2} . It is assumed that there are no sliding motion and no take-off of the support legs. In real human walking, the double-support motion is distributed in time, and consequently the configuration of the human at the beginning of the double support differs from the configuration at the end of this double support. Consequently for the human walking the configurations at the beginning and at the end of the single-support motion are also different. Vector \mathbf{x} of the generalized coordinates for the biped with massless feet is $\mathbf{x} = [q_1, q_2, q_3, q_4, q_5, x, y]^T$. Superscript T means transposition. The mathematical model of the biped is:

$$\mathbf{A}(\mathbf{x})\ddot{\mathbf{x}} + \mathbf{h}(\mathbf{x}, \dot{\mathbf{x}}) = \mathbf{D}\mathbf{\Gamma} + \mathbf{J}_{\mathbf{r}_1}^T \mathbf{r}_1 + \mathbf{J}_{\mathbf{r}_2}^T \mathbf{r}_2, \quad (1)$$

where $\mathbf{A}(\mathbf{x})$ is a 7×7 symmetric positive definite inertia matrix, $\mathbf{h}(\mathbf{x}, \dot{\mathbf{x}})$ is a 7×1 vector, which groups the centrifugal, Coriolis, and gravity forces. $\mathbf{\Gamma}$ is 6×1 vector of the joint torques applied by the biped. We consider six torques applied in the hip-, knee- and ankle-joints. Vectors $\mathbf{r}_i = (r_{ix}, r_{iy})^T$, with $i = 1, 2$, are the ground reactions applied to the massless feet and consequently to the ankle-joints. The following constraint equations are correct when the front or/and rear leg is/are on the bearing surface.

$$\mathbf{J}_{\mathbf{r}_i} \ddot{\mathbf{x}} + \dot{\mathbf{J}}_{\mathbf{r}_i} \dot{\mathbf{x}} = \mathbf{0} \quad \text{for } i = 1 \text{ or/and } 2. \quad (2)$$

Single-support motion: Boundary value problem

In the single-support phase, the ballistic movement takes place on the supporting leg with a flat-foot contact, Fig. 1. A torque is applied only in the ankle-joint of this stance leg in order to maintain the equilibrium of its foot. Let a_2, t_2 , and h_2 refer to the ankle, toe and heel of the transferred leg (shown in Fig. 1 by blue color). The five initial velocities $\dot{q}_i(0)$,

Figure 2: Generalized coordinates, and inter-link torques.

length of the step d and duration T_{SS} of the single-support motion are calculated to reach the final configuration from the initial one and to satisfy the two following velocity conditions $V_{a_2}(0) \cdot \mathbf{a}_2 \mathbf{t}_2 = 0$ and $V_{a_2}(T_{SS}) \cdot \mathbf{a}_2 \mathbf{h}_2 = 0$. They respectively ensure that the toe t_2 of the rear foot rises from the ground without touching the ground again and there is an impactless landing of the heel h_2 on the ground at the end of the single-support motion.

Double-support motion: problem definition

At the end of the single-support phase, the landing massless foot touches the ground with its heel, Fig. 1 c). The other foot keeps contact with the ground through its toe. In double-support phase both feet rotate, Fig. 1 d), the double support motion is ended when the foot of the front leg touches the ground with the toe and the rear foot rises. At this instant, the single-support motion of the next step starts. Variables q_{p1} , q_{p2} , q_1 , q_2 , q_5 and r_{1x} are defined with Bezier polynomial functions $P_j(\tau)$ with five control point p_j ($j = 0, \dots, 4$) and $\tau = (t - T_{SS})/T_{DS}$, T_{DS} being the duration of the double-support motion. At each sampling time the knowledge of $P_j(\tau)$ allows us to calculate the trajectory of x , y , x_{a1} , x_{a2} , q_3 and q_4 , by using geometric and kinematic models, (2), and thus the left term of (1).

Numerical results

Figure 3 a) shows that the evolutions of angles q_{p1} and q_{p2} are synchronized during the double-support phase. Figure 3 b) shows that the magnitude of the torque in the ankle-joint of the rear leg is much greater than the magnitude of the torque in the ankle-joint of the front leg. This seems physically coherent because the biped pushes on the rear leg to move forward during the double-support phase.

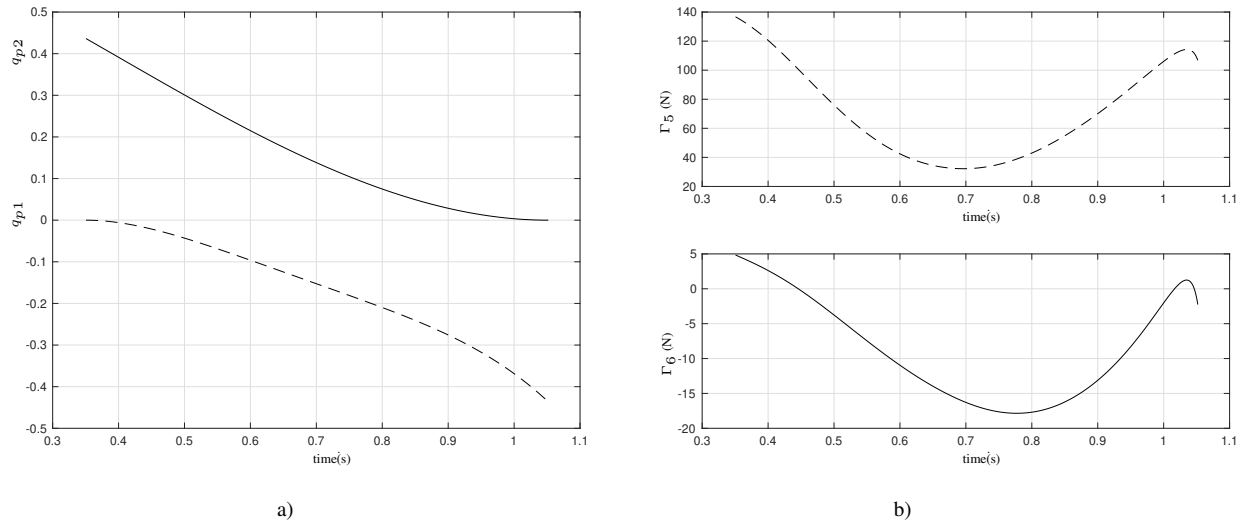

Figure 3: Front leg (solid lines) and rear leg (dashed lines) in double-support phase: a) Orientation angles of feet . b) Ankle torques.

Conclusions

The definition of a walking with a distributed in time double support is a complex problem, [4]. In the papers [1–3], we studied ballistic single-support motion coupled with *instantaneous* double-support phase. The torques in the biped joints at the instantaneous double support are impulsive one. The *distribution in time* of the double support allows to get a cyclic gait with the torques of finite magnitude. The future objective is to increase the time of the single-support motion and decrease the time of double-support motion in order to get biped walking closer to human one.

Summary. This work presents a first step to using a phenomenological model of an SMA spring as an auxiliary damping mechanism in a Pendulum Tuned Mass Damper (PTMD) setup under stochastic excitation. An SMA superelasticity model was considered to approach the hysteretic behaviour of an SMA material. In provision for subsequent simulations, this model's optimal damping parameters were derived with particular care for the implicit relationship between the SMA model parameters and system mean square response.

Introduction

In the field of Pendulum Tuned Mass Dampers (PTMD), many damping modalities have been investigated. This paper presents a novel way of using hysteretic aspects of Shape Memory Alloy (SMA) spring as a damping mechanism in a PTMD system. This investigation looks into damping for a single SMA spring, allowed to move in a one-dimensional space along the horizontal displacement of the pendulum mass. It presents the results of the optimal parameters corresponding to maximum structure displacement variance reduction. The methods address the derivation of moment equations through symbolic computing and solving. These are then used to optimise the system parameters through numerically solving implicit relationship between the SMA parameters and the system's mean square response through an iterative process proposed in [2].

Methods

The system under consideration is presented in Fig. 1. The main structure was assumed to move only along the x -axis. The pendulum is attached to the structure at point A and has length L and angle of inclination θ . The SMA spring is attached at the bottom of the ball mass and at the side floor of the structure. The top floor and wall were assumed to move as a rigid body and the excitation, applied along the x -direction, is modeled as a white noise excitation.

Figure 1: Schematic of the system under consideration

The elongation of the spring, denoted by s , has a minimum length of s_0 . The restoring force g of the SMA spring is here assumed to behave according to the Yan-Nie equivalent linearization model [3],

$$g(s, \dot{s}) = \alpha ks + (1 - \alpha)kz \quad (1)$$

where,

$$z = c_e \dot{s} + k_e s \quad c_e = \frac{b - a}{\sqrt{2\pi}\sigma_s} \left[1 - \operatorname{erf} \left(\frac{a}{\sqrt{2}\sigma_s} \right) \right] \quad k_e = \frac{a + b}{\sqrt{2\pi}\sigma_s} e^{-\frac{a^2}{2\sigma_s^2}} \quad (2)$$

Here a and b are constants defining the phase transition lengths of the SMA material. Note that in order to use this linearized model for the restoring force, the standard deviations σ_s and $\sigma_{\dot{s}}$ of the elongation displacement and velocity must be known. In this case, according to the law of cosines, the elongation displacement s and velocity \dot{s} could be expressed as,

$$s = s_0 - L \sin \theta \quad (3)$$

$$\dot{s} = L \cos \theta \dot{\theta} \quad (4)$$

This system's dynamics under white noise excitation can be described by,

$$\begin{pmatrix} M+m & mL \cos \theta \\ mL \cos \theta & mL^2 \end{pmatrix} \begin{pmatrix} \ddot{x} \\ \ddot{\theta} \end{pmatrix} + \begin{pmatrix} C & -mL \sin \theta \dot{\theta} \\ 0 & (1-\alpha)kc_e L^2 \cos^2 \theta \end{pmatrix} \begin{pmatrix} \dot{x} \\ \dot{\theta} \end{pmatrix} + \begin{pmatrix} K & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} x \\ \theta \end{pmatrix} = \begin{pmatrix} 0 \\ -mgL \sin \theta - (\alpha k + (1-\alpha)kk_e)(L^2 \sin \theta \cos \theta + Ls_0 \cos \theta) \end{pmatrix} \quad (5)$$

where M , C and K are the primary structure mass, damping and stiffness, respectively. The constant m represents the pendulum mass. Here, $k = \frac{F_0 mg}{b}$ where g is the acceleration due to gravity. F_0 , the normalized transformation strength, therefore drives the SMA stiffness. It was chosen to investigate the system with a mass ratio $\frac{m}{M} = 0.2$, a frequency of oscillation of 1.5 Hz and a damping ratio of 0.017. The SMA parameters were chosen to be $a = 0.005m$, $b = 0.08m$ and $\alpha = 0.06$.

Throughout the study, all the state variables (the structure displacement x and pendulum angle θ) were assumed to be zero-mean stationary Gaussian random variables. The following quantities were therefore determined using a small-angle approximation,

$$\sigma_s^2 = L^2 E[\theta^2] \quad \sigma_s^2 = L^2 E[\dot{\theta}^2] \quad (6)$$

Since the relationship between Eqs. (2) and (6) is implicit, it was proposed to use the iterative process described in [2] to determine adequate values for c_e and k_e upon convergence. This was allowed by first deriving the moment derivatives of this system, derived using principles devised in [1]. Additionally, this system's optimal operating point in a domain $L \in [0, 1]$, $F_0 \in [0.1, 0.95]$ was determined through the optimization of a performance index defined by the ratio of the optimized variance (σ_{optim}^2) and the determined uncontrolled primary structure's variance (σ_r^2). For the purpose of optimization, the MATLAB[®] *fmincon* function was used. Namely,

$$\begin{aligned} \min_{L, F_0} \quad & \frac{\sigma_{optim}^2}{\sigma_r^2} \\ \text{s.t.} \quad & 0 \leq L \leq 5 \quad (m) \\ & 0.1 \leq F_0 \leq 0.95 \end{aligned} \quad (7)$$

Results

Figure 2 demonstrates the results of a parameter sweep performed for the described range of values of L and F_0 . It also presents the optimal operating point for this system with $L = 0.4932$ m, $F_0 = 0.2066$ with an optimal reduction of the variance to 13.88% of the uncontrolled structure's variance.

Figure 2: Contour plot of the ratio of derived variance to uncontrolled variance as a function of length and normalized transformation strength

Summary: Most sensory systems in biology exhibit properties that resemble the behaviour of nonlinear dynamic systems [1]. The auditory sensing system is no exception with its nonlinear transfer characteristics enabling amplification and selection features [2]. It was suggested that biological auditory sensing can be modelled as a system tuned near/at a Hopf bifurcation [2]. Theoretical studies showed that the tuning to the bifurcation point can be achieved also if sub-threshold Hopf oscillators are coupled via their output signals [3]. Here, we study experimentally and numerically the properties of a nonlinear cantilever-based acoustic sensing system in dependence of the coupling strength. We show that coupling not only yields a transition between linear and nonlinear characteristics and increases sensitivity but it can be used for bandwidth enhancement of the system as well, enabling coverage of larger frequency ranges.

Introduction

Introducing bio-inspired signal pre-processing into speech and sound processing system strongly increases the performance, as recently shown by Araujo et al [4]. The main pre-processing components are thereby frequency decomposition of the signal, nonlinear (compressive) amplification, and adaptation of sensing properties to different inputs. Nevertheless, software-based implementations prevent real-time performance and high efficiency. Thus, hardware-based implementations are required. These can further improve the signal-to-noise ratio and the above mentioned properties if implemented into the sensing stage directly. We developed an acoustic sensing system with integrated bio-inspired pre-processing based on a silicon cantilever beam with real-time feedback [5]. Thereby, frequency decomposition is obtained using resonant operation. We demonstrated that nonlinear operation similar to a Hopf oscillator can be obtained using certain real-time feedback mechanism [5]. Since the linear or nonlinear characteristics are controlled by the feedback loop, dynamic adaptation of sensor properties can be introduced easily.

The exact mechanism, generating nonlinear dynamics in the inner ear, is still under discussion [6]. However, one proposed mechanism is coupling of the receptor cells and/or the hair bundles on top of these cells. This coupling increases the tolerance against noise and improves the range of non-linear regime [6]. Gomez et al. [3] theoretically showed that coupling of sub-threshold Hopf oscillators can induce a bifurcation as well. This yields an increase of the parameter range for the occurrence of the Hopf bifurcation and improves the sensitivity of the complete system. Here, we study the influence of output-signal coupling on the properties of our acoustic sensing system, consisting of nonlinear cantilevers. In particular, we analyse (i) if a Hopf bifurcation can be achieved due to the coupling, (ii) how the critical coupling strength depends on the sensor properties, and (iii) how the coupling affects sensor properties like sensitivity and bandwidth.

Implementation

Figure 1 schematically shows the coupled cantilever system. We use micro-electro-mechanical systems (MEMS)-based silicon beams with integrated deflection sensing and actuation [7]. After a first amplification stage and decomposition of the sensing signal x into an AC and a DC part using a high-pass and low-pass filter, respectively, feedback and output-signal coupling are realised using the FPGA structure of a STEMLAB-125 board. Two cantilevers with different characteristic frequencies ω are coupled and analysed. Coupling is implemented by first multiplying the sensing signal x_1 of one cantilever by the coupling factor C_f , then adding an offset u_{DC} , and finally using the resulting signal $y_2 = C_{f,1}x_1 + u_{DC}$ to drive the actuation of the second cantilever (see figure 1). Similarly, the signal x_2 from the second cantilever drives the actuation y_1 of the first cantilever. The coupling between both cantilevers is symmetric, i.e. $C_{f,1} = C_{f,2}$. Furthermore, self-feedback given by a_1x_1 is added to the actuation signal, yielding $y_1 = C_{f,1}x_2 + a_1x_1 + u_{DC}$. In this work, the critical coupling strength $C_{critical}$, at which the bifurcation is observed, is determined in dependence of the characteristic frequencies $\omega_{1,2}$ of the sensors and the distance $\mu = a_{crit} - a_{1,2}$ of the feedback strength a from its critical value a_{crit} at the Hopf bifurcation. Then, the response of the sensing system to sound stimuli of various frequencies and amplitudes is analysed.

Results

Figure 2 shows the critical coupling strength $C_{critical}$ in dependence of the ratio of characteristic frequencies ω_1/ω_2 of the two coupled cantilevers and the distance μ from the Hopf bifurcation. It is observed that $C_{critical}$ increases, if ω_1/ω_2 or μ increase, as was expected from the theoretical studies of Gomez et al. [3]. However, for a fixed ω_1/ω_2 and increasing μ , the slope of $dC_{critical}/d\mu$ is decreasing in the experiment while it is increasing for the theoretical prediction by Gomez et al., which is based on a normal form for the Hopf oscillators. To study, if this deviation arises from the coupling mechanism or the oscillator model, we will compare the experimental results with simulations of the system, using a sensor-specific model, and simulations of an adapted Gomez system.

Regarding the sensing properties, we observe higher sensitivities for the coupled system, as expected from the theoretical predictions. Nonlinear transfer characteristics occur, if the system of both cantilevers is tuned near the bifurcation point. Additionally, the range of frequencies, for which the system is sensitive, increases strongly (up to 10 times larger bandwidth). In this case, both sensors do not only show a stronger response to sound frequencies at the two characteristic frequencies, but also in the frequency range in between. This enables bio-inspired acoustic sensing systems covering the auditory frequency range with only a few cantilevers with nonlinear characteristics.

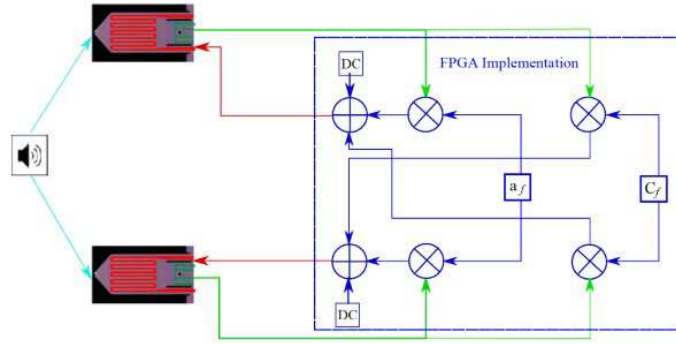

Figure 1: Schematic for feedback and coupling mechanism

Figure 2: $C_{critical}$ as a function of ω_1/ω_2 and μ for different pairs of coupled cantilevers obtained from experiments.

Dynamic loads produced by swinging bells – experimental and numerical investigation of the novel yoke-bell-clapper system with variable geometry

Tomasz Burzyński*, Piotr Brzeski*, Marek Balcerzak* and Przemysław Perlikowski*

*Division of Dynamics, Lodz University of Technology, Lodz, Poland

Summary. Dynamics of the swinging bells is a timely problem considered when the bell's supporting structures are designed or monitored. The geometry of the yoke and the magnitude of excitation force are the crucial parameters determining the yok-bell-clapper system response for a given size and shape of the bell. In this paper we present novel yoke-bell-clapper system with variable geometry and adjustable excitation force. We introduce mathematical model based on the existing prototype. We validate the mathematical model and then assess the influence of the yoke geometry and excitation force on the system response. The simulations are done using sample-based approach. The system that undergoes investigation in the paper is non-linear, piecewise and discontinuous. Created numerical tool can reliably predict the ringing scheme of the bell and associated reaction forces in the supports.

Introduction

Dynamics of the swinging bells is a timely problem that is recently widely considered by scientific community. The phenomena that are the most widely investigated are the bell to the clapper impact modeling, different bell's working regimes, the dynamics of bell towers and the magnitudes of forces transferred between the bells and their supporting structures. The loads generated by swinging bells are in special interest because they may have severe consequences on the bell's supporting structure as recently reported by [1,2,3]. For a given size and shape of the bell, the crucial parameter that determines it's dynamics are the geometry of the yoke and magnitude of excitation force. In the existing studies, when modeling the dynamics of the bell supporting structure the loads generated by swinging bells are either measured by accelerometers placed on the existing constructions or estimated according to some semi-empirical formulas [4].

In this paper we present novel yoke-bell-clapper system with variable geometry and adjustable excitation force. We introduce the mathematical model of the system that is based on the existing prototype and validate it. Our goal is to assess the influence of the yoke's geometry and the excitation force on the bell's and clapper's oscillations amplitude and associated reaction forces in the supports. The simulations are done using sample-based approach, values of system parameters are randomly sampled from the analyzed set of parameter values. As a result we obtain an effective and robust numerical tool that can trustworthy predict the bell's ringing scheme and produced loads.

Experimental stand and mathematical model validation

Figure 1 presents the experimental rig based on the project and patent of the Lodz University of Technology. The rig consists of the yoke, the bell, the clapper, the moving beam and the supporting frame. The idea behind the moving beam is that we can alter the geometry of the yoke, therefore reproduce different bell mounting types and analyze the influence of the parameters describing the yoke's geometry on the system response. The rig is equipped with sensors that measure the kinematics and the dynamics of the system.

The mathematical model representing the yoke-bell-clapper system is build based on the physical model that is also schematically presented in the figure 1. It is a four degree of freedom (DoF) system accommodating the yoke with the bell, the clapper and the yoke's supports. The clapper to the bell collisions are described using a discrete mathematical model based on the coefficient of restitution. The analyzed yoke-bell-clapper system is propelled with a linear motor activated when the bell goes through its stable equilibrium position. The excitation mathematical model is therefore piece-wise and depends on the period of the system.

Figure 1: Experimental rig and schematic model of the experimental rig along with its physical and geometrical quantities involved in the mathematical model of the system.

The mathematical model is validated by performing the series of simulations for chosen yokes' geometries. Each time numerical results were compared with data obtained experimentally. Good matching between experimental data and numerical results is achieved in all scenarios. It shows that our model can accurately represents reality regardless of the yoke's geometry. Important aspects from engineering point of view including: The period of the system, its dynamics, reaction forces, and ringing scheme of the bell are reliably determined.

The influence of the yoke geometry and excitation on the system response

Using validated mathematical model we investigate the influence of the yoke geometry and the excitation force magnitude on the system response. In the analysis we focus on the aspects crucial from practical point of view namely: working regime, amplitude of the bell and clapper motion and dynamical loads acting on the supporting structure. We perform a series of 100,000 simulations using sample-based approach. The results are presented in a form of two parameters color maps. In each map on the horizontal axis there is a parameter determining the yoke's geometry and on the vertical axis the excitation force amplitude. Figure 2(a) shows the variety of ringing schemes that can be obtained depending on the geometry and excitation. Figures 2(b) and 2(c) present the amplitudes of dynamic reaction forces in the yoke supports in the horizontal and vertical direction consecutively.

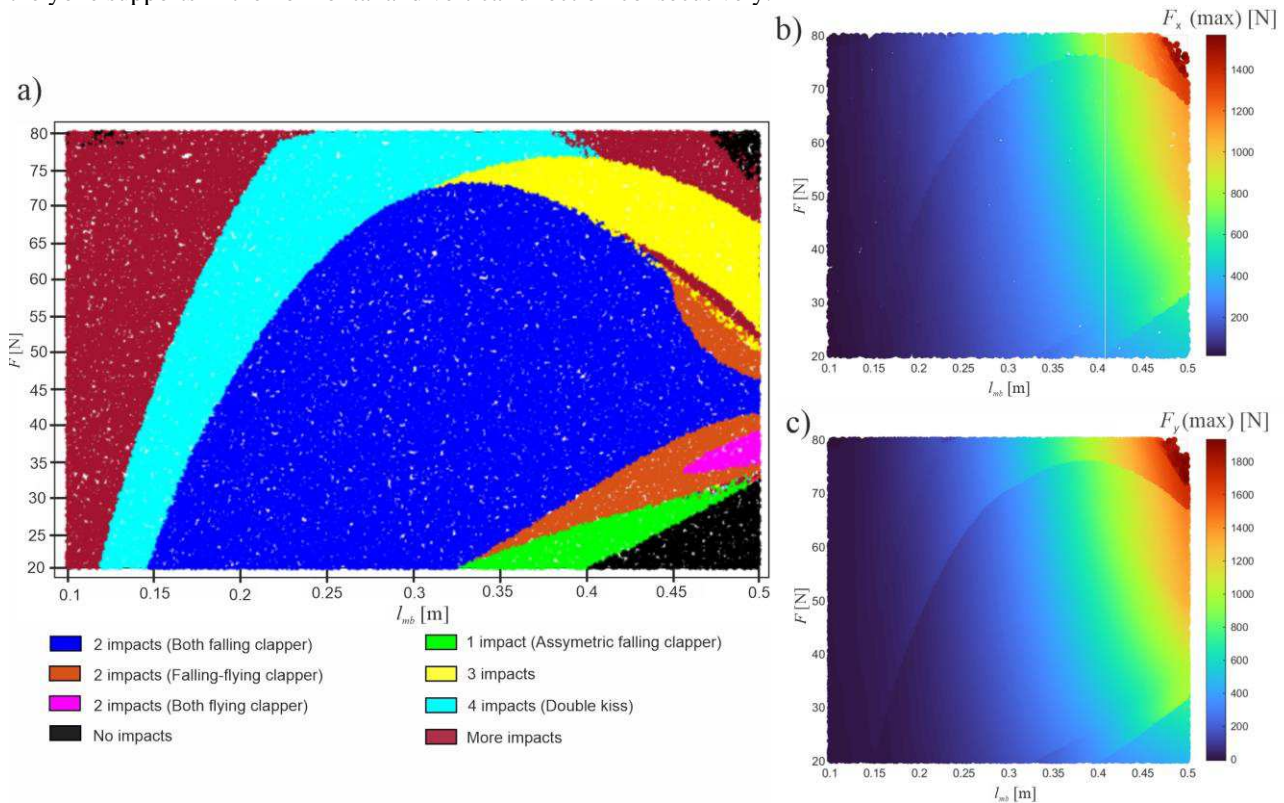

Figure 2: Two parameters colormaps showing a) the behavior of the system after reaching its attractor, amplitude of the reaction force in the supports in the a) horizontal and b) vertical direction.

Conclusions

We present that transition from one ringing scheme to another is usually associated with a step change of produced reaction forces and oscillations amplitude. We also show that for a given yoke's geometry different ringing schemes are possible depending on the excitation force.

Developed numerical algorithm can serve as a reliable tool for engineers during the design phase of the bells, yokes and their supporting structures.

Summary. A unique characteristics of cantilevered beams is their capability of undergoing very large-amplitude oscillations, which has been used in various applications such as energy harvesting and bio-inspired actuation. To examine cantilever motions of extremely large amplitudes, the third-order inextensible nonlinear model cannot be used, hence requiring the application of a geometrically exact model. This study presents an experimental and theoretical investigation on nonlinear extreme dynamics of cantilevers under base excitation. A rotation-based geometrically exact model is developed using Euler-Bernoulli beam theory and inextensibility assumption to examine the cantilever response at extreme motion amplitudes. Precise experiments are conducted using a state-of-the-art in vacuo base excitation experimental set-up to drive the cantilever to extremely large motion amplitudes, and a high-speed camera is used to capture the motion. Extensive comparisons are conducted between experimental and theoretical results and it is shown that the proposed exact model can be used reliably to capture cantilever motions of extreme amplitudes.

Introduction

Cantilevered beams are present in different engineering applications such as vibration energy harvesters, micro gyroscopes, and piezoelectric sensors and actuators. Owing to have one end free, they can undergo large-amplitude vibrations. However, analysing large-amplitude vibration is a difficult task, not only due to the presence of different sources of nonlinearity, but also the fact that the amplitude could grow extremely large, rendering nonlinear truncated models inaccurate and requiring a geometrically exact model. Many investigators have examined the vibrations of cantilevers over the last few decades, starting with the well-known third-order model developed by Crespo da Silva and Glynn [1, 2], which was later further examined by Nayfeh and Pai [3, 4]. Many other studies utilised the third-order model to examine the behaviour of cantilevers, namely Dwivedy and Kar [5] and Mahmoodi et al. [6]. Farokhi et al. [7] continued the studies on this topic by developing a dynamical version of the rotation-based exact nonlinear cantilever model, originally used for static buckling of an elastic continuum [8], capable of capturing motions of extreme amplitudes. This study reports detailed experimental results on extremely large vibrations of a cantilever and shows comparisons between experimental and theoretical results.

Model Development

To derive the rotation-based geometrically exact equation of motion, a cantilevered beam is considered of length L , cross-sectional area A , second moment of area I , Young's modulus E , mass per unit length m , and material damping coefficient η , under harmonic excitation in the form of $z_0 \sin(\omega_z t)$. Making use of the inextensibility assumption, and in the context of the Euler-Bernoulli beam theory, the longitudinal (u) and transverse (w) displacements of the cantilever (the latter with respect to the clamped end), can be formulated in terms of the centreline rotation ψ as

$$u(s, t) = \int_0^s (\cos \psi(\xi, t) - 1) d\xi, \quad w(s, t) = \int_0^s \sin \psi(\xi, t) d\xi. \quad (1)$$

Assuming a vertical configuration for the cantilever with the clamped end at the bottom (see Fig. 1(a)) and taking into account the gravity, the geometrically exact equation of motion for centreline rotation of the cantilever can be derived as

$$\begin{aligned} J \partial_{tt} \psi + m \sin \psi \int_s^L \int_0^{s^*} \left(\partial_{tt} \psi(\xi, t) \sin \psi(\xi, t) + \left(\partial_t \psi(\xi, t) \right)^2 \cos \psi(\xi, t) \right) d\xi ds^* \\ + m \cos \psi \int_s^L \left[-z_0 \omega_z^2 \sin(\omega_z t) + \int_0^{s^*} \left(\partial_{tt} \psi(\xi, t) \cos \psi(\xi, t) - \left(\partial_t \psi(\xi, t) \right)^2 \sin \psi(\xi, t) \right) d\xi \right] ds^* \\ - EI \partial_{ss} \psi - \eta I \partial_{tss} \psi - mg(L - s) \sin \psi = 0. \end{aligned} \quad (2)$$

in which $J = \rho I$ with ρ being the mass density, g is the acceleration due to gravity, and $\partial_s \equiv \partial/\partial s$. Equation 2 is then nondimensionalised and discretised into a 6-degree-of-freedom system using the Galerkin technique while keeping all terms geometrically exact. The resultant set is solved using a continuation technique.

Results

Figure 1(b) shows the in vacuo base excitation experimental set-up used to excite the cantilever in the primary resonance region and to drive it to extremely large amplitude. A high-speed camera system was used to capture vibration response of the cantilever. An image processing code was then developed to extract the beam deformed shape and the motion amplitudes from the videos. In order to examine oscillations of extremely large amplitudes, the cantilever was excited

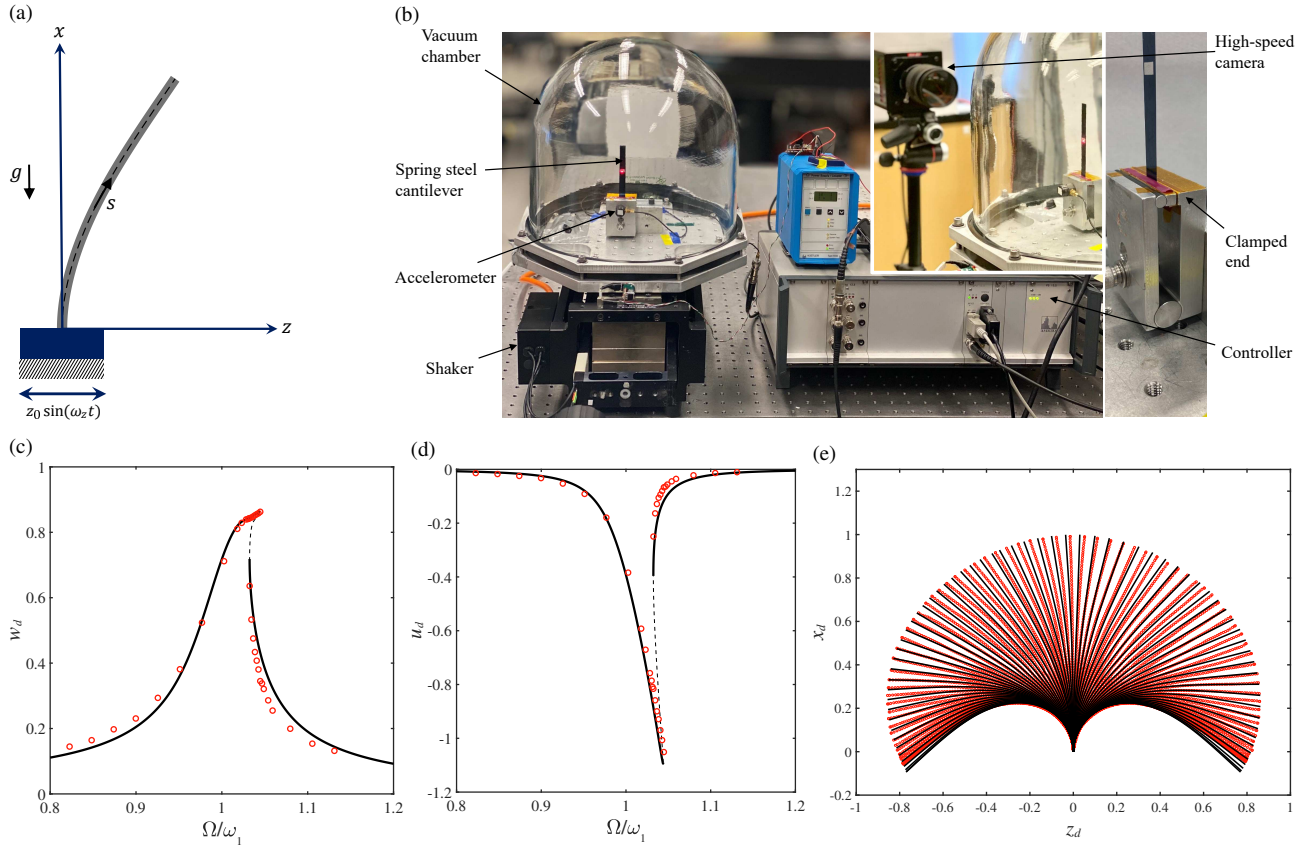

Figure 1: (a) Schematic of the cantilever. (b) In vacuo base excitation experimental set-up. (c, d) Frequency response of the cantilever tip transverse and longitudinal vibration at 0.5g RMS acceleration level, respectively. (e) Motion of the cantilever at peak amplitude in one period of oscillation. In sub-figure (c)-(e), circles denote experimental results and lines show geometrically exact model predictions.

at base acceleration of 0.5g RMS under near-vacuum conditions (i.e. 9% atmospheric pressure). The theoretical and experimental frequency responses of the cantilever are illustrated in Fig. 1(c) and 1(d), and the oscillation of the cantilever at its peak resonance amplitude in one period of oscillation is shown in Fig. 1(e). It is seen in Fig. 1(c, d) that the exact model works very well even at this extreme oscillation amplitude and predicts a frequency response amplitude very close to the experimental one. Additionally, as shown in Fig. 1(e), the exact model does an excellent job at capturing the extreme vibrations of the cantilever, even when the tip of the cantilever bends backwards, as confirmed by the experimental observations. Hence, these results prove the validity of the proposed geometrically exact model and that it can be used reliably for studying cantilever vibrations of extremely large amplitudes.

Conclusions

Nonlinear extreme dynamics of a cantilever was examined experimentally and theoretically. For the experimental part, an in vacuo experimental set-up was used to excite the cantilever in the primary resonance region and to drive the cantilever vibration to extremely large amplitudes, and for the theoretical part, a geometrically exact model based on Euler-Bernoulli beam theory was developed. Comparisons between experimental and theoretical results showed that the proposed exact model is fully capable of capturing vibrations of extremely large amplitudes reliably.

Summary. Piezoelectric actuation represents the most effective out-of-plane actuation mechanism for resonant microstructures as scanning micromirrors and piezoelectric ultrasonic transducers. Nevertheless, predicting the dynamic response of such devices at their design stage is often impractical since numerical computation of periodic orbits from finite element systems is computationally demanding. In this work, we propose a model order reduction strategy based on the direct parametrisation for invariant manifolds tailored for nonlinear piezoelectric structures. The innovative aspect of the method is the introduction of nonlinear terms that arise due to piezoelectric coupling in the reduction procedure.

Introduction

Among the actuation techniques available for the development of micro-electro-mechanical systems (MEMS), piezoelectric actuation is the most effective to achieve large out-of-plane displacements in resonant actuators as scanning micromirrors and piezoelectric ultrasonic transducers. Indeed, its enhanced linearity, fast feedback response, and high exerted forces provide a mean to achieve high performance with moderate power consumption and easy control of the device. However, the large amplitudes developed by devices as scanning micromirrors are still affected by geometric nonlinearities and by the hysteretic behaviour of piezoelectric materials, which in turn makes the dynamic response of the device nonlinear. Such effects need to be predicted at the design stage of MEMS components, hence making numerical methods of paramount importance for their design. Since full-order numerical simulations are computationally demanding for performing parametrised analyses of mechanical components, dimensionality reduction techniques are essential [1, 2]. Within the context of vibratory systems, the Direct Parametrisation for Invariant Manifolds (DPIM) [3, 4] represents the most effective method for deriving accurate reduced models of structures actuated at resonance. In the present work, we derive an extension of the method initially introduced for systems subjected to geometric nonlinearities to account for the nonlinear converse piezoelectric effect as modeled by the Landau-Devonshire theory of ferroelectrics. The proposed approach is applied to predict the nonlinear dynamic response of MEMS micromirrors and its results are compared with experimental data.

Method

The dynamic response of piezo-MEMS undergoing large displacements and subjected to converse piezoelectric effect is governed by the conservation of linear momentum formulated as follows [5]:

$$\int_{\Omega} \rho \ddot{\mathbf{u}} \cdot \mathbf{w} \, d\Omega + \int_{\Omega} (\mathbf{S}^e - \mathbf{S}^p) : \delta \mathbf{e} \, d\Omega = 0, \quad (1)$$

where all quantities are reported in material configuration Ω . ρ is the density, \mathbf{w} is the test function, $\delta \mathbf{e}$ is the first variation of the Green-Lagrange strain tensor. The second Piola-Kirchhoff stress tensor is decomposed in elastic \mathbf{S}^e and inelastic components \mathbf{S}^p , which in the present framework are given by the following constitutive models [6]:

$$\mathbf{S}^e = \mathcal{A} : \mathbf{e}, \quad \mathbf{S}^p = \mathcal{Q} : \mathcal{A} : (\mathbf{p} \otimes \mathbf{p}), \quad (2)$$

with \mathcal{A} elasticity tensor, \mathcal{Q} electrostrictive tensor, and \mathbf{p} polarisation vector. In general \mathbf{p} is time-dependent and with non-zero average value. Upon finite element discretisation of Eq. (1) and addition of damping the following discrete system of ordinary differential equations is retrieved:

$$\mathbf{M}\ddot{\mathbf{U}} + \mathbf{C}\dot{\mathbf{U}} + \mathbf{K}\mathbf{U} + \mathbf{G}(\mathbf{U}, \mathbf{U}) + \mathbf{H}(\mathbf{U}, \mathbf{U}, \mathbf{U}) = \mathbf{F}^p(\mathbf{U}, \mathbf{p}), \quad (3)$$

with \mathbf{p} function of time. Dimensionality reduction of Eq. (3) is achieved by parametrising the motion of the system along an invariant-based span of the phase space. We recast Eq. (3) in first order by introducing the velocity $\mathbf{V} = \dot{\mathbf{U}}$ and we introduce a nonlinear coordinate change between the normal coordinates \mathbf{z} that describe the motion of the system along the embedding and the nodal degrees of freedom of the model [7, 8]:

$$\mathbf{U} = \boldsymbol{\Psi}(\mathbf{z}), \quad \mathbf{V} = \boldsymbol{\Upsilon}(\mathbf{z}). \quad (4)$$

The dynamics along the defined subspace is expressed as:

$$\dot{\mathbf{z}} = \mathbf{f}(\mathbf{z}), \quad (5)$$

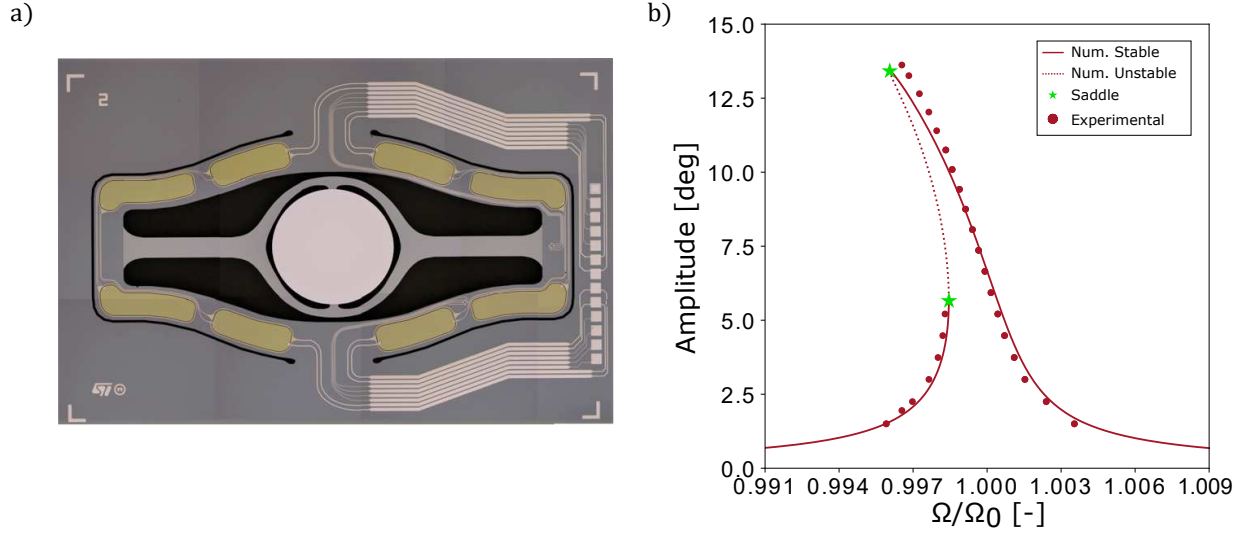

Figure 1: (a) optical microscope image of the tested device. (b) Preliminary comparison between experimental data and numerical frequency response curves. Numerical curves are obtained using a complex normal form style parametrisation.

with $\mathbf{f}(\mathbf{z})$ reduced dynamics. An important remark of the presented formulation is that the polarization field \mathbf{p} is assumed as known. In the present work, the polarisation is measured from experimental data and fed to the model to compute the piezoelectric forces $\mathbf{F}^p(\mathbf{U}, \mathbf{p})$ beforehand. This provides an efficient modeling approach as already evidenced in past works. When combined with the proposed model order reduction strategy it provides an efficient framework for predicting the nonlinear dynamic response of piezoelectrically actuated microstructures.

First results reported on a MEMS device are reported in Fig. 1. Fig. 1(a) reports the device under consideration, which is a MEMS micromirror developed by STMicroelectronics. In Fig. 1(b) a preliminary comparison between numerical simulations and experimental data is reported, highlighting the remarkable agreement of the proposed approach.

Conclusion

We here reported a model order reduction method for nonlinear piezoelectric structures based on the direct parametrisation for invariant manifolds. The starting equation is the conservation of linear momentum for structures subjected to finite transformations and to converse piezoelectric effect, the latter modeled using the Landau-Devonshire theory of ferroelectrics. The resulting system exhibits a follower force controlled by the polarization of the piezoelectric material and by the displacement of the structure, which in turn modifies the vibratory response of the system. Preliminary results obtained on a real MEMS device show promising results both in terms of computational performance and accuracy.

Modeling Nonlinearities in MEMS Micro Mirrors: From Single Chip to Wafer Level

Ulrike Nabholz*, Jan E. Mehner[†] and Peter Degenfeld-Schonburg*
 *Robert Bosch GmbH Corporate Research, 71272 Renningen, Germany
[†]Chemnitz University of Technology, 09107 Chemnitz, Germany

Summary. The performance requirements for MEMS sensors and actuators, such as scanning micro mirrors, are increasing as emerging applications in the fields of highly-automated driving or augmented reality are in increasing demand. During final testing, a device is rejected as soon as it does not fulfil the performance specifications which decreases yield and thus increases the overall cost. In many cases, unexpected device failure or performance issues can be traced back to nonlinear system behaviour. This entails the need for system models which take nonlinear sensor dynamics into account and a fundamental understanding of the underlying nonlinear physics is often essential for an improved MEMS design. Here, we present a comprehensive analysis of nonlinear dynamics in scanning MEMS micro mirrors ranging from careful measurements and modeling of nonlinear system behaviour on the level of individual chips up to wafer-level testing of several hundred devices. The underlying nonlinear mode-coupling phenomenon, known as spontaneous parametric down-conversion (SPDC) exhibits a sudden transition from mostly linear to nonlinear system behaviour. The threshold amplitude or rather critical point only lies within the operational amplitude of a device, when a specific frequency resonance condition (a 1:1:1 internal resonance) for the mechanical modes of the device is closely matched. Due to fabrication imperfections of MEMS process technologies small deviations in the geometry between several devices of the same design occur which consequently influences the frequency spectrum strongly influence the frequency spectrum of each individual device and therefore decide about the fulfilment of the resonance condition. We demonstrate the benefits that can be achieved by employing the insights gained from single-chip measurements and models to the analysis of a large number of devices on wafer level and suggest a possible path towards successful design iterations. Moreover, above the threshold we show that the micro mirror displays fundamental nonlinear behavior ranging from stationary state bifurcations to dynamical instabilities.

Introduction

One main requirement for scanning MEMS micro mirrors for automotive as well as for consumer applications is the reachable deflection angle. Yet, our experimental observations show that even micro mirrors of the same design layout often show drastic differences in their maximum deflection [3]: Some devices reach the required deflection angle while others exhibit instabilities in their deflection and sometimes even fracture.

These drastic differences in the device behaviour can be attributed to small differences in the mode spectrum caused by geometry variations due to the process tolerances of surface micromachining. In the case of the scanning MEMS micro mirror at hand, the nonlinear dynamic behaviour which occurs in some cases is due to a fundamental nonlinear model, more prominently known from nonlinear optics, namely spontaneous parametric down-conversion (SPDC). In the mechanical domain, where the nonlinear mode coupling originates from geometric nonlinearities, SPDC or three-wave mixing has only been studied in recent years [1, 3].

For SPDC, a model of an externally driven, damped Duffing oscillator with a cubic nonlinearity is used for the drive mode. Additionally, two so-called parasitic modes of the same type are coupled to the drive mode through a three-wave coupling term. In addition, as discussed in [2], a nonlinear damping term needs to be included.

Full Model for Single Chips

With the a simple model of three nonlinearly coupled ordinary differential equations, the observed effects can be simulated and thus explained physically. They include bifurcations and hysteresis, as well as unstable behaviour caused by a resonant actuation of parasitic modes and thus amplitude depletion of the drive mode. Additionally, critical slowing-down and limit cycles can explain the observed phenomena.

The system parameters needed to emulate the behaviour can be measured directly using laser doppler vibrometry. They can also be obtained from simple optical measurements, where the deflection angle is measured during the undisturbed and during the disturbed operation of the mirror.

Fig. 1 shows the modelled behaviour of a micro mirror that shows SPDC behaviour. As mentioned above, SPDC is a spontaneous process and thus, the figure shows the behaviour below threshold (identical to the nonlinearly damped Duffing oscillator) as well as the behaviour above threshold, where the two parasitic modes gain amplitude and disturb the oscillation of the drive mode. The critical point model represents the threshold deflection angle, that is the transition from uncoupled behaviour to SPDC behaviour with the two additional parasitic modes. This model is of vital importance for the large scale application and wafer level testing that will be elaborated on in the next section.

Critical Point Model for Wafer Level

The simple analytical model for the critical deflection angles that was shown as a red line in Fig. 1, becomes relevant when measurements need to be carried out for a larger number of devices in order to assess their nonlinear behaviour.

Thus, it is especially important for engineering applications, since it allows for a differentiation between devices that lie within the specifications and devices that lie outside

As we show in [3], mode coupling can be predicted with low computational effort. The result of the prediction only includes at what angle mode coupling occurs in a specific mirror and does not characterize the full range of nonlinear dynamic effects as was the case for the full model above. Yet, this prediction is sufficient for the decision on whether or not a device meets the requirements pertaining to the deflection angle. It points out the individual chips with critical deflection angles below a certain threshold. Apart from this, it increases knowledge about the design and thus provides input for design iterations and optimization.

Fig. 2 show the results of the critical point model [4]. The design parameter $\delta = f_{0,d} - f_{0,p1} - f_{0,p2}$ on the horizontal axis gives the relation of the linear mode frequencies of the three coupled modes, where $f_{0,0}$ denotes the frequency of the drive mode and $f_{0,p1}$ and $f_{0,p2}$ the frequencies of the two parasitic modes. In other words, δ represent the 1:1:1 internal resonance condition.

Figure 1: Transient representation of a sweep with increasing frequency. The drive mode is shown in blue, for the case of mode coupling, the line is solid. For comparison, the dotted blue line represents the behaviour of the drive mode without any mode coupling. The dashed lines in grey and black show the two parasitic modes during mode coupling. The red line denotes the critical point model which depicts the onset of SPDC and will be of great importance in the following section.

Figure 2: Validation of the critical point model: The measured critical deflection angles (631 points) which mark the onset of mode coupling, where red dots and blue circles distinguish critical angles below and above the specified deflection angle, are compared to the prediction from the critical point model, shown as a black line.

Conclusion

We showed that when the modes of a mechanical structure fulfil an internal resonance condition and show a large coupling strength, nonlinear phenomena such as SPDC can occur. The behaviour of single chips was modelled using the full model for three coupled equations of motion with the relevant nonlinear terms from structural mechanics. Wafer level testing of the critical threshold for the onset of mode coupling was successfully matched with the prediction of the much simpler critical point model. The design parameter δ provides leverage for adjusting the mode coupling of a MEMS design. Thus, we explained both the underlying nonlinear dynamics effects and their implications for unwanted nonlinear system behaviour. Connecting these two parts is highly relevant for the development of not only MEMS micro mirrors, but any resonant MEMS sensor or actuator. A range of similar coupling mechanisms due to geometric nonlinearities is also conceivable.

A fast, efficient algorithm for quantification of rare events in dynamical systems

Antoine Blanchard*, Themistoklis P. Sapsis*

*Department of Mechanical Engineering, Massachusetts Institute of Technology, USA

Summary. We introduce a fast, efficient algorithm for quantification of rare events in dynamical systems. The algorithm iteratively learns the “black-box” relationship between parameters (the inputs) and extreme observations (the outputs). To keep the number of black-box evaluations to a minimum, the algorithm cleverly selects the “next-best point” that it should sample based on how much that point will improve our estimate of the output statistics. “Improvement” is quantified by the so-called Q-criterion whose computation (and that of its gradient) can be done analytically, which allows for the possibility of the input space being high-dimensional. We show that the proposed sampling algorithm outperforms other standard sampling approaches.

Background

Extreme events may be thought of as short-lived episodes during which an observable (e.g., drag force, temperature, or stock price) significantly deviates from its mean value. They often have disastrous consequences, as with rogue waves, avalanches, wildfires or extreme weather conditions (see figure 1 and [1]). Quantification of extreme events is particularly difficult because they often arise in complex, high-dimensional, nonlinear systems, and give rise to heavy-tail probability density functions (pdf). The fact that extreme events occur with very low probability means that reliable quantification of the statistics requires an unfathomable amount of data. If the data is collected from a large-scale experiment or a computer simulation with millions of degrees of freedom, the task of extreme-event quantification is virtually hopeless. Thus, the challenge is to come up with a way to estimate the heavy-tail statistics of the system using as few samples as possible.

Figure 1: Examples of extreme events arising in nature.

Mohamad & Sapsis [2] recently proposed a sampling strategy for quantification of extreme events in dynamical systems. The basis for their approach was to approximate the unknown “black box” $y = F(x)$ as the realization of a Gaussian process. Specifically, starting from an initially small dataset, their algorithm uses Gaussian process (GP) regression [4] to construct a surrogate map, and then determines the next-best sample for which evaluation of the black box will most improve knowledge of the statistics. At each iteration, the sought-after pdf can be approximated using the posterior distribution of the surrogate map. In their work, the criterion used to determine the next-best point is problematic for two reasons. First, it takes the form of an integral over the input space, which is intractable in high dimensions. Second, there is no closed-form expression for the gradient of their criterion, which forces them to use non-gradient-based optimizers.

Overview of the algorithm

Our algorithm is inspired by that of Mohamad & Sapsis [2], but considerably improves its scope and efficiency. Assuming that we have available a dataset of input–output pairs $\mathcal{D}_n = \{x_i, F(x_i)\}_{i=1}^n$, we proceed iteratively as follows:

Step 1. Train a GP regressor on \mathcal{D}_n , and compute surrogate mean f_n and covariance σ_n^2 .

Step 2. Determine the next-best point by solving the minimization problem

$$x^* = \underset{x}{\operatorname{argmin}} Q(x; f_n, \mathcal{D}_n). \quad (1)$$

Step 3. Evaluate the expensive map F at the new point, and append $\{x^*, F(x^*)\}$ to \mathcal{D}_n . Then, go back to Step 1.

To compute the criterion $Q(\tilde{x}; f_n, \mathcal{D}_n)$ at some candidate point \tilde{x} , we proceed as follows:

Step Q1. Construct $\tilde{\mathcal{D}}_n$ by appending $\{\tilde{x}, f_n(\tilde{x})\}$ to \mathcal{D}_n . (Note that we use the surrogate map f_n rather than F .)

Step Q2. Predict the covariance $\tilde{\sigma}_n^2$ using the GP regressor trained on \mathcal{D}_n , and return

$$Q(\tilde{x}; f_n, \mathcal{D}_n) = \int \frac{\tilde{\sigma}_n^2(x) p_x(x)}{p_n(f_n(x))} dx. \quad (2)$$

In the above, $p_x(x)$ and $p_n(f_n(x))$ respectively denote the joint pdf of the inputs (which is assumed to be known) and the approximate pdf of the output as predicted by the surrogate map. Criterion (2) is already an improvement over the

A Multi-Dimensional Atlas Algorithm for Variable-Mesh Boundary-Value Problems

Summary. In development since 2007, the MATLAB-based, object-oriented, software platform COCO provides general-purpose support for construction of nonlinear constraints and, in applications to optimization, the corresponding adjoint conditions. COCO atlas algorithms implement continuation strategies that grow constraint manifolds successively from an initial solution guess. Until recently, an alpha implementation in COCO of the multi-dimensional MULTIFARIO package in the `atlas-kd` atlas algorithm was unable to handle problems with changing dimension and/or interpretation of variables and constraints, e.g., boundary-value problems with adaptive meshes. This paper describes a recent upgrade to the `atlas-kd` atlas algorithm that not only provides a resolution to this conundrum, but makes problem-dependent implementation straightforward and consistent with the existing COCO paradigm for construction of constraints and monitor functions. Here, in lieu of a definition of an inner product on an underlying infinite-dimensional vector space, the manifold geometry is characterized using the Euclidean inner product on a suitably-defined finite-dimensional projection. Several examples are considered from the theory of periodic orbits in autonomous and periodically-excited nonlinear dynamical systems.

Fundamentals

The trajectory collocation problem

Following [1], consider the autonomous differential equation $\dot{y} = f(y, p)$ on the interval $[0, T]$ for some positive real number T . Here, the vector field $f : \mathbb{R}^n \times \mathbb{R}^q \mapsto \mathbb{R}^n$ is parameterized by a vector of problem parameters $p \in \mathbb{R}^q$. Choose the integers N and m and the sequence $\{\kappa_j\}_{j=1}^N$ such that $\sum_{j=1}^N \kappa_j = N$. Let $u = (v_{bp}, T, p) \in \mathbb{R}^{Nn(m+1)+1+q}$, where

$$v_{bp}^\top = \left(\cdots \quad v_{(m+1)(j-1)+1}^\top \quad \cdots \quad v_{(m+1)j}^\top \quad \cdots \right) \quad (1)$$

and j ranges from 1 to N . Then,

$$\tilde{y}(t) = \sum_{i=1}^{m+1} \mathcal{L}_i \left(\frac{2N}{T\kappa_j} \left(t - \frac{T}{N} \sum_{k=1}^{j-1} \kappa_k \right) - 1 \right) v_{(m+1)(j-1)+i} \quad (2)$$

is a candidate approximant for $y(t)$ on the interval $\frac{T}{N} \left(\sum_{k=1}^{j-1} \kappa_k + [0, \kappa_j] \right)$ for every $j = 1, \dots, N$. Here, \mathcal{L}_i is the i -th Lagrange polynomial of degree m defined on the uniform partition of $[-1, 1]$. We obtain a system of $(N-1)n + Nnm$ nonlinear equations by imposition of continuity on \tilde{y} and the collection of collocation conditions

$$0 = \frac{d\tilde{y}}{dt} \left(\frac{T}{N} \left(\sum_{k=1}^{j-1} \kappa_k + \frac{\kappa_j}{2}(1+z_l) \right) \right) - f \left(\tilde{y} \left(\frac{T}{N} \left(\sum_{k=1}^{j-1} \kappa_k + \frac{\kappa_j}{2}(1+z_l) \right) \right), p \right) \quad (3)$$

for $j = 1, \dots, N$ and $l = 1, \dots, m$, where z_l is the l -th root of the Legendre polynomial of degree m on the interval $[-1, 1]$. Provided that a solution u^* to these equations is regular, there exists an $n + q + 1$ -dimensional manifold through u^* so that every local solution lies on this manifold. The imposition of up to $n + q + 1$ additional constraints (satisfied by u^*) then reduce consideration to lower-dimensional submanifolds of the original solution manifold. The conditions

$$v_1 - v_{N(m+1)} = 0 = \tilde{v}^\top \cdot v_{bp} \quad (4)$$

for some suitably constructed \tilde{v} reduce consideration to a local q -dimensional manifold of periodic orbits.

Continuation with a variable mesh

The periodic-orbit problem in the previous section is characterized by the integers N and m , corresponding to the number of mesh intervals and polynomial degree, respectively, the sequence $\{\kappa_j\}_{j=1}^N$ of scaled interval widths, and the reference discretization \tilde{v} , all of which may change during analysis of the collection of solutions obtained for different values of the problem parameters p . Indeed, \tilde{v} is usually updated before each new solution is sought, using a discretization v_{bp} from a previously located, nearby solution. Similarly, N and $\{\kappa_j\}_{j=1}^N$ (and, less often, m) may be updated every so often in order to satisfy a desired error tolerance. Each such choice restricts attention to a particular variable space, with its unique interpretations and numbers of problem variables and problem constraints (but identical manifold dimension). As long as one is not concerned with global comparisons between solutions obtained at different stages of the analysis, sequences of solutions may be generated iteratively through a predictor-corrector framework as implemented in an *atlas algorithm*, wherein

interpolation is used by the predictor to accommodate changes to N or $\{\kappa_j\}_{j=1}^N$. When global comparisons are of concern, as is the case for closed one-dimensional manifolds and all manifolds of dimension ≥ 2 , these may additionally be implemented on the approximant \tilde{y} rather than on the problem discretizations (cf. [2]). Alternatively, as proposed recently in [3], comparisons may be performed in a projected space in terms of invariantly defined solution properties, sufficient in number to ensure a regular embedding of the solution manifold for the underlying infinite-dimensional problem.

A software implementation

The COCO (<https://sourceforge.net/projects/cocotools/>) software development originates in an effort to provide general-purpose, problem-independent support for i) the construction of *composite continuation problems* (i.e., decomposable into glued-together subproblems with an excess of unknowns relative to the total number of constraints) without concern for the sought manifold dimensionality, and ii) the subsequent analysis of the solution manifold for a given choice of dimension. COCO's construction paradigm allows for solution properties to be defined in terms of subsets of problem variables defined at different stages of construction, for example, the difference between the periods of the individual solutions to two coupled periodic-orbit problems. For variable-mesh problems, such solution properties are said to be invariantly defined if they correspond to a discretized evaluation of a property of the solution to the underlying infinite-dimensional problem, e.g., the mean of a variable or the magnitude of a complex-valued Fourier coefficient. In a recent upgrade to COCO, an implementation of the MULTIFARIO (<https://sourceforge.net/projects/multifario/>) package for multi-dimensional continuation [4] in the `atlas-kd` atlas algorithm that previously offered no support for variable-mesh continuation problems now provides such support, independently of the nature of the original problem. This functionality is achieved by performing global comparisons in a projection onto a finite-dimensional Euclidean space in terms of invariantly defined solution properties that may be constructed solely in terms of individual discretizations. As an example, Fig. 1 depicts the two-dimensional frequency-amplitude response surface of a hardening Duffing oscillator obtained with `atlas-kd` by performing all global comparisons in the five-dimensional projection onto the excitation period T , excitation amplitude A , first-harmonic Fourier coefficients (scaled by $T/2$), and first-harmonic Fourier amplitude $|c_1|$ (scaled by $T/2$).

Figure 1: Two-dimensional frequency-amplitude response surface for a hardening Duffing oscillator.

Conclusions

The COCO construction paradigm provides general-purpose support for the definition of small numbers of solution properties that can be used for detecting special points during continuation. Remarkably, the same functionality supports a low-complexity approach for multi-dimensional continuation of variable-mesh boundary-value problems without requiring a user-defined inner product in terms of pairs of discretizations with different interpretations and numbers of problem variables and constraints. The COCO-compatible `atlas-kd` atlas algorithm implements this new paradigm with only minimal modifications to the algorithms inherited from MULTIFARIO.

A new co-simulation approach for mechanical systems with nonlinear components

Evangelos Koutras, Elias Paraskevopoulos and Sotirios Natsiavas

Department of Mechanical Engineering, Aristotle University, 54124 Thessaloniki, Greece

Summary. Co-simulation is used to enable global simulation of a coupled system via the composition of simulators. Within this work, a new co-simulation approach is developed for mechanical systems with nonlinear components. Specifically, a model two-degree-of-freedom oscillator, including Duffing type nonlinearities, was investigated first by applying the method of multiple scales. This provided reliable information on its dynamics under primary external resonance. Moreover, the new co-simulation approach was presented and compared with the classical co-simulation methods from the literature. Here, the main focus is placed on mechanical subsystems. However, the new methods have general validity and can be applied to couple arbitrary solvers.

Introduction

Co-simulation or solver coupling has already been applied extensively to various engineering fields [1, 2]. The basic idea consists in a decomposition of the global model into two or more sub-models. The different subsystems are connected by coupling variables, which are exchanged only at the macro-time points (also called communication points). Between these points, the subsystems integrate independently from each other, using their own solver. Generally, the subsystems can be coupled by physical force/torque laws (applied forces/torques) or by algebraic constraint equations (reaction forces/torques) [3, 4].

Two well-known co-simulation approaches are used: a parallel and a sequential, known as Jacobi and Gauss-Seidel, respectively, as their properties are similar to the respective linear iterative solvers. Furthermore, co-simulation approaches can be subdivided into explicit, implicit and semi-implicit methods. Finally, concerning the decomposition of the overall system into subsystems, three different possibilities can be distinguished. Namely, force/force, force/displacement and displacement/displacement decomposition.

Figure 1: Example mechanical model

Description of the new co-simulation method

Within this work, emphasis is placed on the proper decomposition of the original system into two (or more) subsystems. Specifically, the decomposition takes place only at constraints of the initial model, which are artificially introduced through auxiliary bodies, in case they do not exist. The previously described procedure for the original mechanical model, shown in Figure 1, is depicted in Figure 2. Moreover, following recent work of the authors, the constraint equations and the equations of motion of each sub-model are formulated as a system of exclusively second-order ordinary differential equations (ODEs), bypassing numerical challenges associated with differential-algebraic equations [6, 7]. The distinct difference of the proposed approach, in comparison to the formerly developed co-simulation methods, lies in the dynamic nature of the master/orchestrator, which is now treated as a separate subsystem. Finally, through an appropriate weak formulation, the constraint equations and the OEMs of interface (master) model are expressed in a convenient and consistent first order ODE form, which carries over all the advantages of the corresponding second order ODE form [8].

Figure 2: Equivalent model of initial mechanical model (Figure 1)

Numerical results and discussion

Here, a mechanical system with nonlinear components is examined [9, 10]. Specifically, the dynamic behavior of a two-degree-of-freedom oscillator involving stiffness characteristics modelled by linear and cubic terms is investigated by applying the method of multiple scales (see Figure 1). In the cases examined, the external forcing possesses a component with frequency close to one of the natural frequencies of the linearized model (for typical results, see Figure 3). A detailed analysis of the convergence and the numerical error behavior is carried out in order to examine the different properties of the new co-simulation scheme developed, in comparison to the already existing approaches. A set of characteristic results are presented in Figure 4. Despite the fact that the models examined are simple and purely mechanical, the techniques used can also be extended and applied to arbitrary multibody or structural dynamics systems.

Summary. Dimensionality reduction through parametrisation of the system motion along a low dimensional invariant-based span of the phase space represents the most efficient technique for deriving reduced order models (ROM) of structures vibrating with large amplitudes. In this work we present the first release of an efficient software for deriving reduced models of structures based on the Direct Parametrisation of Invariant Manifolds (DPIM). The package exploits an algorithmic implementation of the method tailored for mechanical systems, hence achieving low memory consumption and unprecedented speed. Examples of large scale systems of industrial interest are shown and comparisons with experimental data and full order numerical simulations are reported.

Introduction

The computation of periodic orbits in large scale finite element models of vibrating structures represents a major challenge from a numerical standpoint. Indeed, full order simulations have computational times and memory requirements that make numerical integration schemes directly applied to finite element models rarely applicable at an industrial level [1]. As a result, dimensionality reduction techniques need to be applied. In this framework, the lack of invariance of modal subspaces hinder the applicability of linear projection methods as the modal decomposition or the proper orthogonal decomposition [2], since the embedding defined by this class of techniques is not invariant. Furthermore, the identification of coupled modes, that need to be accounted for in order to define a proper ROM, is generally impossible. As a result, nonlinear reduction methods are expected to provide higher accuracy and cheaper computational demands [3]. Among this class of techniques, the Direct Parametrisation Method for Invariant Manifolds [4, 5] allows deriving invariant subspaces together with the dynamics along such sets in an efficient manner. In this work, we report a numerical package that exploits a specific implementation of the method tailored for vibratory systems. Examples of structures of industrial relevance analysed with the proposed method are reported, together with validation against full order numerical simulations.

Method

Nonlinear vibrations of continuous structures discretised by the finite element method and featuring geometric nonlinearities are considered. In this framework, the discretised equations of motion stemming from the FE procedure leads to the following system of differential equations:

$$\begin{aligned} \mathbf{M}\dot{\mathbf{V}} + \mathbf{C}\mathbf{V} + \mathbf{K}\mathbf{U} + \mathbf{G}(\mathbf{U}, \mathbf{U}) + \mathbf{H}(\mathbf{U}, \mathbf{U}, \mathbf{U}) &= \mathbf{F}, \\ \dot{\mathbf{U}} &= \mathbf{V}, \end{aligned} \quad (1)$$

with \mathbf{M} mass matrix, \mathbf{C} damping matrix, \mathbf{K} stiffness matrix, \mathbf{U} nodal displacement, \mathbf{V} nodal velocity, $\mathbf{G}(\mathbf{U}, \mathbf{U})$ quadratic nonlinearity tensor, $\mathbf{H}(\mathbf{U}, \mathbf{U}, \mathbf{U})$ cubic nonlinearity tensor, and \mathbf{F} external forcing vector. $(\dot{\cdot})$ denotes the time derivative operator. The number of degrees of freedom of Eq. (1) typically between 10^3 and 10^9 . Dimensionality reduction is performed using the DPIM. To this aim, we introduce a nonlinear change of coordinates aimed at parametrising the system motion along a low dimensional invariant based-span of the phase space. The mappings introduced to parametrise nodal displacement and velocity are defined as [6]:

$$\mathbf{U} = \boldsymbol{\Psi}(\mathbf{z}), \quad \mathbf{V} = \boldsymbol{\Upsilon}(\mathbf{z}), \quad (2)$$

where \mathbf{z} are normal coordinates, i.e. the coordinates that describe the system motion along the embedding. The reduced dynamics is given as:

$$\dot{\mathbf{z}} = \mathbf{f}(\mathbf{z}). \quad (3)$$

Both mappings $\boldsymbol{\Psi}(\mathbf{z})$, $\boldsymbol{\Upsilon}(\mathbf{z})$ and reduced dynamics $\mathbf{f}(\mathbf{z})$ are obtained upon their substitution into Eq. (1), operation that yields the following invariance equations:

$$\begin{aligned} \mathbf{M}\nabla_{\mathbf{z}}\boldsymbol{\Upsilon}(\mathbf{z})\mathbf{f}(\mathbf{z}) + \mathbf{C}\boldsymbol{\Upsilon}(\mathbf{z}) + \mathbf{K}\boldsymbol{\Psi}(\mathbf{z}) + \mathbf{G}(\boldsymbol{\Psi}(\mathbf{z}), \boldsymbol{\Psi}(\mathbf{z})) + \mathbf{H}(\boldsymbol{\Psi}(\mathbf{z}), \boldsymbol{\Psi}(\mathbf{z}), \boldsymbol{\Psi}(\mathbf{z})) &= \mathbf{0}, \\ \mathbf{M}\nabla_{\mathbf{z}}\boldsymbol{\Psi}(\mathbf{z})\mathbf{f}(\mathbf{z}) &= \mathbf{M}\boldsymbol{\Upsilon}(\mathbf{z}). \end{aligned} \quad (4)$$

The resulting reduced model can then be solved to retrieve the frequency response curve of the associated structure.

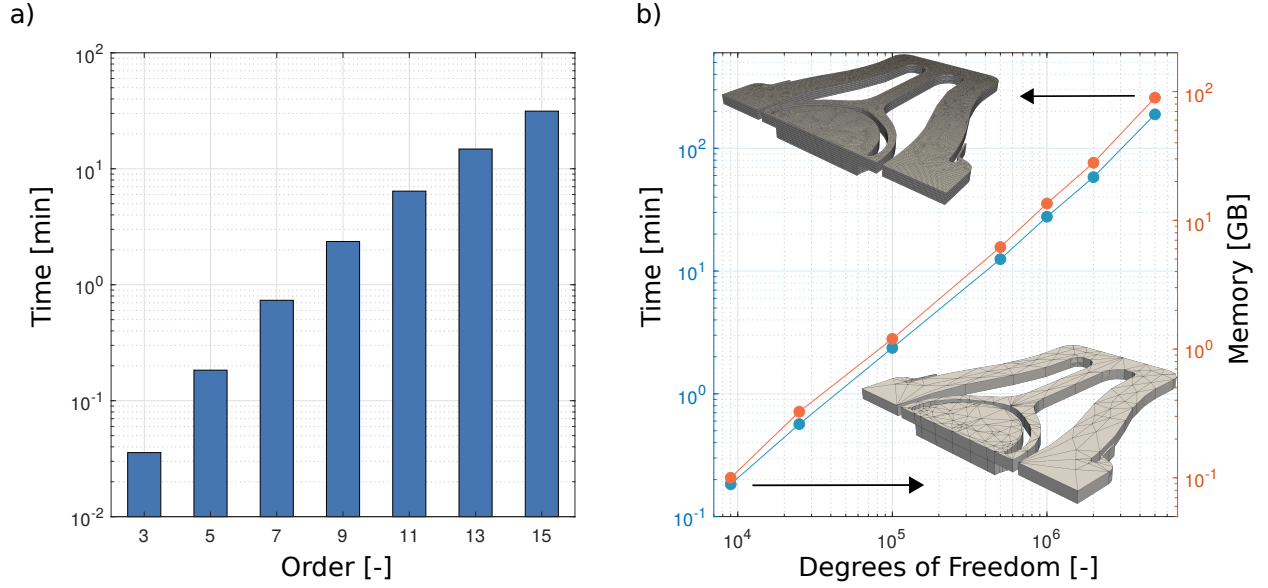

Figure 1: (a) Computing times required to reach a given parametrisation order, for a mesh of 9732 degrees of freedom. (b) Computing times required to perform an order 5 parametrisation for meshes of increasing refinement. All the analyses were performed on a desktop workstation with an AMD®Ryzen 5950X processor and 128GB RAM.

Mappings and reduced dynamics are polynomial functions of the normal coordinates and for each monomial the linear system of the associated homological equation needs to be solved. The DPIM is formulated from the general theory provided by the parametrisation method for invariant manifold, see [7], and has been applied to FE structures in [5] and [4]. In the proposed software, the homological equations are solved at the elementary level for 3D elements, which in turn allows avoiding the computation of the full nonlinearity tensor of the system beforehand, leading to very important savings in memory consumption. Furthermore, we leverage the symmetries of the formulation to avoid computing all monomials associated to the expansion, the latter extensively detailed in [4]. This in turn allows deriving an efficient formulation and yields a technique applicable to large finite element models.

The resulting algorithm has been implemented in a Julia package that provides a mean to identify frequency response curves of structures actuated at resonance with high accuracy and performance. An example of the performance provided by the technique is reported in Fig. 1, where results obtained for a single master mode reduction are highlighted. Fig. 1(a) reports the expected time required to parametrise a system of 9732 degrees of freedom up to an asymptotic development of order 15. Fig. 1(b) details the computational time and memory required to parametrise finite element systems of increasing number of degrees of freedom.

Conclusions

In the present contribution we provide an overview of algorithms and results provided by an open-source model order reduction package. This software aims at providing a tool for fast and accurate analysis of nonlinear structures, hence accelerating the design of structural components. Example applications highlight how the proposed package can play a major role in several fields as the semiconductor industry.

A port-Hamiltonian formulation for the full von-Kármán plate model

Andrea Brugnoli[†], Denis Matignon^{*}

[†]University of Twente, Netherlands

^{*}ISAE-SUPAERO, Université de Toulouse, France

Summary. In this contribution, a port-Hamiltonian reformulation of the full von-Kármán dynamical model for geometrically non-linear plates is detailed, including the collocated boundary control and observation. Starting from the canonical equations, a set of variables is chosen so as to make the total energy quadratic. The model, reformulated in these variables, highlights a port-Hamiltonian structure ruled by a state-modulated interconnection operator.

Classical model

The classical full von-Kármán dynamical model is presented in Bilbao et al. [2015]. The problem, defined on an open connected set $\Omega \subset \mathbb{R}^2$, takes the dimensionless form

$$\begin{aligned} \dot{\mathbf{u}} &= \text{Div } \mathbf{N}, & \mathbf{N} &= \Phi(\boldsymbol{\varepsilon}), & \boldsymbol{\varepsilon} &= \text{Grad } \mathbf{u} + 1/2 \text{grad } w \otimes \text{grad } w, \\ \ddot{w} &= -\text{div Div } \mathbf{M} + \text{div}(\mathbf{N} \text{grad } w), & \mathbf{M} &= \Phi(\boldsymbol{\kappa}), & \boldsymbol{\kappa} &= \text{Grad grad } w, \end{aligned} \quad (1)$$

where $\mathbf{u} \in \mathbb{R}^2$ is the in-plane displacement, w is the vertical displacement, $\boldsymbol{\varepsilon}$ is the in-plane strain tensor, $\boldsymbol{\kappa}$ is the curvature tensor, \mathbf{N} is the in-plane stress resultant and \mathbf{M} is the bending stress resultant. The notation $\mathbf{a} \otimes \mathbf{b} = \mathbf{ab}^\top$ denotes the dyadic product of two vectors. The div operator is the divergence of a vector field, and grad the gradient of a scalar field. The operator $\text{Grad} = \frac{1}{2}(\nabla + \nabla^\top)$ designates the symmetric part of the gradient (i. e. the deformation gradient in continuum mechanics). For a tensor field $\mathbf{U} : \Omega \rightarrow \mathbb{R}^{2 \times 2}$, with components U_{ij} , the divergence $\text{Div}(\mathbf{U})$ is a vector, defined column-wise as

$$\text{Div}(\mathbf{U}) := \sum_{i=1}^2 \partial_{x_i} U_{ij}, \quad \forall j = \{1, 2\}.$$

The linear tensor mapping Φ is positive and preserves symmetry:

$$\Phi(\mathbf{A}) = \nu \text{Tr}(\mathbf{A})\mathbf{1} + (1 - \nu)\mathbf{A}, \quad \mathbf{A} = \mathbf{A}^\top \implies \Phi(\mathbf{A}) = \Phi(\mathbf{A})^\top, \quad \text{where} \quad \mathbf{1} = \text{Diag}(1, 1).$$

The total energy of the model (Hamiltonian functional)

$$H = \frac{1}{2} \int_{\Omega} \left\{ \|\dot{\mathbf{u}}\|^2 + \dot{w}^2 + \mathbf{N} : \boldsymbol{\varepsilon} + \mathbf{M} : \boldsymbol{\kappa} \right\} d\Omega, \quad \text{where} \quad \mathbf{A} : \mathbf{B} = \text{Tr}(\mathbf{A}^\top \mathbf{B}) \quad (2)$$

consists of the kinetic energy and both membrane and bending deformation energies. This model proves conservative, see Bilbao et al. [2015]. Indeed, this implies that a port-Hamiltonian realization of the system exists. We shall demonstrate how to construct a port-Hamiltonian realization, equivalent to (1).

The equivalent port-Hamiltonian system (pHs)

To find a suitable port-Hamiltonian system, we first select a set of new energy variables to make the Hamiltonian functional quadratic. The selection is the same as for both the linear plate problems in Brugnoli et al. [2019a,b]:

$$\boldsymbol{\alpha}_u = \dot{\mathbf{u}}, \quad \alpha_w = \dot{w}, \quad \mathbf{A}_\varepsilon = \boldsymbol{\varepsilon}, \quad \mathbf{A}_\kappa = \boldsymbol{\kappa}. \quad (3)$$

The energy is quadratic in these variables

$$H = \frac{1}{2} \int_{\Omega} \left\{ \|\boldsymbol{\alpha}_u\|^2 + \alpha_w^2 + \Phi(\mathbf{A}_\varepsilon) : \mathbf{A}_\varepsilon + \Phi(\mathbf{A}_\kappa) : \mathbf{A}_\kappa \right\}. \quad (4)$$

By computing the variational derivative of the Hamiltonian, one obtains the so-called co-energy variables:

$$\mathbf{e}_u := \delta_{\boldsymbol{\alpha}_u} H = \dot{\mathbf{u}}, \quad e_w := \delta_{\alpha_w} H = \dot{w}, \quad \mathbf{E}_\varepsilon := \delta_{\mathbf{A}_\varepsilon} H = \Phi(\mathbf{A}_\varepsilon), \quad \mathbf{E}_\kappa := \delta_{\mathbf{A}_\kappa} H = \Phi(\mathbf{A}_\kappa). \quad (5)$$

Before stating the final formulation, consider the operator $\mathcal{C}(w)(\cdot) : L^2(\Omega, \mathbb{R}_{\text{sym}}^{2 \times 2}) \rightarrow L^2(\Omega)$ acting on symmetric tensors

$$\mathcal{C}(w)(\mathbf{T}) = \text{div}(\mathbf{T} \text{grad } w). \quad (6)$$

Proposition 1 *The formal adjoint of the $\mathcal{C}(w)(\cdot)$ is given by*

$$\mathcal{C}(w)^*(\cdot) = -\frac{1}{2} [\text{grad}(\cdot) \otimes \text{grad}(w) + \text{grad}(w) \otimes \text{grad}(\cdot)]. \quad (7)$$

Proof 1 Consider a smooth scalar field $v \in C_0^\infty(\Omega)$ and a smooth symmetric tensor field $\mathbf{U} \in C_0^\infty(\Omega, \mathbb{R}_{\text{sym}}^{2 \times 2})$ with compact support. The formal adjoint of $\mathcal{C}(w)(\cdot)$ satisfies the relation

$$\langle v, \mathcal{C}(w)(\mathbf{U}) \rangle_{L^2(\Omega)} = \langle \mathcal{C}(w)(v)^*, \mathbf{U} \rangle_{L^2(\Omega, \mathbb{R}_{\text{sym}}^{2 \times 2})}. \quad (8)$$

The proof follows from the computation

$$\begin{aligned} \langle v, \mathcal{C}(w)(\mathbf{U}) \rangle_{L^2(\Omega)} &= \langle v, \operatorname{div}(\mathbf{U} \operatorname{grad} w) \rangle_{L^2(\Omega)}, & \text{Integration by parts,} \\ &= \langle -\operatorname{grad} v, \mathbf{U} \operatorname{grad} w \rangle_{L^2(\Omega, \mathbb{R}^2)}, & \text{Dyadic product properties,} \\ &= \langle -\operatorname{grad} v \otimes \operatorname{grad} w, \mathbf{U} \rangle_{L^2(\Omega, \mathbb{R}_{\text{sym}}^{2 \times 2})}, & \text{Symmetry of } \mathbf{U}, \\ &= \langle -1/2(\operatorname{grad} v \otimes \operatorname{grad} w + \operatorname{grad} w \otimes \operatorname{grad} v), \mathbf{U} \rangle_{L^2(\Omega, \mathbb{R}_{\text{sym}}^{2 \times 2})}. \end{aligned} \quad (9)$$

This means

$$\mathcal{C}(w)^*(\cdot) = -\frac{1}{2} [\operatorname{grad}(\cdot) \otimes \operatorname{grad}(w) + \operatorname{grad}(w) \otimes \operatorname{grad}(\cdot)], \quad (10)$$

leading to the final result.

The pH realization is then given by the following system

$$\frac{\partial}{\partial t} \begin{pmatrix} \alpha_u \\ \mathbf{A}_\varepsilon \\ \alpha_w \\ \mathbf{A}_\kappa \end{pmatrix} = \begin{bmatrix} \mathbf{0} & \operatorname{Div} & \mathbf{0} & \mathbf{0} \\ \operatorname{Grad} & \mathbf{0} & -\mathcal{C}(w)^* & \mathbf{0} \\ 0 & \mathcal{C}(w) & 0 & -\operatorname{div} \operatorname{Div} \\ \mathbf{0} & \mathbf{0} & \operatorname{Grad} \operatorname{grad} & \mathbf{0} \end{bmatrix} \begin{pmatrix} \delta_{\alpha_u} H \\ \delta_{\mathbf{A}_\varepsilon} H \\ \delta_{\alpha_w} H \\ \delta_{\mathbf{A}_\kappa} H \end{pmatrix}, \quad (11)$$

The second line of system (11) represents the time derivative of the membrane strain tensor. To close the system, variable w has to be accessible. For this reason, its dynamics has to be included. The augmented system reads

$$\frac{\partial}{\partial t} \begin{pmatrix} \alpha_u \\ \mathbf{A}_\varepsilon \\ w \\ \alpha_w \\ \mathbf{A}_\kappa \end{pmatrix} = \underbrace{\begin{bmatrix} \mathbf{0} & \operatorname{Div} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \operatorname{Grad} & \mathbf{0} & \mathbf{0} & -\mathcal{C}(w)^* & \mathbf{0} \\ 0 & 0 & 0 & 1 & 0 \\ 0 & \mathcal{C}(w) & -1 & 0 & -\operatorname{div} \operatorname{Div} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \operatorname{Grad} \operatorname{grad} & \mathbf{0} \end{bmatrix}}_{\mathcal{J}} \begin{pmatrix} \delta_{\alpha_u} H \\ \delta_{\mathbf{A}_\varepsilon} H \\ \delta_w H \\ \delta_{\alpha_w} H \\ \delta_{\mathbf{A}_\kappa} H \end{pmatrix}. \quad (12)$$

Given the results in Brugnoli et al. [2019a,b] and Proposition 1, the operator \mathcal{J} is formally skew-adjoint. If only the kinetic and deformation energies are considered, it holds $\delta_w H = 0$. In general this terms allows accommodating other potentials, for example the gravitational one. Suitable boundary variables are then obtained considering the power balance

$$\dot{H} = \langle \gamma_0 \mathbf{e}_u, \gamma_\perp \mathbf{E}_\varepsilon \rangle_{\partial\Omega} + \langle \gamma_0 \mathbf{e}_w, \gamma_{\perp\perp,1} \mathbf{E}_\kappa + \gamma_0 (\mathbf{E}_\varepsilon \mathbf{n} \cdot \operatorname{grad} w) \rangle_{\partial\Omega} + \langle \gamma_1 \mathbf{e}_w, \gamma_{\perp\perp} \mathbf{E}_\kappa \rangle_{\partial\Omega}, \quad (13)$$

where $\gamma_0 \mathbf{e}_u = \mathbf{e}_u|_{\partial\Omega}$ is the Dirichlet trace, $\gamma_\perp \mathbf{E}_\varepsilon = \mathbf{E}_\varepsilon \mathbf{n}|_{\partial\Omega}$ is the normal trace (\mathbf{n} is the outward normal vector), $\gamma_{\perp\perp,1} \mathbf{E}_\kappa = -\mathbf{n} \cdot \operatorname{Div} \mathbf{E}_\kappa - \partial_s (\mathbf{n}^\top \mathbf{E}_\kappa \mathbf{s})|_{\partial\Omega}$ is the effective shear force at the boundary (\mathbf{s} is the tangent vector at the boundary), $\gamma_1 \mathbf{e}_w = \partial_n \mathbf{e}_w|_{\partial\Omega}$ is the normal derivative trace and $\gamma_{\perp\perp} \mathbf{E}_\kappa = \mathbf{n}^\top \mathbf{E}_\kappa \mathbf{n}$ is the normal to normal trace. The boundary conditions are consistent with the ones assumed in Puel and Tucsnak [1996] for deriving a global existence result for this model.

Conclusions

We have presented a pHs formulation of the full von-Kármán model. The dynamics of the system exhibits a state modulated interconnection operator, while the energy remains quadratic in the chosen variables. Of particular interest is the discretization of such a model for simulation and control purposes. The Partitioned Finite Element Method (PFEM), an extension of mixed finite elements to pHs, seems to be particularly suitable to achieve a structure-preserving discretization of this model, as in Cardoso-Ribeiro et al. [2020] for the 2D Shallow Water Equation, which exhibits the same kind of polynomial nonlinearity.

Summary. Methods to analyze the macroscopic behaviour of systems which are either given as discrete agent-based model or as laboratory experiments are discussed. For demonstration, we address a challenging real-live experiment as application problem within the social sciences: a simplified evacuation scenario is considered where pedestrians have to pass a corridor manoeuvring around a triangular obstacle either left or right. Their decision is influenced by the shortest route to the exit and the route choice of nearby pedestrians. The route choice is investigated under varying the position of the obstacle and by this the length of each route. The macroscopic measure defined as difference of the pedestrian flux left and right from the obstacle shows bistability and a hysteresis behaviour. The branch of unstable flow situations separating the two stable branches where all pedestrians pass the obstacle either left or right was successfully detected by using a control based continuation. In addition to the analysis of stable and unstable pedestrian flow situations in the pedestrian experiments with humans, a particle model is presented for which the control based continuation algorithm computed the branch of unstable flow situations and reproduced the findings of the pedestrian experiments.

Control-Based Continuation for Laboratory Experiments and Microscopic Simulations

Typically, information from laboratory experiments or microscopic simulations is restricted to ω -limit sets, in the simplest case to stable stationary states. By definition, a system state is moving away from unstable states which can therefore not be directly observed in laboratory experiments or direct simulations. Furthermore, a detailed understanding of the parameter dependent behavior is missing as this would require exhaustive experimental runs or microscopic computations scanning the parameter space. In contrast to this, macroscopic mathematical models successfully formulated for many problems in science and engineering, often allow for a detailed understanding of parameter dependencies of the dynamical behaviour as there are tools available for low-dimensional mathematical models to perform an analytical or numerical bifurcation analysis.

In the present work a method is presented which allows to perform a continuation of stable as well as unstable stationary states in laboratory experiments or microscopic simulations. This approach stabilizes unstable states by adding a non-invasive control which vanishes at the stationary state. The non-invasive control doesn't change the stationary state itself but its neighborhood and by this its stability properties. Often, the dynamic properties of the macroscopic behaviour of a considered laboratory experiment or microscopic simulation system depends on one or several parameters and it is of interest to explore the dynamics depending on such a parameter and to perform a continuation of e.g. stationary states. This approach is called control based continuation [1, 2, 3, 4, 5] and allows to detect also branches of unstable states in addition to the stable branches of the bifurcation diagram.

Suppose the system of interest is represented by

$$\dot{x} = f(x), \quad (1)$$

where the function $f : \mathbb{R} \rightarrow \mathbb{R}$ is not explicitly given but the system can be explored by experimental observations measuring the time series $x(t)$.

A non-invasive feedback control is added to the system (1) so that a stationary state of the system with control is also a stationary state of (1) but unstable states are changed to stable ones. This requires that the laboratory experiment and the microscopic simulation is accessible by a control altering the original set-up slightly. The control algorithm used follows a suggestion of [6] and is a feedback control with state observer:

$$\dot{x} = f(x) + a \cdot (y - x) \quad (2)$$

$$\dot{y} = b \cdot (y - x) \quad (3)$$

Equation (2) consists of the original system (1) by adding a control term $a \cdot (y - x)$ which forces for $a > 0$ and a large enough the system to the control target y . The aim is to choose y as unknown unstable stationary state and to stabilize this state with the control. In [2, 3, 4, 5] the unknown target y is computed by using a Newton-method which requires derivative information of suitable quality. The second equation (3) finds this state automatically and for a suitable parameter b unstable stationary states are changed to stable ones.

Varying now a parameter crucial for the system dynamics by changing its value using predictor-corrector methods and adding ideas like pseudo-arclength continuation it is possible to perform a control-based continuation along branches of the bifurcation diagram consisting of stable as well as unstable states and also passing saddle-node bifurcation points.

Pedestrian Evacuation Scenario: Real Experiment with Humans and Particle Simulations

The above described approach for control based continuation is demonstrated and tested for a simplified evacuation scenario for pedestrian crowds. In this set-up, pedestrians have to pass a corridor maneuvering around a triangular obstacle

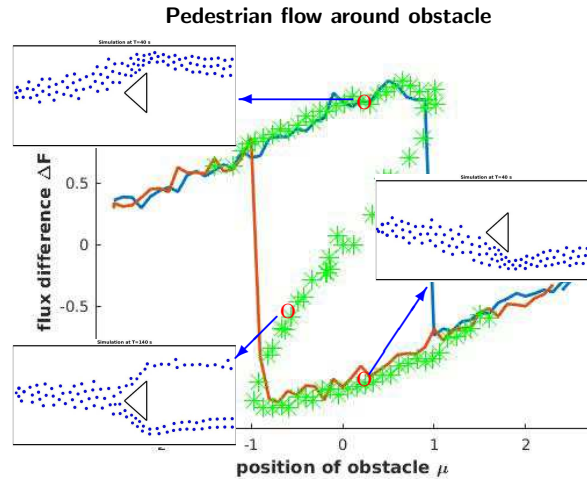

Figure 1: Macroscopic measure of pedestrian flux difference left and right from the obstacle. The insets show the microscopic pedestrian flow situation. The upper and lower branch are stable ones which basins of attraction are separated by an unstable branch. The control-based continuation detected also the unstable branch.

either left or right [7]. The pedestrian's decision is influenced by the shortest route to the exit and the route choice of other pedestrians in a certain neighborhood. The symmetry of the set-up is broken by changing the position of the obstacle and by this the length of each route. The macroscopic measure to be investigated is defined as the difference of the pedestrian flux left and right from the obstacle using the obstacle position as parameter.

As result, the considered pedestrian evacuation scenario shows bistability and a hysteresis behaviour both for the particle model as well as for a real pedestrian experiment with humans. The bifurcation diagram of the particle simulation is shown in Fig. 1. The control-based continuation detects in addition to the two stable branches where all pedestrians pass the obstacle either left or right also an unstable state of the pedestrian flow separating the two stable branches. The insets show the microscopic particle configuration of the observed stable and unstable states of the pedestrian flow.

Conclusion and Outlook

The presented approach is applicable to a wide range of applications in complex systems given by microscopic models or experiments. It extends the gained insight one gets by direct simulations and experiments by adding information about unstable states and by computing the branches of bifurcation diagrams effectively summing up parameter dependent macroscopic system information.

Summary. In the hadron colliders the transverse dynamics of a charge particle in a magnetic lattice is well modeled by a Hamiltonian formalism and the Poincaré map of the system is a polynomial symplectic map with a elliptic fixed point (reference orbit) in two or three degrees of freedom. The presence of fast-slow variables or slow modulations in the dynamics has been considered to estimate the dynamic aperture (i.e. the transverse phase space region that guarantees a long term stability of the orbits) or to perform the beam shaping in the synchrotron motion. Recently, the possibility of slowly modulating the linear frequencies of the reference orbit (linear tunes) in presence of non-linear resonances in the phase space has been proved to provide a very efficient mechanism for beam extraction by means of the adiabatic resonance trapping phenomenon (Multiturn Extraction). The multiturn extraction has been verified in real experiments at PS (CERN). Here, we propose a new approach for adiabatic extraction by considering time dependent symplectic maps, where the adiabatic trapping is induced by a modulated dipole or quadrupole kicker. This approach can be particularly relevant when the modulation of the linear tunes is not workable. We discuss the extension of the adiabatic theory results to the symplectic map models and the possible applications to leptonic collider where the dissipation and fluctuations effects are not negligible. We illustrate the results by numerical simulations.

Multi-turn extraction in hadron storage rings using modulated dipole or quadrupole

The adiabatic trapping phenomenon into a nonlinear resonance and the possibility of adiabatic transport in the phase space have been experimentally proven to provide an very efficient extraction mechanism (Multi Turn Extraction (MTE)) in high energy hadron storage rings [2, 3]. In the experiments, sextupole and octupole magnets are used to excite a non-linear resonance in transverse phase space [4] and the linear frequencies (linear tunes [4]) are slowly modulated crossing the resonance value and performing the adiabatic trapping of particles. The transverse beam dynamics is described by the one-turn symplectic map (Poincaré map) and the main issues are to extend the adiabatic theory results for Hamiltonian systems to the case of slowly modulated symplectic map in the neighborhood of an elliptic fixed point where the dynamics is almost integrable and the perturbation theory applies. The application to the beam extraction problem requires to optimize and control the trapping efficiency and the quality of the extracted beams [5]. To extend the applicability of this techniques to hadron accelerators, where the change of the linear tunes and the multipolar components in a magnetic lattice can be a complex procedure, we consider the possibility of controlling the adiabatic trapping in the phase space using a dipole or quadrupole ‘kicker’ in the magnetic lattice whose frequency is slowly modulated to excite a resonance condition with the linear tunes and whose amplitude can be used to optimize the trapping efficiency. The optimization of the MTE is a key issue since the loss of particles in the phase space decreases the luminosity of the beam and create parasitic losses in the accelerator. One of the goal of MTE is to divide the original beam into a fixed number of beamlets with the almost the same number of particle and a defined emittance [1]. The advantage of introducing a modulated kicker is twofold: from one hand it allows to introduce new control parameters in the dynamics that can be easily varied to optimize the efficiency of MTE; from the other hand, the changes of the kicker parameters are easily implemented in a magnetic lattice. The simplest, though non-trivial, model of betatron motion in a hadron storage ring is the 2-dimensional symplectic map

$$\mathcal{M} \begin{pmatrix} q_n \\ p_n \end{pmatrix} = \begin{pmatrix} q_{n+1} \\ p_{n+1} \end{pmatrix} = R(\omega_0) \begin{pmatrix} q_n \\ p_n + k_3 q_n^2 + k_4 q_n^3 + \varepsilon(n) \cos \omega(n)n \end{pmatrix} \quad (1)$$

where $R(\omega_0)$ is the rotation matrix evaluated at the frequency ω_0 (linear tune), n is the turn number and $\varepsilon(n)$ and $\omega(n)$ are the amplitude and the frequency of a dipole kicker that can be adiabatically varied as a function of n . The kicker frequency crosses a resonance value with the linear tune ω_0 (i.e. $\omega = m\omega_0 + \delta$ with δ varying adiabatically in the interval $\delta \in [-\delta_0, \delta_0]$). Using the perturbation theory it is possible to prove that the adiabatic trapping phenomenon in the phase space of the map (1) is described by an interpolating Hamiltonian provided by the Birkhoff Normal Forms Theory

$$\mathcal{H} = \omega_0 J + \frac{\omega_2}{2} J^2 + \varepsilon A_m J^{3/2} \cos(m\theta - \omega t) \quad (2)$$

and to give an explicit correspondence among the parameters of the modulated map (1) and that of the interpolating Hamiltonian (2). According to the results of adiabatic theory [6], we have explicitly computed the trapping probability in the nonlinear resonance for the Hamiltonian system (2) and we have pointed out the dependence of this probability from the kicker parameters. We have numerically checked the applicability of trapping probability estimates in the case of the map (1) (see next section) and that could be extended to more realistic models of the betatron motion defined by 4-dimensional symplectic maps, under suitable conditions.

Figure 1: Left: example of the beam splitting obtained by modulating adiabatically the parameters of a dipole element. Right: efficiency of the trapping mechanism as a function of the final dipolar perturbation strength (see Eq. 3) evaluated numerically together with the analytical formula.

Numerical simulations and results

We have performed accurate numerical simulations of the map (1) to study the adiabatic trapping into a 3-order resonance and to check the validity of the trapping probability analytic estimate obtained from the Hamiltonian (2). In Fig. 1 (left) we show an example of the beam splitting obtained modulating adiabatically the parameters of a dipole element according to the following equations

$$\varepsilon(n) = \begin{cases} \varepsilon_f n/N & n < N \\ \varepsilon_f & N \leq n \leq 2N \end{cases} \quad \omega(n) = \begin{cases} \omega_i & n < N \\ \omega_i + (\omega_f - \omega_i)(n - N)/N & N \leq n \leq 2N \end{cases} \quad (3)$$

whereas in Fig. 1 (right) we plot the efficiency of the trapping mechanism (i.e. the fraction of particles trapped in the resonance region with respect to the total number of particles in the initial beam given the initial particle distribution) comparing the numerical results with the analytical formulas.

Using the results of the Birkhoff Normal Forms theory for symplectic maps near an elliptic fixed point, we propose a theoretical approach that justifies the use of the interpolating Hamiltonian for a modulated map and point out the applicability conditions of the adiabatic theory results to symplectic maps in a neighborhood of an elliptic fixed point.

Conclusions

The adiabatic trapping into resonance for Hamiltonian systems is a robust phenomenon that can be extended to modulated symplectic maps in the neighborhood of an elliptic point when a resonance condition is satisfied in the phase space. Even if a rigorous proof is not yet available, our results show that it is possible to get estimates of the trapping probability for a particle distribution and to apply the adiabatic theory to realistic model of particle dynamics in hadron colliders. This step is not only relevant in itself, but it is also an essential one in view of applications. Indeed, recently, it has been possible to make adiabatic theory the basis of a successful and novel operational beam manipulation that splits the beam transversely into several beamlets to enable loss-free multi-turn extraction. The new results presented here allow extending the capabilities of performing beam splitting beyond what is known today, thus opening new scenarios for accelerator physics. The ultimate goal of this research is to open the possibility of performing these novel beam manipulations in lepton circular rings.

A surface of connecting orbits between two saddle slow manifolds in a return mechanism of mixed-mode oscillations

Bernd Krauskopf*, Elle Musoke* and Hinke M. Osinga*

*Department of Mathematics, University of Auckland, Auckland, New Zealand

Summary. We employ a Lin's method set-up to compute a surface of heteroclinic connections between two saddle slow manifolds in the four-dimensional Olsen model for peroxidase-oxidase reaction. As will be shown, this surface organises the return mechanism of mixed-mode oscillations that involve a slow passage through a Hopf bifurcation.

We consider a model for peroxidase-oxidase reaction first introduced by Olsen [6], which we study here in the scaled form presented in [4]; it is given as the system of ordinary differential equations

$$\begin{cases} \dot{A} &= \mu - \alpha A - ABY, \\ \dot{B} &= \varepsilon(1 - BX - ABY), \\ \dot{X} &= \lambda(BX - X^2 + 3ABY - \zeta X + \delta), \\ \dot{Y} &= \kappa\lambda(X^2 - Y - ABY), \end{cases} \quad (1)$$

for the vector of chemical concentrations $(A, B, X, Y) \in \mathbb{R}^4$. The system parameters are fixed here, as in [4], to $\alpha = 0.0912$, $\delta = 1.2121 \times 10^{-4}$, $\varepsilon = 0.0037$, $\lambda = 18.5281$, $\kappa = 3.7963$, $\mu = 0.9697$, and $\zeta = 0.9847$. For this choice, the three concentrations A , X , and Y can be considered as fast and B as slow. System (1) has been of interest because it exhibits mixed-mode oscillations (MMOs), which are characterised by a mixture of small-amplitude oscillations (SAOs) that usually arise locally in phase space and large-amplitude oscillations (LAOs) that are generally associated with a global return to the region of SAOs. To date, mechanisms for MMOs are quite well understood in slow-fast systems of dimension three; see, for example, the survey paper [5] as an entry point to the literature on MMOs. For four-dimensional slow-fast systems, on the other hand, new mechanisms and types of MMOs may arise. The case study of the Olsen model (1) presented here shows that the return mechanism of the MMOs involves heteroclinic connecting orbits between two saddle slow manifolds. It follows on from earlier work in [1], where the same parameter regime was considered but a model reduction to a three-dimensional system (via a quasi-steady-state assumption) was performed. In contrast, we now consider and compute all relevant objects in the full (A, B, X, Y) -space of system (1).

In the spirit of geometric singular perturbation theory [3], we start with the limit of $\varepsilon = 0$ and consider the three-dimensional fast subsystem for the fast variables A , X , and Y , where the slow variable B is now a parameter. The equilibria of the fast subsystem, which are parametrised by B , form the critical manifold C in the (A, B, X, Y) -space of system (1). A linear stability analysis shows that C consists (in the physically relevant region of positive A , B , X , and Y) of four branches of hyperbolic equilibria of the fast subsystem: a branch denoted C_+^4 of stable equilibria; a branch C^3 of saddle equilibria with one unstable eigenvalue; a branch C^2 of saddle equilibria with two unstable eigenvalues; and a second branch C_-^4 of stable equilibria. These branches connect at points F_1 and F_2 of fold bifurcation and H of Hopf bifurcation, and the superscripts indicate the dimensions of their stable manifolds in (A, B, X, Y) -space.

Our specific interest is in the two branches C^3 and C^2 because they are saddle objects with different dimensions of stable and unstable manifolds. While C^3 and C^2 only exist for $\varepsilon = 0$, according to Fenichel theory [3], they persist as locally invariant slow manifolds S^3 and S^2 for sufficiently small $\varepsilon > 0$; note that orbit segments on a slow manifold remain slow for $O(1)$ time. Moreover, the one-dimensional manifolds S^3 and S^2 lie $O(\varepsilon)$ close to C^3 and C^2 , and they have stable and unstable manifolds of the same dimensions as those of C^3 and C^2 . Hence, S^3 has a three-dimensional stable manifold $W^s(S^3)$, consisting of orbit segments that, in forward time, approach S^3 along a fast direction and then remain slow while following S^3 ; similarly, S^2 has a three-dimensional unstable manifold $W^u(S^2)$ consisting of orbit segments that, in backward time, approach S^2 along a fast direction and then remain slow while following S^2 .

The two three-dimensional objects $W^s(S^3)$ and $W^u(S^2)$ are expected to intersect generically in a two-dimensional surface \mathcal{H} of connecting orbits between S^3 and S^2 ; in forward time, any such connecting orbit first slowly follows the curve S^2 , makes a transition across to the curve S^3 , and then follows it slowly. In order to find \mathcal{H} , we use two ingredients: firstly, we adapt the technique in [2] for the computation of one-dimensional slow manifolds and their (un)stable manifolds to the four-dimensional setting of system (1) and, secondly, we employ a Lin's method approach [7] to define two orbit segments, in $W^s(S^3)$ and $W^u(S^2)$, respectively, that have end points in a chosen three-dimensional section. Closing the gap between them along a specified direction, by continuation of solutions to an overall boundary value problem, allows us to find a first heteroclinic orbit, which is then swept out in a further continuation run to obtain the surface \mathcal{H} .

Figure 1 shows the two-dimensional surface \mathcal{H} in projection onto the three-dimensional (B, A, X) -space of system (1), together with the critical branches C_+^4 , C^2 , C_-^4 and C^3 . Notice that \mathcal{H} spirals out from the saddle branch C^2 and then approaches the saddle branch C^3 in a non-spiralling fashion; here, S^2 and S^3 (not shown) are indistinguishably close to

Figure 1: Three-dimensional projection onto (B, A, X) -space of the MMO periodic orbit Γ and the surface $\mathcal{H} = W^s(S^3) \cap W^u(S^2)$ (red-blue faded) of system (1) for $\varepsilon = 0.0037$, shown in relation to the following objects for $\varepsilon = 0$: the curves C_+^4 (black), C^2 (dashed raspberry), C_-^4 (black) and C^3 (dashed teal) of the critical manifold; the fold point F_1 (orange dot) and the Hopf bifurcation point H (pink dot); the singular jump branch \mathcal{J} from F_1 to C_-^4 and its counterpart \mathcal{J}^* (magenta curves) from the counterpart on C^2 , at equal distance from H , to C^3 ; and the surface \mathcal{P} (transparent midnight grape) of periodic orbits arising from H .

C^2 and C^3 on the scale of Fig. 1. The surface \mathcal{H} consists of orbit segments of an intermediate timescale in both $W^s(S^3)$ and $W^u(S^2)$, namely those that “make it all the way across” in forward time from near C^2 (where \mathcal{H} is shaded red) to near C^3 (where \mathcal{H} is shaded blue). As we checked, orbit segments close to but not on \mathcal{H} quickly diverge from this surface in both forward and backward time in the X - and Y -directions.

Figure 1 is for $\varepsilon = 0.0037$ when one finds a stable MMO periodic orbit Γ , which is also shown. Starting near the attracting branch C_-^4 , observe the SAOs of decreasing and then increasing amplitude that are generated by a slow passage through the Hopf bifurcation point H . Well past H and the surface \mathcal{P} of periodic orbits of the fast subsystem, Γ leaves the branch C^2 by following the surface \mathcal{H} very closely to a vicinity of the critical branch C^3 . Somewhat past the fold point F_1 , it subsequently has a sudden excursion in the X - and Y -directions to return back to C_-^4 ; the process then repeats.

We conclude that the surface \mathcal{H} of connecting orbits is a crucial part of the return mechanism that is responsible for a single LAO per period of Γ . We further observe that Γ returns to C_-^4 very near where the critical jump orbit \mathcal{J} from F_1 for $\varepsilon = 0$ returns (this point is given by the B -value of F_1). Similarly, the take-off point on C^2 is close to that of the counterpart \mathcal{J}^* of \mathcal{J} , which lies on the other side of \mathcal{H} at the same B -distance. The suggestion from Fig. 1 is, hence, that the concatenation of \mathcal{J} and \mathcal{J}^* with the respective parts of C_-^4 , C^2 and C^3 acts as a singular limit of Γ as ε approaches 0. Indeed, how the MMOs of the Olsen model (1) depend on parameters is a subject of our ongoing research.

Analysis of a Singularly Perturbed Continuous Piecewise Linear System

A. Yassine Karoui* and Remco I. Leine*

*Institute for Nonlinear Mechanics, University of Stuttgart, Germany

Summary. The dynamics of piecewise linear systems can often be reduced to lower dimensional invariant cones using an appropriate Poincaré map. These invariant cones can be understood as a generalization of the center manifold concept to nonsmooth systems. In this paper, we show that the singular perturbation technique applied to a slow-fast continuous piecewise linear system can deliver a good approximation of the invariant cone. The proposed approximation approach is demonstrated on an oscillator with a unilateral spring as an example of a continuous piecewise linear system in \mathbb{R}^3 .

Introduction

Recently, there has been a greater focus placed upon piecewise linear systems, due to their ability to model many complex physical phenomena. Typical applications range from mechanical systems involving dry friction [10], to neuron models [5], electronic circuits [2] and control systems [11]. Furthermore, continuous piecewise linear systems (hereafter, CPWL) are widely used to reproduce and understand various bifurcation phenomena of smooth nonlinear dynamical systems. The dynamics of CPWL systems can exhibit very interesting effects, which are impossible to observe in smooth systems [4]. A prominent example of this rich dynamic behavior was reported in [4], where the continuous matching of two stable subsystems can result in an unstable dynamics. The authors show that this behavior is possible, only if the CPWL system has an invariant cone, which is characterized by a fixed point of a corresponding Poincaré map and serves as a reduced system to investigate the stability and bifurcations of the full system. Therefore, the existence and computation of invariant cones for systems lacking smoothness are of interest. Unfortunately, the generation of invariant cones requires the numerical solution of a system of nonlinear equations and is therefore not suitable as a constructive reduction method towards a lower-dimensional dynamical model. However, the invariant cones can be understood as a generalization of center manifold theory to piecewise linear systems with an equilibrium on the switching manifold. Moreover, the long-term behavior of the full system can be described by a lower-dimensional model obtained from reducing the system to its dynamics on the invariant cone, if the latter is attractive. This perspective shows a clear similarity between invariant cones of piecewise linear systems and smooth invariant manifolds, which are used to obtain reduced order models for general differentiable systems.

For smooth nonlinear systems, projections to linear subspaces are usually used for model reduction, even though these are not invariant with respect to the original nonlinear dynamics. A reduced dynamics on an attractive invariant set, however, constitutes a mathematically more justifiable model reduction, since the trajectories of the reduced system on the invariant set are actual solutions of the full system. Relying on smoothness properties of the system, the existence and uniqueness of smooth invariant manifolds, seen as an extension of the underlying linear subspaces, have been addressed in the framework of spectral submanifolds (SSMs) [6]. The idea of model reduction in the framework of SSMs is based on a specific choice of slow variables, which determine the steady-state behavior of the system and are used as master coordinates to enslave the remaining state variables, therefore giving birth to a reduced model containing the long term characteristics of the full system. This fundamental idea emanated originally from a slow-fast decomposition using singular perturbation theory for smooth nonlinear systems. Therefore, the investigation of slow-fast CPWL systems using perturbative approximations could pave the way for the development of novel reduction methods for systems with nonsmooth nonlinearities.

The aim of this paper is to derive an approximation in closed form of the eigenvector defining the invariant half-lines of the cone for a specific homogeneous CPWL mechanical system using the theory of singular perturbations. This allows to obtain a reduced order model, for which the switching plane is modified such that the reduced dynamics is also of CPWL nature.

This paper is organized as follows. A brief overview on invariant cones along with an important result from [4] on their existence and stability are presented in next section. Then, the theory of singular perturbations is described with a focus on piecewise linear systems. In the last section, a slow-fast oscillator in \mathbb{R}^3 with a unilateral spring is analyzed. An explicit expression for its invariant half-lines is derived using singular perturbation theory, and a reduced model with a modified switching condition is obtained.

Invariant cones of continuous piecewise linear systems in \mathbb{R}^3

Without loss of generality, we consider a CPWL system with a single switching plane $\Sigma = \{\mathbf{x} \in \mathbb{R}^3 : y = 0\}$ written as:

$$\dot{\mathbf{x}} = \mathbf{F}(\mathbf{x}) = \begin{cases} \mathbf{A}^+ \mathbf{x} & \text{for } y \geq 0 \\ \mathbf{A}^- \mathbf{x} & \text{for } y < 0 \end{cases}, \quad (1)$$

where $\mathbf{x} = (x_1 \ x_2 \ y)^T \in \mathbb{R}^3$ and \mathbf{A}^\pm are 3×3 real constant matrices satisfying the continuity condition $\mathbf{A}^+ - \mathbf{A}^- = (\mathbf{A}^+ - \mathbf{A}^-) \mathbf{e}_3 \mathbf{e}_3^T$, with \mathbf{e}_3 being the third vector of the standard basis of \mathbb{R}^3 . Therefore, both matrices are only different in the third column.

For the sake of brevity, we will use the compact form

$$\Upsilon(\eta) = \Upsilon^\pm = \begin{cases} \Upsilon^+ & \text{if } \eta \geq 0 \\ \Upsilon^- & \text{if } \eta < 0 \end{cases}, \quad (2)$$

where Υ^\pm are either matrices or scalars. Hence, system (1) can be written as $\dot{\mathbf{x}} = \mathbf{A}(y)\mathbf{x} = \mathbf{A}^\pm \mathbf{x}$. The origin is always an equilibrium point of system (1), and it is the unique equilibrium if \mathbf{A}^\pm are both nonsingular. Suppose that an initial condition \mathbf{x}_0 lies in one of the domains $\mathcal{U}^\pm = \{\mathbf{x} \in \mathbb{R}^3 : y \gtrless 0\}$, and that the corresponding trajectory remains in the same domain for any given time $t \in (0, \infty)$ and therefore does never reach the switching plane Σ . In this case, the system behaves purely in a smooth fashion and the conventional theory for differentiable systems can be applied. The interesting behavior occurs, however, if the trajectory crosses Σ at a finite time, which can lead to various dynamical behaviors in general piecewise linear systems, such as direct crossing, sliding, grazing or jumping. In this work, we consider the class of CPWL systems, for which the dynamics can only include direct crossing behavior and the uniqueness of solutions for every initial condition is ensured. To understand the composed motion of both subsystems, we consider the following subsets of Σ :

$$\Sigma_{>} := \{\mathbf{x} \in \Sigma : \mathbf{e}_3^T \mathbf{A}^+ \mathbf{x} = \mathbf{e}_3^T \mathbf{A}^- \mathbf{x} > 0\}, \quad \Sigma_{<} := \{\mathbf{x} \in \Sigma : \mathbf{e}_3^T \mathbf{A}^+ \mathbf{x} = \mathbf{e}_3^T \mathbf{A}^- \mathbf{x} < 0\}$$

For $\mathbf{x}^* \in \Sigma_{<}$ or $\mathbf{x}^* \in \Sigma_{>}$, the flow transitions from one domain into the other through \mathbf{x}^* . In the following, we will assume that initial values \mathbf{x}_0 are chosen from the set $\mathbf{x}_0 \in \Sigma_{<}$. A trajectory is then given by $\varphi(\mathbf{x}_0, t) = e^{\mathbf{A}^- t} \mathbf{x}_0$ and enters \mathcal{U}^- by means of the flow of the system $\dot{\mathbf{x}} = \mathbf{A}^- \mathbf{x}$. It reaches the switching plane again for the first time at $\mathbf{x}_1 \in \Sigma_{>}$. Hence, there is a positive finite time $t^-(\mathbf{x}_0) = \min\{t > 0 : \mathbf{e}_3^T e^{\mathbf{A}^- t} \mathbf{x}_0 = 0, \mathbf{e}_3^T e^{\mathbf{A}^- t} \mathbf{A}^- \mathbf{x}_0 > 0\}$. Similarly $t^+(\mathbf{x}_1)$ can be defined for $\mathbf{x}_1 \in \Sigma_{>}$. Since the flow is piecewise linear, one can see that t^- and t^+ are constant on half-lines, i.e. $t^\pm(\lambda \mathbf{x}) = t^\pm(\mathbf{x})$ with $\lambda \in (0, \infty)$. For initial conditions $\mathbf{x}_0 \in \Sigma$, the following half-maps are defined:

$$\begin{aligned} P^- : \Sigma_{<} &\rightarrow \Sigma & P^+ : \Sigma_{>} &\rightarrow \Sigma \\ \mathbf{x}_0 &\mapsto e^{\mathbf{A}^- t^-(\mathbf{x}_0)} \mathbf{x}_0 =: P^-(\mathbf{x}_0) & \mathbf{x}_1 &\mapsto e^{\mathbf{A}^+ t^+(\mathbf{x}_1)} \mathbf{x}_1 =: P^+(\mathbf{x}_1) \end{aligned}$$

Hence, the Poincaré map reads:

$$P(\mathbf{x}_0) := P^+(P^-(\mathbf{x}_0)) = e^{\mathbf{A}^+ t^+(P^-(\mathbf{x}_0))} e^{\mathbf{A}^- t^-(\mathbf{x}_0)} \mathbf{x}_0 \quad (3)$$

Since system (1) is positively homogeneous and the vector field satisfies $\mathbf{F}(\mu \mathbf{x}) = \mu \mathbf{x}$, $\forall \mathbf{x} \in \mathbb{R}^3$, $\mu > 0$, the Poincaré map P transforms half-lines contained in Σ and passing through the origin into half-lines contained in the same plane, also passing through the origin. A more general construction is given by the following theorem stated in [7]:

Theorem 1 *Let $\bar{\mathbf{x}} \in \Sigma$ be an eigenvector of the nonlinear eigenvalue problem $P(\bar{\mathbf{x}}) = \mu \bar{\mathbf{x}}$, with some real positive eigenvalue μ . Then there is an invariant cone for system (1). Moreover,*

- If $\mu > 1$, then the origin is an unstable equilibrium.
- If $\mu = 1$, then the cone consists of periodic orbits.
- If $\mu < 1$, then the stability of the origin is dependent of the stability of P w.r.t. the complimentary directions.

Therefore, system (1) has an invariant cone if there exists a half-line contained in Σ that is invariant for the Poincaré map P . The nonlinear eigenvalue problem $P(\bar{\mathbf{x}}) = \mu \bar{\mathbf{x}}$ determines the invariant cone and involves the six independent variables $\bar{\mathbf{x}} \in \mathbb{R}^3$, μ , $t^-(\bar{\mathbf{x}})$ and $t^+(P(\bar{\mathbf{x}}))$, which can be obtained numerically as solution of the nonlinear equation system given by:

$$0 = \mathbf{G}(\mathbf{x}, t^-, t^+, \mu) = \begin{pmatrix} e^{\mathbf{A}^+ t^+} e^{\mathbf{A}^- t^-} \mathbf{x} - \mu \mathbf{x} \\ \mathbf{e}_3^T e^{\mathbf{A}^- t^-} \mathbf{x} \\ \mathbf{e}_3^T \mathbf{x} \\ \mathbf{x}^T \mathbf{x} - 1 \end{pmatrix} \quad (4)$$

This system of equations includes the definition of the Poincaré map, the first return to Σ at the time t^- , the location of the initial condition on Σ and a normalization. The zeros of \mathbf{G} can be solved numerically to obtain the 6 independent unknowns characterizing the invariant cone. Although the problem of existence and number of invariant cones in general piecewise linear systems is still open, it has been proved that there exists at most one invariant cone for some degenerate CPWL cases in [3] and [4] and at most two invariant cones for observable three dimensional CPWL cases in [1]. For the sake of completeness, we recall here an important result from [4] (Theorem 2 - Statement (a)) on the number and stability of invariant cones for a specific case, which is considered in the mechanical system studied in this work.

Theorem 2 Suppose that system (1) satisfies the observability condition, i.e. the observability matrix

$$\mathbf{O} = \begin{pmatrix} \mathbf{e}_3^T \\ \mathbf{e}_3^T \mathbf{A}^- \\ \mathbf{e}_3^T (\mathbf{A}^-)^2 \end{pmatrix}$$

has full rank. Further, assume that the eigenvalues of matrices \mathbf{A}^\pm are $\lambda_1^\pm = \lambda^\pm$ and $\lambda_{2,3}^\pm = \alpha^\pm \pm i\beta^\pm$, with $\beta^\pm > 0$ and introduce the parameters

$$\gamma^+ = \frac{\alpha^+ - \lambda^+}{\beta^+}, \quad \text{and} \quad \gamma^- = \frac{\alpha^- - \lambda^-}{\beta^-}.$$

Then the following statement holds: If $\gamma^+ \gamma^- > 0$, then system (1) has only one invariant cone, which is two-zonal (i.e. lives in the two linear zones) and hyperbolic, asymptotically stable for $\gamma^+ + \gamma^- > 0$ and unstable for $\gamma^+ + \gamma^- < 0$.

Note that due to the continuity condition, the observability matrix is independent of the chosen matrix, \mathbf{A}^+ or \mathbf{A}^- . In the next section, a brief introduction to singular perturbation theory with an emphasis on CPWL system is given.

Singular perturbation theory for CPWL systems

For an n -dimensional smooth system having s slow variables and a small perturbation parameter ε , which is responsible for a time-scale separation, classical geometric perturbation theory can be used to obtain a reduced-order model. The limiting case $\varepsilon \rightarrow 0$ gives an f -dimensional critical manifold \mathcal{M}_c , where $f = n - s$. According to Fenichel's theorem, if \mathcal{M}_c is normally hyperbolic, then there exists an f -dimensional slow invariant manifold \mathcal{M}_s , on which the dynamics is a perturbation of order $\mathcal{O}(\varepsilon)$ of the dynamics on \mathcal{M}_c . This theorem can be applied to slow-fast CPWL systems only on the subsets of the state space that do not include the switching manifold. This yields two linear locally invariant slow half-manifolds \mathcal{M}_s^\pm , each aligned with the slow eigenspaces of \mathbf{A}^+ or \mathbf{A}^- . Furthermore, a forward invariant neighborhood enveloping the linear critical manifold, which is continuous at the switching manifold, has been shown to exist under suitable conditions [9]. For this, the critical manifold \mathcal{M}_c , which is not normally hyperbolic on Σ , has to be attracting. Consider a slow-fast ODE system of the form:

$$\begin{aligned} \dot{\mathbf{x}} &= \begin{cases} \mathbf{f}^+(\mathbf{x}, \mathbf{y}; \varepsilon) & \text{for } h(\mathbf{x}, \mathbf{y}) \geq 0 \\ \mathbf{f}^-(\mathbf{x}, \mathbf{y}; \varepsilon) & \text{for } h(\mathbf{x}, \mathbf{y}) < 0 \end{cases} \\ \varepsilon \dot{\mathbf{y}} &= \begin{cases} \mathbf{g}^+(\mathbf{x}, \mathbf{y}; \varepsilon) & \text{for } h(\mathbf{x}, \mathbf{y}) \geq 0 \\ \mathbf{g}^-(\mathbf{x}, \mathbf{y}; \varepsilon) & \text{for } h(\mathbf{x}, \mathbf{y}) < 0, \end{cases} \end{aligned} \quad (5)$$

where $\mathbf{x} = (x_1 \ \cdots \ x_s)^T \in \mathbb{R}^s$ are the slow variables, $\mathbf{y} = (y_1 \ \cdots \ y_f)^T \in \mathbb{R}^f$ are the fast variables, $0 \leq \varepsilon \ll 1$ is the small parameter and $\frac{d(\cdot)}{dt} := \frac{d(\cdot)}{dt}$ denotes the derivative with respect to the "slow" time scale t . The switching manifold is therefore given by the scalar function $h(\mathbf{x}, \mathbf{y}) = 0$. We assume that the functions \mathbf{f}^\pm , \mathbf{g}^\pm and h are linear with respect to \mathbf{x} and \mathbf{y} and that the system is continuous at the switching manifold. Furthermore, suppose that $h(\mathbf{0}, \mathbf{0}) = 0$. At the origin, we also assume that the switching manifold is not tangent to all fast directions, which means that ∇h has at least one non-zero component. Without loss of generality, one can assume $\frac{\partial h}{\partial y_1} \neq 0$. This assumption leads to a more general configuration, where both the slow and fast dynamics contain a switch. Otherwise, a degenerate system is obtained, where only the slow dynamics has a switch and the fast dynamics is $\mathbf{g}^\pm = \mathbf{g}$. In order to simplify the switching condition, an invertible transformation $(\mathbf{x}, \mathbf{y}) \rightarrow (\tilde{\mathbf{x}}, \tilde{\mathbf{y}})$ is introduced, with a new set of coordinates $\tilde{\mathbf{x}} = \mathbf{x}$ and $\tilde{\mathbf{y}} = (h(\mathbf{x}, \mathbf{y}) \ y_2 \ y_3 \ \cdots \ y_f)^T$. Since \tilde{y}_1 is a new fast variable, the slow-fast system has the same form as (5) except that the switching manifold is determined by $\tilde{y}_1 = 0$. Taking the new coordinates and setting the small parameter $\varepsilon = 0$ in (5) yields the critical system

$$\dot{\mathbf{x}} = \mathbf{f}^\pm(\mathbf{x}, \mathbf{y}; 0) \quad (6)$$

$$0 = \mathbf{g}^\pm(\mathbf{x}, \mathbf{y}; 0) \quad (7)$$

where the (\cdot) is dropped for simplicity, and the \pm switch is governed by equation (2) with $y_1 = \eta$.

The critical manifold is obtained as $\mathcal{M}_c = \{(\mathbf{x}, \mathbf{y}) \in \mathbb{R}^{s+f} : \mathbf{y} = \mathbf{h}_c^\pm(\mathbf{x})\}$, where $\mathbf{y} = \mathbf{h}_c^\pm(\mathbf{x})$ are the solutions of the two algebraic constraints (7) and describe the behavior of the fast variables as a function of the slow variables. Note that \mathbf{h}_c^\pm are both linear functions of \mathbf{x} and that the matching from both linear subsystems is continuous. The dynamics on \mathcal{M}_c is governed by

$$\dot{\mathbf{x}} = \mathbf{f}^\pm(\mathbf{x}, \mathbf{h}_c^\pm(\mathbf{x}); 0). \quad (8)$$

The Jacobians $\frac{\partial \mathbf{g}^\pm}{\partial \mathbf{y}}(\mathbf{x}) \Big|_{\mathbf{y}=\mathbf{h}_c^\pm, \varepsilon=0}$ along both critical manifolds are assumed to fulfill the stability condition, so that a relevant reduction to the slow dynamics can be obtained. For CPWL systems, the existence of a forward invariant neighborhood around the critical manifold has been shown in [9], if \mathcal{M}_c is globally exponentially stable. Therefore, and for the

sake of brevity, we assume global exponential stability of the critical manifold, which is naturally given for the specific example considered in this work. We refer to [9] for more details on the stability properties of \mathcal{M}_c and the proof of the existence of a forward invariant neighborhood. For systems of the form (1), the singular perturbation technique is performed on each linear subsystem to obtain the linear locally invariant slow half-manifolds. This is described in the following, where the \pm switching is dropped for simplicity and only the linear region defined by $y_1 \geq 0$ is considered. Obviously, the approach is analogous for the other linear region. The matching of both linear invariant half-manifolds and the corresponding switching condition are discussed explicitly for the example in the next section.

The s -dimensional, locally invariant slow manifold is defined as $\mathcal{M}_s^+ = \{(\mathbf{x}, \mathbf{y}) \in \mathbb{R}^{s+f} : \mathbf{y} = \mathbf{h}_s^+(\mathbf{x})\}$. Since the state space is decomposed into two linear parts, the invariance property of \mathcal{M}_s^+ must be understood in a local way. Inserting $\mathbf{y} = \mathbf{h}_s^+$ and $\dot{\mathbf{y}} = \frac{\partial \mathbf{h}_s^+}{\partial \mathbf{x}} \dot{\mathbf{x}}$ into the fast dynamics $\varepsilon \dot{\mathbf{y}} = \mathbf{g}^+(\mathbf{x}, \mathbf{y}, \varepsilon)$ yields:

$$\varepsilon \frac{\partial \mathbf{h}_s^+}{\partial \mathbf{x}} \mathbf{f}^+(\mathbf{x}, \mathbf{h}_s^+; \varepsilon) = \mathbf{g}^+(\mathbf{x}, \mathbf{h}_s^+; \varepsilon). \quad (9)$$

In each linear region, the asymptotic expansion given by

$$\mathbf{h}_s^+(\mathbf{x}) = \mathbf{h}_0^+(\mathbf{x}) + \varepsilon \mathbf{h}_1^+(\mathbf{x}) + \mathcal{O}(\varepsilon^2) \quad (10)$$

is used in the invariance equation (9). By equating the coefficients of powers of ε one can see that $\mathbf{h}_c^+(\mathbf{x}) = \mathbf{h}_0^+(\mathbf{x})$, which means that the critical manifold is the zero-order approximation of the slow manifold. Moreover, the first order term $\mathbf{h}_1^+(\mathbf{x})$ is obtained as:

$$\mathbf{h}_1^+ = \frac{\partial \mathbf{g}^+}{\partial \mathbf{y}} \Big|_{\mathbf{y}=\mathbf{h}_0^+; \varepsilon=0}^{-1} \left[\frac{\partial \mathbf{h}_0^+}{\partial \mathbf{x}} \mathbf{f}^+(\mathbf{x}, \mathbf{h}_0^+; 0) - \frac{\partial \mathbf{g}^+}{\partial \varepsilon} \Big|_{\mathbf{x}, \mathbf{h}_0^+; 0} \right]. \quad (11)$$

Three-dimensional oscillator with a unilateral spring

The approximation of the invariant cone by means of singular perturbation theory is demonstrated on the CPWL system shown in Figure 1. The system consists of a mass m and a massless rod, each coupled to the environment by a spring-damper element. In addition, the mass is connected to the rod by one linear and one unilateral spring, with stiffnesses k_3 and k_{N3} , respectively. The unilateral spring is active only when the relative displacement $q_1 - q_2$ is positive, where q_1 and q_2 are the displacements of the mass and the massless rod, respectively. Let $\mathbf{x} = (x_1 \ x_2 \ y)^T \in \mathbb{R}^3$ be the state vector, where the components are defined as follows:

$$x_1 = q_1, \quad x_2 = \dot{q}_1, \quad y = q_1 - q_2. \quad (12)$$

In this set of coordinates, the equations of motion have the form of system (1), where \mathbf{A}^\pm are constant matrices given by

$$\mathbf{A}^\pm = \begin{pmatrix} 0 & 1 & 0 \\ -\frac{k_1}{m} & -\frac{c_1}{m} & -\frac{k_3^\pm}{m} \\ \frac{k_2}{c_2} & 1 & -\frac{k_2+k_3^\pm}{c_2} \end{pmatrix} \quad \text{with} \quad \begin{cases} k_3^+ = k_3 + k_{N3} & \text{for } y \geq 0 \\ k_3^- = k_3 & \text{for } y < 0 \end{cases}, \quad (13)$$

with all damping and stiffness coefficients assumed to be non-negative. The switching manifold is defined as $\Sigma = \{\mathbf{x} \in \mathbb{R}^3 | y = 0\}$ and the state space consists of two half-spaces $\mathcal{U}^\pm = \{\mathbf{x} \in \mathbb{R}^3 | y \gtrless 0\}$. By statement (a) of Theorem 2 and after performing simple calculations for fixed sets of parameters which fulfill the assumptions on the matrices \mathbf{A}^\pm , we deduce that this system has only one invariant cone which is hyperbolic and asymptotically stable. As the existence of a stable invariant cone is now established, the next step is to apply singular perturbation theory to approximate the cone. In order to bring the system to a singularly perturbed form, the damping constant c_2 is assumed to be a small parameter ($c_2 = \varepsilon$). Next, we split the state vector \mathbf{x} into slow variables $\mathbf{x}_s = (x_1 \ x_2)^T \in \mathbb{R}^2$ and a scalar fast variable y .

Figure 1: Mechanical system of a slow-fast oscillator in \mathbb{R}^3 .

Figure 2: Illustration of the attracting invariant cone approximated by two half-planes \mathcal{M}_s^\pm with a switch at $x_1 = 0$ for the parameter set $\varepsilon = c_2 = 0.1, c_1 = 0.4, m = 1, k_1 = k_2 = 1, k_3 = 0, k_{N3} = 2$. A general trajectory of the full system (solid line) is attracted to the half-planes and synchronizes with a trajectory of reduced dynamics (dashed line). The critical manifold gives a conservative periodic orbit (red line) and is therefore not suitable as an approximation of the full system.

The equations of motion in the slow-fast form read as:

$$\dot{\mathbf{x}}_s = \mathbf{f}^\pm(\mathbf{x}_s, y) = \begin{pmatrix} x_2 \\ -\frac{k_1}{m}x_1 - \frac{c_1}{m}x_2 - \frac{k_3^\pm}{m}y \end{pmatrix} \quad (14)$$

$$\varepsilon \dot{y} = g^\pm(\mathbf{x}_s, y, \varepsilon) = k_2x_1 + \varepsilon x_2 - (k_2 + k_3^\pm)y. \quad (15)$$

The critical manifolds in the half-spaces \mathcal{U}^\pm are obtained as isolated solutions $h_0^\pm(\mathbf{x}_s)$ of the equations $g^\pm(\mathbf{x}_s, h_0^\pm(\mathbf{x}_s), 0) = 0$ and read as:

$$h_0^\pm(\mathbf{x}_s) = \frac{k_2}{k_2 + k_3^\pm}x_1 \quad (16)$$

Herein, $h_0^+(\mathbf{x}_s)$ is only applicable for $h_0^+(\mathbf{x}_s) \geq 0$, which in view of $k_2, k_3^+ \geq 0$ comes down to $x_1 \geq 0$. Similarly $h_0^-(\mathbf{x}_s)$ is only applicable for $x_1 < 0$. Hence, we may define the critical manifold by

$$h_0(\mathbf{x}_s) = \begin{cases} h_0^+(\mathbf{x}_s) & \text{for } x_1 \geq 0 \\ h_0^-(\mathbf{x}_s) & \text{for } x_1 < 0 \end{cases} \quad (17)$$

The Jacobians $\left. \frac{\partial g^\pm}{\partial y}(\mathbf{x}_s) \right|_{y=h_0^\pm, \varepsilon=0}$ along the critical manifold are strictly negative and fulfill the stability condition, and the dynamics on this manifold is given by $\dot{\mathbf{x}}_s = \mathbf{f}^\pm(\mathbf{x}_s, y = h_0(\mathbf{x}_s); 0)$. For the special choice $c_1 = 0$, this dynamics is purely conservative and yields a periodic orbit, which does not reflect the dissipative nature of the original system ($\varepsilon \neq 0$) and therefore cannot be used to approximate the long time behavior of the full system, as shown in Figure 2. Thus, terms of $\mathcal{O}(\varepsilon)$ must be included to obtain a dissipative reduced-order model. Using the equations (10) and (11), the locally invariant slow half-manifolds of the two linear subsystems read as:

$$y_{\text{slow}} = h_s^\pm(\mathbf{x}_s) = \frac{k_2}{k_2 + k_3^\pm}x_1 + \frac{\varepsilon k_3^\pm}{(k_2 + k_3^\pm)^2}x_2 + \mathcal{O}(\varepsilon^2), \quad \text{with } k_3^\pm = \begin{cases} k_3 + k_{N3} & \text{for } y_{\text{slow}} \geq 0 \\ k_3 & \text{for } y_{\text{slow}} < 0 \end{cases}. \quad (18)$$

The dynamics of the 2-dimensional system, reduced to the linear locally invariant slow manifolds in both regions, is governed by $\dot{\mathbf{x}}_s = \mathbf{f}^\pm(\mathbf{x}_s, h_s^\pm(\mathbf{x}_s))$. The switching condition in this case is not trivial anymore, since the stiffness k_3^\pm depends on y_{slow} itself. This problem is illustrated in Figure 3. The colored areas and their corresponding limits are obtained from (18) by solving the inequalities $y_{\text{slow}} \geq 0$ (yellow region for h_s^+) and $y_{\text{slow}} < 0$ (orange region for h_s^-), which matches the physical switching condition. In the white area, none of the inequalities are satisfied, whereas the dark area shows the region where both inequalities are fulfilled. To circumvent this problem of switching between h_s^\pm , one could take $x_1 = 0$ as a switching plane, since the x_2 terms in (18) are of order ε . At this modified switching plane, the linear slow manifolds, obtained as two half-planes $\mathcal{M}_s^\pm = \{\mathbf{x} \in \mathbb{R}^3 | y = h_s^\pm(\mathbf{x}_s)\}$, are askew and meet only at the equilibrium point. This leads to a reduced system containing a jump at $x_1 = 0$. However, the trajectories of the reduced system are still a good approximation and follow the trajectories of the full system, which converge asymptotically towards \mathcal{M}_s^\pm as shown in Figure 2. In order to obtain a continuous reduced system, \mathcal{M}_s^\pm can be continued up to their intersection line. This leads to the avoidance of jumps in the reduced dynamics at Σ .

Figure 3: Illustration of the admissibility regions for h_s^+ (yellow area with the solid black line as limit) and h_s^- (orange area with the dash-dotted black line as limit). The white area is the region for which both h_s^\pm are not admissible. The magenta dashed line shows the intersection of the two linear slow manifolds. Example for the parameter set $\varepsilon = c_2 = 0.1, c_1 = 0, m = 1, k_1 = k_2 = 1, k_3 = 0, k_{N3} = 2$.

Figure 4: Illustration of the invariant cone for $\varepsilon = c_2 = 0.1, c_1 = 0.4, m = 1, k_1 = k_2 = 1, k_3 = 0, k_{N3} = 2$. The magenta line shows the intersection line of the two locally invariant half-planes. The blue line is the intersection line of \mathcal{M}_s^+ with the switching manifold Σ , which lies exactly on the direction of the eigenvector from the numerical solution of equation (4).

Continued reduced slow dynamics

The main disadvantage of taking $x_1 = 0$ as a switching plane in (18) is that the reconstruction of the fast variable y contains a jump leading to a Filippov system [8] for the reduced dynamics. For the purpose of obtaining a continuous matching of the two locally invariant half-planes, the switching plane can be modified and fixed at the intersection line defined by $\mathcal{M}_s^+ \cap \mathcal{M}_s^-$. Setting $h_s^+ = h_s^-$ yields:

$$\left(-\frac{k_2}{k_2 + k_3^+} + \frac{k_2}{k_2 + k_3^-}\right)x_1 + \left(\frac{k_3^-}{(k_2 + k_3^-)^2} - \frac{k_3^+}{(k_2 + k_3^+)^2}\right)x_2 = 0. \quad (19)$$

This condition $h_s^+ = h_s^-$ is then used in (18) as switching condition instead of y_{slow} . Even though this line does not lie on the physical switching plane Σ , defined by $y = 0$, the reduced dynamics gives a better approximation of the dynamics of the full system. This is illustrated in Figure 4, where the reduced dynamics on the slow manifolds (dashed line) contains only a kink at the switching instead of a jump. The trajectory of the reduced system follows the solution of the full system more closely than trajectories containing a jump at $x_1 = 0$. Figure 5 compares the time histories of the displacements q_1 and q_2 over some periods of decaying oscillations from the full system (black), the reduced system with a jump (blue) and the reduced model from the continued invariant half-planes (red). The continued reduced dynamics shows a closer agreement with the full system than the reduced model containing jumps.

Approximation of the invariant half-lines

Since the global stability of the continuous critical manifold \mathcal{M}_c is ensured and the two slow manifolds \mathcal{M}_s^\pm are locally invariant and attracting, a typical trajectory in \mathcal{U}^+ would cross Σ from right to left at a point that can be assumed in the $\mathcal{O}(\varepsilon)$ neighborhood of \mathcal{M}_s^+ . For sufficiently small ε , the trajectory would then approach \mathcal{M}_s^- and follow it closely

Figure 5: Time histories for $\varepsilon = c_2 = 0.2$, $c_1 = 0$, $m = 1$, $k_1 = k_2 = 1$, $k_3 = 0$, $k_{N3} = 2$. The black, blue and red lines show the displacements from the full system, the reduced system with a jump and the continued reduced system, respectively.

until the next crossing with Σ . Hence, we can assume that every transition from right to left through Σ is in a $\mathcal{O}(\varepsilon)$ neighborhood of \mathcal{M}_s^+ . Consequently, the intersection line of \mathcal{M}_s^+ and Σ presents a good approximation of an invariant half-line of the invariant cone and can be obtained by setting $y_{\text{slow}}^+ = 0$ in (18) as :

$$\mathbf{r}_{\text{inv}} = \left\{ x_1 = -\varepsilon \frac{k_3^+}{k_2(k_2 + k_3^+)} x_2, y = 0 \right\}. \quad (20)$$

Using the definitions in (12), this half-line is visualized as the blue line in Figure 4 in the original coordinates of the system $(q_1, \dot{q}_1, q_2)^T$. For ε sufficiently small, this simple closed form approximation matches the invariant half-lines obtained from the numerical solution of (4). Obviously, this argumentation is analogous if we assume trajectories starting near the intersection of \mathcal{M}_s^- and Σ and leads to an approximation of the other invariant half-line, which corresponds to a Poincaré map defined as $P = P^-(P^+)$.

Conclusion

This study set out to explore the connection between singular perturbation theory applied to a slow-fast CPWL system and its invariant cones. The results show that the invariant half-lines of the corresponding invariant cone can directly be approximated in a closed form from a geometric perspective by computing the intersection of the locally invariant slow manifolds and the switching plane. Moreover, this work has also highlighted that trajectories of the reduced dynamics with a modified switching condition, which was obtained from the intersection line of the two slow manifolds, can closely approximate trajectories of the full system. Further research might explore the applicability of these findings for higher dimensional CPWL systems.

Universitat de les Illes Balears, C/ Valldemossa km 7.5, 07122 Mallorca, Spain*

Summary. We study in this paper the dynamics of quantum nanoelectronic resonant tunneling diodes (RTDs) as excitable neuromorphic spike generators. We disclose the mechanisms by which the RTD creates excitable all-or-nothing spikes and we identify a regime of bursting in which the RTD emits a random number of closely packed spikes. The control of the latter is paramount for applications in event-activated neuromorphic sensing and computing. Finally, we discuss a regime of multi-stability in which the RTD behaves as a memory.

Introduction

Spike information processing and transmission in the form of events that occur at continuous times has numerous advantages over digital encoding and signaling [1]. It is a key mechanism in the dynamics of neurons and the brain, which suggests its value in the development of biologically-inspired artificial intelligence. Neurons are *excitable systems*; they respond to an external stimulus by realizing a large amplitude response, typically in the millisecond and millivolt range, before returning to their rest state, provided that said stimulus is larger than a certain threshold. Several neuromorphic circuits have been proposed which attempt to emulate the transmission of information in the brain and the nervous systems [2,3,4], including the IBM TrueNorth chip and the Intel Quark SE chi. These approaches are still based on adapting the conventional Complementary Metal Oxide Semiconductor architecture, and have some drawbacks, such as low frequency (kHz) and much higher power consumption than the brain.

Results

In this work, we provide a detailed analysis on the performance of quantum nanoelectronic resonant tunneling diodes (RTDs) as neuromorphic spike generators. Resonant tunneling diodes are promising candidates and are the fastest electronic oscillators up to date, reaching frequencies in the order of the hundreds of GHz, with a world record of 1.98 THz. Double barrier quantum well RTDs exhibit a nonlinear current-voltage characteristic with regions of negative differential conductance (NDC) [1] (fig. 1). This property is key for the potential configuration of RTDs as excitable spike generators [5]. Excitable systems respond to an above-threshold stimulus by realizing a large amplitude response, typically in the millisecond and millivolt range, before returning to their rest state. For the duration of the response, known as lethargic time, the system is unable to respond to any other stimulus, irrespective of its amplitude [6]. Here, a theoretical model is proposed following the first-principle calculations of [5] accounting for an RTD with a single NDC connected to a DC voltage source (see fig. 1 inset).

The system of two first-order differential equations for the current and voltage derived from Kirchoff laws reads

$$\mu \dot{V} = I - f(V), \quad (1)$$

$$\mu^{-1} \dot{I} = V_0 - V - RI. \quad (2)$$

Here, $V(t)$ is the voltage across the RTD and $I(t)$ is the total current. V_0 is the bias DC voltage, R is the circuit intrinsic resistance and the parameter μ is the stiffness coefficient defined as $\mu = \sqrt{\frac{C}{L}}$, where L and C are the equivalent inductance and capacitance, respectively, which sets the circuit's natural frequency. The system's response depends on three parameters: the bias voltage, the circuit's resistance and a parameter accounting for the stiffness of the dynamics. Provided that this stiffness coefficient is sufficiently small, the system exhibits an adiabatic limit cycle with stages of slow and fast dynamics when biased in the NDC region and a stable fixed point when biased elsewhere (fig. 2.b). If the bias is set in the proximity to the NDC region and the system is perturbed with a perturbation above a certain threshold, it responds with a spike reminiscent of the slow-fast limit cycle. If the system is subjected to noise instead of a single perturbation, it randomly generates spikes depending on the noise intensity. If the bias is set in the proximity to the I-V curve valley, the spikes appear agglomerated in bursts (fig. 2.c), which has already been observed in experiments [5].

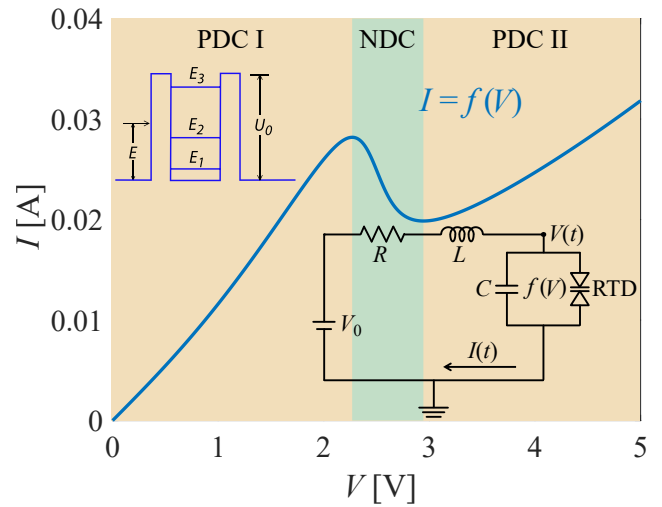

Figure 1: DBQW RTD connected to DC voltage.

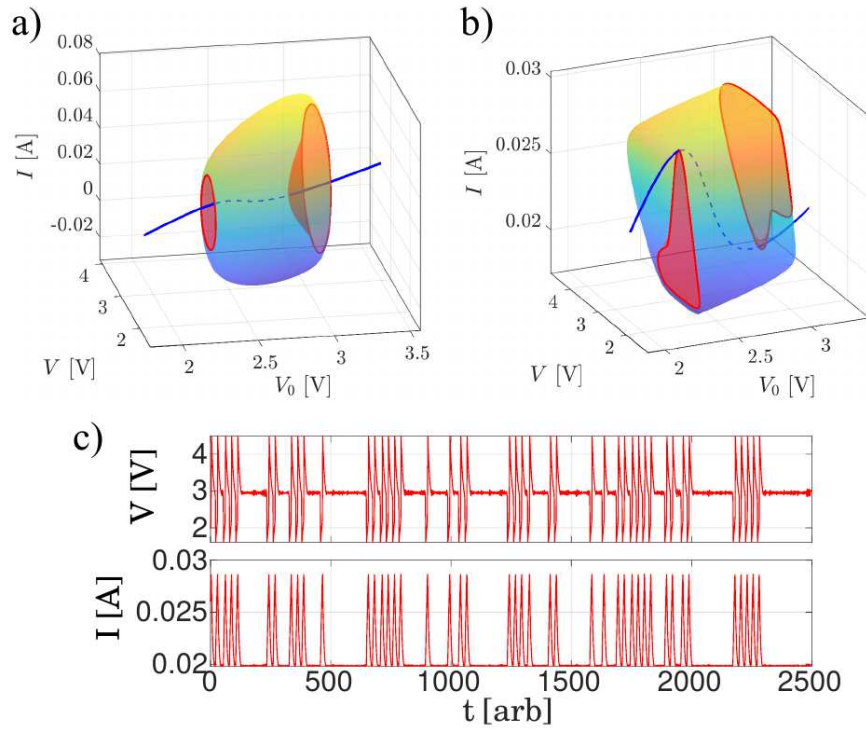

Figure 2: a,b) RTD response as a function of the bias voltage. Limit cycles are smooth (a) or stiff (b) depending on the stiffness coefficient. c) RTD response to external noise in the form of bursts of spikes.

An extensive study on the system's responses in terms of the parameters mentioned above is performed. Depending on the I-V characteristic, there may be narrow ranges of bias voltage at each side of the NDC region where the system is bistable. A critical value for the resistance is also found, above which the system exhibits a rich variety of multistabilities, with multiple fixed points and homoclinic curves. The bistability ranges and the lethargic time are measured as functions of the stiffness coefficient and the resistance, and they are found to be mainly dependent on the former, with little influence by the latter. In particular, the lethargic time is found to be inversely proportional to the circuit's inductance.

Conclusions

A Liénard-type nonlinear oscillator was proposed to model the dynamics of a double barrier quantum well resonant tunneling diode (DBQW RTD) connected to an electrical DC input. The configurations where the circuit behaves as an excitable spike generator were disclosed in a perspective to design and fabricate optoelectronic, nanoscale devices able of transmission, reception and storage of spike-coded information. The RTD oscillator may exhibit one or more equilibrium solutions in the form of a fixed point or a limit cycle. In particular, the stiffness coefficients determines whether or not the system behaves as a smooth oscillator or a spike generator.

Delayed loss of stability in multiple time scale models of natural phenomena

Mattia Sensi*

*MathNeuro Team, Inria at Université Côte d’Azur, Biot, France

Summary. Numerous real-world phenomena exhibit mechanisms evolving on greatly different time scales. In this talk, we focus on delayed loss of stability in two classes of mathematical models, namely epidemics and neuroscience, specifically synaptic transmission, and comment on the possible asymptotic, and in one case transient, behaviour of such systems.

Introduction

Numerous natural phenomena exhibit mechanisms evolving on greatly different time scales, e.g. days against months or even years. The presence of multiple time scales gives rise to complex phenomenon, such as the focus of this talk, i.e. the so-called delayed loss of stability [1, 7]. Geometric Singular Perturbation Theory (GSPT) [2, 6] is a powerful tool to analyze such systems: by considering each time scale separately, GSPT allows to deduce information on the behaviour of the original model.

In this talk, we present various multiple time scale systems, both in standard and non-standard form [9], and describe their behaviour using different techniques from GSPT. In particular, we showcase the delayed loss of stability of orbits passing nearby critical manifolds (the sets of equilibria of the fast limit) of such systems. We focus on the entry-exit relation (also known as way-in/way-out, delayed loss of stability, or Pontryagin delay) which we use to analyze the passage of orbits near the critical manifolds.

In its simplest form, the entry-exit function is applied to planar systems of the form

$$\begin{aligned} x' &= \epsilon f(x, z, \epsilon), \\ z' &= z g(x, z, \epsilon), \end{aligned}$$

with $0 < \epsilon \ll 1$, $x, z \in \mathbb{R}$, $f(x, 0, 0) > 0$ and $\text{sign}(g(x, 0, 0)) = \text{sign}(x)$.

As shown in Figure 1, one can derive a Poincaré map $x_0 \mapsto p_\epsilon(x_0)$ from a horizontal line $\{z = z_0\}$ to itself. The x -axis $z = 0$ changes stability, from attracting to repelling, at $x = 0$. Orbits which are attracted towards it at a point $(x, z) = (x_0, z_0)$, with $x_0 < 0$, will eventually leave a neighbourhood of the x -axis and re-intersect the line $\{z = z_0\}$ at a point with $(x, z) = (p_\epsilon(x_0), z_0)$, with $p_\epsilon(x_0) > 0$. As $\epsilon \rightarrow 0$, the exit point $p_\epsilon(x_0)$ approaches the value $p_0(x_0)$ given implicitly by the following integral:

$$\int_{x_0}^{p_0(x_0)} \frac{g(x, 0, 0)}{f(x, 0, 0)} dx = 0.$$

Such a formula can be generalized to higher-dimensional systems, at the cost of additional assumptions which, as we explain, are not always trivially satisfied.

Figure 1: A visualization of the entry-exit map for a planar system.

The models

Compartmental epidemics models

The first models we present are the compartmental models, in non-standard GSPT form, studied in [3]. In all the models, the fast processes are the ones related to infection and recovery, whereas the slow processes are the ones related to loss of immunity or demography. The passage of an orbit close to the critical manifold, represented in all cases by the absence of infectious individuals in the population, allows us to bring the system in standard form through a rescaling of the variables, and to predict the beginning of another “wave” through the entry-exit function.

We analyzed three epidemics models given as slow-fast SIR (Susceptible-Infected-Recovered) and SIRS compartmental models, and proved that when the basic reproduction number R_0 is greater than 1, the system will converge to an endemic equilibrium characterized by an $\mathcal{O}(\epsilon)$ fraction of the population still in the infected compartment.

Then, we studied an SIRWS (where the “W” represents individuals in a Waning immunity phase), and we applied a geometrical argument, sketched in Figure 2, to prove the asymptotic convergence towards a unique endemic equilibrium or towards a limit cycle.

Finally, we present the SIRS compartmental model on homogeneous networks studied in [4]; one fundamental difference with the SIRS model studied in [3] is the existence of stable limit cycles. All the results obtained in the aforementioned papers heavily rely on the entry-exit function, and one critical assumption needed in order to use this tool (namely, separation of eigenvalues of the linearization of the systems along the critical manifold) is not always satisfied along solutions of the SIRS model on networks. We comment on such a limitation, and provide a possible solution to overcome such an issue.

Figure 2: Concatenation of slow and fast orbits, giving rise to a limit cycle.

A short theoretical digression

As a follow-up to the criticality emerging from the model studied in [4], we shortly describe an ongoing project [5] which aims at generalizing the possibilities of application of the entry-exit function.

Specifically, we consider a class of 1-fast/2-slow systems of ODEs, and provide entry-exit relations for systems whose linearizations do not exhibit separation of eigenvalues on the critical manifold. We argue that such an approach could be generalized to higher-dimensional systems.

Synaptic transmission via neurotransmitter release

Then, we showcase the application of the entry-exit function to a planar system in standard GSPT form studied in [8]. The entry-exit function can be used, in this context, to compute the delay between subsequent spikes in the neural activity and capture possible response of a post-synaptic neuron to an input (formed by one or several spikes) received by a pre-synaptic neuron. This response always incurs a minimal delay (diffusion time to cross the synaptic cleft, the space in between the two neurons) but can increase substantially depending on the neural type and possible pathological behaviour of the underlying neural population. The entry-exit function hence allows to fine-tune the model so as to capture all these scenarios within a parsimonious framework, and fit to data of both excitatory and inhibitory synapses.

Lastly, we propose a generalization of the previous system, in which the quadratic component of the critical manifold is replaced with a quartic curve. We study how the shape of the quartic, as well as other parameters of the system, may affect both the transient and asymptotic behaviour of the system, since both are of interest in such applications.

Summary. This work aims to apply mass redistribution method to explicit schemes in non-smooth contact dynamics, especially the CD-Lagrange scheme. New properties are being investigated to better address the issues of impact for structural transient dynamics. Mass redistribution method improves energy balance and stability for CD-Lagrange scheme. Results for a simple contact problem are presented.

Non-smooth Contact Dynamics and mass redistribution method

In structural transient dynamics, problems with impact belong to the family of Non-Smooth Contact Dynamics (NSCD) problems. An impact causes a discontinuity in velocity, and therefore a non-defined acceleration. Integrating in time requires thus dedicated schemes. A first family, event-driven schemes, adjust the time-step to set impact times at discrete times. They fail in case of numerous and close impacts leading to a high computation time. A second family, time-stepping schemes, can deal with multiple impacts between two discrete times keeping time-step constant. Time-stepping schemes are thus more robust for practical finite elements problems.

The first NSCD time-stepping scheme is Moreau-Jean's scheme [1, 2]. It introduces a new contact formulation written in terms of velocity and impulsion. It allows stability at impact and a better energy balance, and is equivalent to classical Signorini's condition. But writing contact in terms of velocity does not solve exactly position. A residual penetration remains during contact. Chen, Acary et al. [5] extend Moreau's velocity formulation to Newmark's family. All these schemes are implicit.

A first family of NSCD explicit schemes is Paoli-Schatzman's one [3]. They use a contact formulation in terms of position, and central difference method for time-integration. For velocity/impulse contact formulation, the only explicit scheme is CD-Lagrange [4]. It uses the central difference method too for time-integration, but preserves properties of Moreau-Jean's family.

A active research field in NSCD is currently the mass redistribution method. Following the work of Khenous, Laborde and Renard [6], new spatial discretizations appear with massless node for contact. This improves the energy balance, and velocity stability for contact nodes after release. Dabaghi [7] applies this technique to Paoli-Schatzman's schemes leading to similar improvements.

In the present work redistribution mass method is applied to CD-Lagrange scheme. The purpose is to exhibit the interest of mass redistribution method to velocity/impulse contact formulation and a explicit scheme. This new scheme would be well suited to non-linear impact dynamics involved in tire simulations.

CD-Lagrange scheme with redistributed mass : a 1D example

Here a one-dimensional problem is presented to illustrate the main features of mass redistribution on a CD-Lagrange scheme. The impacting bar problem is chosen. It is a common benchmark case for NSCD integration schemes [4, 5, 7, 8]. This case is a discrete bar impacting on a rigid barrier, with a linear elastic material law.

Here the skin is defined as being the last element of the bar. Modifying mass consists of removing mass of contact node and distributing it uniformly on other nodes. It results in two problems : one for the bulk, and one for the skin. The bulk problem is dynamic with kinetic and internal stresses. The skin problem is similar to a static one. The contact node having no mass, no kinetical term is involved in equation of dynamic.

This leads to a difficulty for schemes with velocity as main unknown (like CD-Lagrange): the contact node velocity can not be determined by the equation of dynamic. The solution is to set the normal velocity depending on state of contact. It is fixed to zero for an active contact, and to the normal velocity of preceding mass node otherwise. This means that the skin deforms only when the contact is active. After release, a deformed state can thus persist. In such a case the skin force acting on bulk domain is set to zero. As a consequence the contact problem no longer contains kinetic terms, but only forces based on stresses in skin.

Figure 1: Redistributed mass on a discrete bar

Figures 2 and 3 show respectively the contact node position and velocity over time for analytical, classical CD-Lagrange and redistributed mass CD-Lagrange solutions.

The analytical solution of the continuous problem is known. The bar gets closer to the barrier with constant speed and impacts it (around $t = 0,5 \times 10^{-4}s$). The contact persists until the compression wave reaches the free end and returns.

Figure 2: Contact node position

Figure 3: Contact node velocity

Then the bar releases contact (around $t = 1.5 \times 10^{-4} s$) and moves away with the same constant speed as before impact.

Time-integration schemes compute discrete solutions with commons features : a residual penetration remains after impact, because of the velocity contact condition. This residual penetration is the same for both CD-Lagrange schemes. Redistributing mass has no influence on discrete position. For velocity, if the discrete solutions stay close from analytic one before the contact release, spurious oscillations appear after. For redistributed mass CD-Lagrange, they vanish slightly faster.

Discrete energy over time is depicted on figure 4. This energy contains only conservative terms: kinetic, internal and complementary energy. At impact time the loss of energy for CD-Lagrange is the kinetic energy of contact node, as its velocity is set to zero. For CD-Lagrange with redistributed mass, no energy is lost as the node is massless. But at contact release, some energy is injected.

Figure 4: Energy : conservative terms

Conclusion and future work

Embedding mass redistribution in CD-Lagrange scheme allows to improve three features: a new contact problem, simpler without kinetic terms; a conservative impact; a weakening of spurious oscillations slightly improved.

The next step of this work is to extend it to three-dimensional problems. A major issue is dealing with incompatible meshes, that leads to a higher complexity for the impact problem.

Bifurcations in Piecewise Smooth, Delay Differential Systems

Amit Shukla*, N.W.A. Strijbosch[†] and Henk Nijmeijer[†]

**Department of Mechanical and Manufacturing Engineering, Miami University, Oxford, Ohio, USA*

[†]*Department of Mechanical Engineering, Eindhoven University of Technology, The Netherlands*

Summary. This paper presents bifurcation study of piecewise smooth differential delay equations (PWS-DDEs) where the state variable determines which differential delay equation is active. This paper aims to add to the existing research performed on bifurcation studies of PWS-DDEs by developing an algorithm to perform bifurcation studies of a general form of PWS-DDEs, such that it can be used for any bifurcation study of a PWS-DDEs system. Bifurcation studies are performed using a simplified model of a controlled inverted pendulum to study the effect of parameters. During the bifurcation studies, new type of bifurcations that arise for PWS-DDEs are defined.

Introduction

The ability to predict the stability of periodic behavior can be of importance in the research into for instance Parkinson [2] or other balance disorders. Methods to determine periodic solutions for differential delay equations (DDEs) or piecewise smooth (PWS) systems are well described. To find periodic solutions of DDEs the collocation method is often used [3, 4, 5, 6]. In [1] the collocation method as used for DDEs is extended such that it is able to find periodic solutions of PWS-DDEs. This paper presents bifurcation studies of a general form of PWS-DDEs. We study the influence of smooth switching manifold on the parametric bifurcations for a controlled inverted pendulum. Bifurcation studies are presented for systems with smooth switching manifolds using the algorithm developed.

Model

The state space model of the inverted pendulum is given by

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} x_2(t) \\ \sin x_1(t) - x_2(t) - u(x(t - \tau)) \end{bmatrix} \quad (1)$$

where $x_1 := \theta$ and $x_2 := \dot{\theta}$, where θ is the angle and u is a torque determined by a controller. Delays in for instance the sensors or computational delays are modeled by using the delayed values of the angle and angular velocity to determine the torque u . The parameters (mass, length, and damping coefficient) in this model are scaled to unity. Some studies suggest that central nervous system uses control switching strategies that deactivate the controller in certain (stable) subspaces of the state space, to minimize control effort [7]. The switching strategies are a function of these delayed values, hence one way to describe the control input on the system can be:

$$u(x(t - \tau)) = \begin{cases} 0 & \text{when } x(t - \tau) \in \chi_{unctrl} \\ K_p x_1(t - \tau) + K_d x_2(t - \tau) & \text{when } x(t - \tau) \in \chi_{ctrl} \end{cases} \quad (2)$$

with $\chi_{unctrl} \cup \chi_{ctrl} = \mathbb{R}^2$, with K_p and K_d the proportional and derivative gain, respectively. The switching strategy studied here is to only control the system if magnitude of the angle is large. The subspaces $\chi_{unctrl} = \{x \in \mathbb{R}^2 | |x_1| \leq e\}$ and $\chi_{ctrl} = \{x \in \mathbb{R}^2 | |x_1| > e\}$ define this switching strategy where e is the value of $|\theta(t - \tau)|$ which defines the switching plane.

Bifurcation studies

A bifurcation study along parameter K_p is performed to study the effect of switching manifold. The bifurcation behavior is characterized by appearance of topologically nonequivalent phase portraits under variation of the parameter μ . The bifurcation studies are performed using the switching plane with $e = 0.1$. The parameters of the model are $K_p = 2$, $K_d = 1$ and $\tau = 0.5$, if not mentioned differently. The bifurcation diagram along the bifurcation parameter K_p is depicted in Figure 1. The whole branch consist of stable periodic solutions and the unstable equilibrium point at the origin. The evolution of a branch at $K_p = 1$ is given in Figure 2. Due to the sudden periodic solutions that originate similar to a Pitchfork bifurcation this phenomena will be referred to as the *Pseudo-pitchfork bifurcation*. There are two differences between pseudo-pitchfork bifurcation and the pitchfork bifurcation: the periodic solutions do not originate from the main branch and stability along the main branch does not change at the bifurcation point. For phase portrait C in Figure 1 one side has a stable periodic solution, and the other side there are two stable periodic solutions and on each side of the bifurcation point the solutions are stable. To study the behavior that causes the bifurcation, a section of the whole branch around the bifurcation point is depicted in Figure 3. In this case, for $\mu < \mu_0$, with μ_0 the bifurcation point, there is one unstable equilibrium one periodic solution, and for $\mu \geq \mu_0$ there is still one unstable equilibrium and two stable periodic solutions. This is called an *X-bifurcation*. The most challenging part of these studies is an inherent inability to capture all bifurcations at any critical point due to an inherent numerical approach and this remains part of future work for authors.

 Figure 1: Bifurcation diagram along parameter K_p with the magnitude switching manifold

Figure 2: Evolution of periodic solutions close to Pseudo-pitchfork bifurcation

Figure 3: Evolution of periodic solutions close to X-bifurcation

Conclusions

Two new bifurcations are observed for the system using a smooth switching control strategy for a PWS-DDE system.

Coexistence of conservative and dissipative dynamics in forced vibro-impact oscillator with Amonton-Coulomb friction

Pavel Kravets*, Oleg Gendelman* and Dmitrii Rachinskii †

**Faculty of Mechanical Engineering, Technion – Israel Institute of Technology, Haifa, 3200003, Israel*

†*Department of Mathematical Sciences, The University of Texas at Dallas, Richardson, Texas, 75080, USA*

Summary. The qualitative differences in the behaviors of Hamiltonian and dissipative systems are profound. In particular, in Hamiltonian systems the existence of asymptotically stable solutions is impossible due to the Liouville's theorem. By contrast, dissipative systems usually exhibit eventual attraction of all phase trajectories to ω -limit sets such as fixed points, (quasi-) periodic or strange attractors. In this work we present a class of dissipative mechanical systems which demonstrate mixed global dynamics, i.e., coexistence of both attracting and Hamiltonian-like behaviors. Our main model is a well-known system of harmonically forced vibro-impact oscillator with Amonton-Coulomb friction. In a vast majority of previous studies, it also includes viscous friction, and the global dynamics of its state space is governed by the aforementioned attractors. However, if we omit viscous friction, we observe that the state space is divided into regions with “regular” attraction, as well as regions with profoundly Hamiltonian dynamics, e.g., KAM-like tori. We show that such local Hamiltonian behavior occurs for the phase trajectories with non-vanishing velocities. The stability analysis of the periodic solutions confirms the above statement. We also demonstrate that similar mixed global dynamics can be observed in a broader class of models including systems with x -dependent potentials as well as multi-particle systems.

Introduction

Model formulation

We consider a single-degree-of-freedom unit mass particle which displacement is constrained by two rigid walls ($l < x(t) < r$). The particle is subject to external sinusoidal forcing of period $T = 2\pi/\omega$ and the Amonton-Coulomb dry friction [1, 2]. The equation for motions $l < x(t) < r$ is

$$\ddot{x} + f \operatorname{sgn}(\dot{x}) = F \cos(\omega t). \quad (1)$$

We assume that $F > f$, since otherwise any motion comes to stop. When $x(t) = r, l$ the following impact rule [3] is applied:

$$\dot{x}(t^-) = -\dot{x}(t^+). \quad (2)$$

Dynamics of system (1)–(2), and its dependence on parameters, will be illustrated by the global phase portrait of the stroboscopic time T map $\Phi : (x(0), \dot{x}(0)) \mapsto (x(T), \dot{x}(T))$. In particular, a fixed point of Φ corresponds to a periodic solution of system (1)–(2).

Numerical investigations

A typical phase portrait of Φ with $f = 0$ is shown on Figure 1a. It presents an invariant island containing a fixed point and periodic orbits which are surrounded by invariant curves representing quasiperiodic motions. Another region of quasiperiodic motions is observed for large velocities. Between these two regions there is a chaotic sea (gray dots). Furthermore, a horizontal segment of fixed points represents periodic solutions without impacts $x(t) = -\frac{F}{\omega^2} \cos(\omega t) + C$.

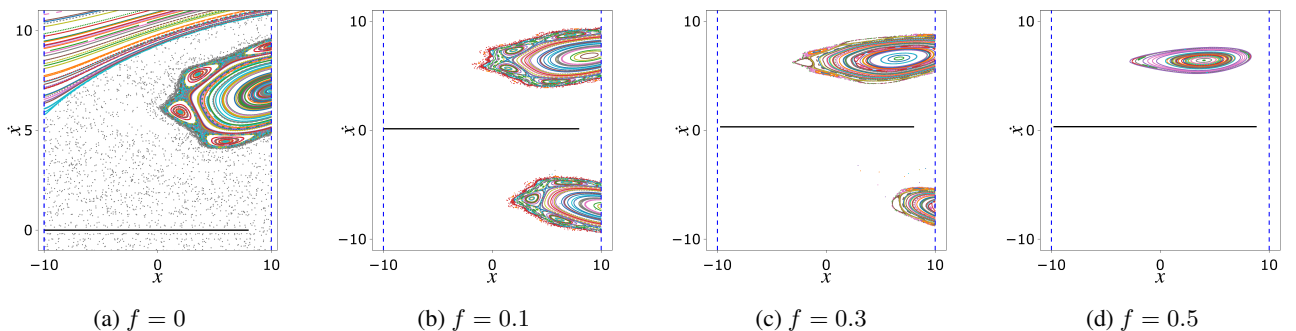

Figure 1: Evolution of the phase portrait with increasing friction. Other parameters are the following: $F = 1$, $\omega = 1$, $R := r - l = 20$.

Introducing friction drastically changes the phase portrait (Figures 1b–d). In particular, the segment of fixed points corresponding to periodic solutions without impacts becomes an attractor. However, the invariant island of Hamiltonian dynamics persists, thus, we observe coexistence of dissipative and conservative behaviors. The trajectories from the invariant island have a non-vanishing velocity, and, therefore, we call such solutions *non-sticking*.

Analysis

Hamiltonian dynamics of system (1)–(2) can be explained by lifting it to the unconstrained Hamiltonian system

$$\ddot{q} + \frac{\partial V}{\partial q} = \frac{f}{R}, \quad V(t, q) = \frac{F}{R} \cos(\omega t) W(q), \quad W(q) = \begin{cases} q, & 0 \leq q < 1, \\ 2 - q, & 1 \leq q < 2, \end{cases} \quad W(q+2) = W(q). \quad (3)$$

Any non-sticking solution of (3) is mapped to a non-sticking solution of (1)–(2) by the simple relationship

$$x = R \cdot W(q) + l. \quad (4)$$

Therefore, if all solutions starting from a domain Ω of the state space of system (1)–(2) are non-sticking and Ω is invariant for the time T map Φ of this system, then Ω is a region of Hamiltonian dynamics. In particular, at least a small invariant region Ω of Hamiltonian dynamics exists around every fixed point of non-degenerate non-resonant center type.

Stability analysis

Stability and type of a fixed point and the corresponding periodic solution is determined using the Floquet theory as follows. Any trajectory of (1)–(2) can be represented as a sequence of motions and events of the following types: *free flight* ($\dot{x} \neq 0$), *sticking* ($\dot{x} = 0$ over a nonzero interval of time), *reflection from the wall* ($x = r, l$) and a *turning point* (change of sign of \dot{x}). Thus, the Jacobi matrix Φ' can be obtained as a product of corresponding matrices (matrix related to an instantaneous event is known as *saltation matrix* [4]). In particular, it is easy to show that matrices for free flights and reflections of the walls have unit determinants. Thus, non-sticking trajectories, $\det(\Phi') = 1$ which corresponds to the phase area preservation.

Extensions

Mixed global dynamics can also be observed in systems with x -dependent potentials as well as systems with higher degrees of freedom. For instance, one can consider system of $n \geq 2$ elastically colliding particles with masses m_i placed between the same two walls. Again, in order to spot regions of Hamiltonian-like behavior we should check non-sticking periodic trajectories of non-resonant center type. The linear stability analysis can be easily extended to the case of many particles, however, in order to be volume-preserving the Jacobian Φ' should be symplectic. It turns out that the saltation matrix S related to the particle collision is not necessary symplectic. However, if the product of velocities of the two colliding particles has the same sign before and after the collision, then the corresponding saltation matrix (for $n = 2$)

$$S = \begin{bmatrix} A^T & 0 \\ B & A \end{bmatrix} \quad \text{with} \quad A = \frac{1}{m_1 + m_2} \begin{bmatrix} m_1 - m_2 & 2m_1 \\ 2m_2 & m_2 - m_1 \end{bmatrix} \quad \text{and} \quad B = \frac{2F \cos(\omega t_*) (m_1 - m_2) m_1 m_2}{m_1 + m_2 (m_2 \dot{x}_1(t_*^-) - m_1 \dot{x}_2(t_*^-))} \begin{bmatrix} -1 & 1 \\ 1 & -1 \end{bmatrix}, \quad (5)$$

is symplectic. When $m_1 = 1$, $m_2 = 0.9$, $F = 1$, $\omega = 2\pi$, $f = 0.005$, $R = 2$, the two-particle system has a $3T$ -periodic solution which linearization is symplectic. Figure 2 presents invariant tori in a neighborhood of this solution. The tori coexist with an attractor consisting of periodic solutions without collisions or impacts.

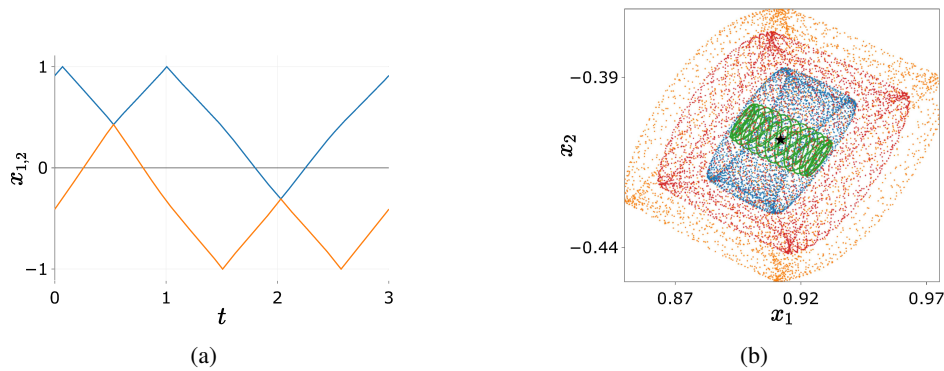

Figure 2: Panel (a): Time trace of a $3T$ -periodic solution of the two-particle system with $m_1 = 1$ (blue), $m_2 = 0.9$ (orange). Panel (b): Projection of the phase portrait of the time T map Φ onto the (x_1, x_2) -plane exhibiting several invariant tori near a period 3 point (star).

Compact weighted residual formulation for periodic solutions of systems undergoing unilateral contact and frictional occurrences

Mathias Legrand¹ and Christophe Pierre²

¹*Department of Mechanical Engineering, McGill University, Montreal, Canada*

²*Department of Mechanical Engineering, Stevens Institute of Technology, Hoboken, New Jersey, USA*

Summary. A very compact weighted residual formulation is proposed for the construction of periodic solutions of oscillators subject to unilateral contact and frictional occurrences. The key idea is to express all governing equations as equalities, which can then be satisfied in a weighted residual sense.

Toy system

In order to introduce the proposed formulation, a simple toy system, illustrated in Figure 1, is considered. It is a simple geometrically nonlinear mass-spring system lying on a moving belt of constant linear velocity v . The mass is denoted by m and the stiffness, by k . The length of the spring at rest (in a vertical position when the mass is lying on the belt) is L . The vertical displacement of the mass is $y(t)$ and vertical separation from the belt is possible. The horizontal displacement is $x(t)$. The position at rest is $(x, y) = (0, 0)$. The frictional force acting on the mass is $r_T(t)$ while the unilateral contact

Figure 1: One-dimensional mass-spring moving on a rotating belt. Point A is fixed. The position of point B is $(x(t), y(t))$. The belt is assumed to be infinitely long.

force is $r_N(t)$. The relative tangential velocity between the mass and the belt is $\dot{u}_T(t) = -v + \dot{x}(t)$. In the remainder, time is often dropped for readability purposes.

Signorini unilateral contact and Coulomb's friction conditions expressed as equalities

Given the parametrization of the system of interest, the classical Signorini conditions are expressed as the complementarity conditions

$$r_N \geq 0, \quad y \geq 0, \quad r_N \cdot y = 0 \quad (1)$$

which can be recast into various equivalent nonsmooth equalities, one of which being

$$\forall \rho_N > 0, \quad r_N - \max(r_N - \rho_N y, 0) = 0. \quad (2)$$

Briefly said, the set of points solution to Equation (1) and Equation (2) is the same [1, 2]. Also, with the considered parameterization, Coulomb's friction classically says the following: given a closed contact in the normal direction,

$$\begin{cases} \dot{u}_T = 0 & \implies |r_T| \leq \mu r_N \\ \dot{u}_T \neq 0 & \implies |r_T| = \mu |r_N| \text{ and } \exists \alpha \geq 0 \mid r_T = -\alpha \dot{u}_T \end{cases} \quad (3)$$

where μ is the coefficient of friction. Among others, the above condition can equivalently be recast into the nonsmooth equality [2, 7]

$$\min(|\dot{u}_T|, \mu r_N - |r_T|) = 0 \quad (4)$$

or

$$\forall \rho_T > 0, \quad |\dot{u}_T| - \max(|\dot{u}_T| - \rho_T(\mu r_N - |r_T|), 0) = 0. \quad (5)$$

Newton's impact law

Depending on the context of the investigation, an impact law $\dot{y}^+ = -e \dot{y}^-$ relating the pre- and post-impact velocities, \dot{y}^- and \dot{y}^+ respectively, through a coefficient of restitution $e \in [0, 1]$ might be required for the well-posedness of the formulation since Equation (1) alone might not guarantee the uniqueness of the solution [4]. The idea is to test whether a penetration between the bodies in contact has occurred and then enforce the unilateral contact conditions at the velocity level with the above impact law inserted. Altogether, this reads [2]:

$$\begin{cases} y < 0 & \implies r_N \geq 0, \quad \dot{y}^+ + e \dot{y}^- \geq 0, \quad r_N \cdot (\dot{y}^+ + e \dot{y}^-) = 0 \\ y \geq 0 & \implies r_N = 0 \end{cases} \quad (6)$$

which can be recast into the single equality

$$\forall \rho_N, \quad (\text{sign } y - 1)(r_N - \max(r_N - \rho_N(\dot{y}^+ + e\dot{y}^-), 0) + (\text{sign } y + 1)r_N = 0 \quad (7)$$

with the convention $\text{sign } y = 1$ if $y \geq 0$ and $\text{sign } y = -1$ otherwise.

Governing equations

Given the geometric nonlinearity induced by the action of the spring on the mass, we introduce the quantity

$$\gamma(x, y) = \frac{\sqrt{x^2 + (L + y)^2} - L}{\sqrt{x^2 + (L + y)^2}}. \quad (8)$$

The two coupled nonlinear and nonsmooth Ordinary Differential Equations

$$m\ddot{x} + k\gamma(x, y)x - r_T = 0 \quad (9a)$$

$$m\ddot{y} + k\gamma(x, y)(y + L) - r_N + mg = 0 \quad (9b)$$

together with either Equation (2) and Equation (4), or Equation (7) and Equation (4), govern the dynamics of the system considered. In Equation (9b), g is the gravity constant. Depending on the level of regularity of the targeted solution, Equation (9) might have to be read in the distributional sense.

Weighted residual formulation

It is suggested to search for periodic solutions by solving the above formulation in a weighted residual sense. All unknowns of the problem are expanded on an appropriate truncated basis of T -periodic functions with N members, commonly the Fourier basis in the Harmonic Balance Method but not necessarily, as follows:

$$x(t) = \sum_k x_k \phi_k(t), \quad y(t) = \sum_k y_k \phi_k(t), \quad r_N(t) = \sum_k N_k \phi_k(t), \quad r_T(t) = \sum_k T_k \phi_k(t). \quad (10)$$

Depending on the smoothness of the selected basis functions, time derivatives might either be obtained by pointwise differentiation in time or expanded on a less smooth basis and related to the differentiated quantity in a weak sense. Concerning Equation (7) which requires access to \dot{y}^+ and \dot{y}^- , a Discontinuous Galerkin scheme could be used [6]. If we decide to solve Equation (9), Equation (2) and Equation (4), the weighted residual formulation would take the following form: once the expressions of Equation (10) are inserted in the selected governing equations, find the $4N$ unknowns x_k , y_k , N_k and T_k which satisfy

$$\int_0^T \phi_k(t)(\text{Eq. (9a)}) dt = \int_0^T \phi_k(t)(\text{Eq. (9b)}) dt = \int_0^T \phi_k(t)(\text{Eq. (2)}) dt = \int_0^T \phi_k(t)(\text{Eq. (4)}) dt = 0, \quad \forall k. \quad (11)$$

The above integrals can be numerically computed using an appropriate quadrature scheme such as a Riemann sum. The resulting system of nonlinear equations can be also solved using a nonsmooth Newton solver, for instance. The proposed strategy can be seen as a very compact form of the AFT methodology [5] without regularization and shares similarities with the DLFT technique [3] which also relies on the AFT. The rate of convergence of the proposed procedure might depend on the two parameters ρ_N and ρ_T , which have to be assigned a value in the solvers.

Conclusions

The proposed formulation is very compact and involves simple implementations such as basic integral quadrature schemes and existing nonlinear solvers. Its engineering value lies in its capability to generate coarse approximations without difficulty in contrast to much more advanced time-stepping or event-driven schemes [2]. It can be extended to more elaborate mechanical systems in a straightforward fashion. However, the convergence rate in terms of the number of unknowns is expected to be low and should be investigated with great care.

Dynamic non-smooth fold bifurcations influenced by oscillations and noise

Rachel Kuske*, Chris Budd[†], Cody Griffith[‡]

[‡]University of British Columbia, CA, and 908 Devices, USA

Summary. We contrast the behavior of dynamic bifurcations for smooth and non-smooth fold bifurcations in the presence of oscillatory and noisy forcing. Dynamic bifurcation refers to the state transition or “tipping” that takes place when a parameter slowly varies through a value corresponding to a bifurcation in the static model. Note that the dynamic models correspond to non-autonomous systems with multiple time scales. Through a canonical model with an underlying static nonsmooth fold bifurcation, we see that the transition is delayed as in the smooth case, depending on the rate of change of the parameter, but the functional form for the non-smooth case is different. We also compare and contrast how oscillatory forcing can shift the tipping or dynamic bifurcation, in both smooth and NS cases. We extend to a higher degree of freedom models with NS fold bifurcations, studying a Stommel model, a two-box ocean model for temperature and salinity. Within this higher dimensional model, we find additional differences for the non-smooth case in the presence of certain types of random forcing.

Contrasts of tipping points in smooth and non-smooth fold bifurcations

We consider a non-autonomous single degree of freedom (DOF) model ,

$$\dot{x} = -\mu + 2|x| - x|x| + A \sin(\Omega t), \quad \dot{\mu} = -\epsilon, \quad x(0) < 0, \quad \mu(0) > 0, \quad \epsilon \ll 1, \quad (1)$$

with A and $\Omega = \epsilon^{-\lambda}$ the amplitude and frequency, respectively, of the oscillatory forcing and slowly varying bifurcation parameter μ . For the static system $\epsilon = 0$ there is an underlying non-smooth (NS) fold bifurcation at $\mu = x = 0$ as shown in Fig. 1. Using a series of multiple scale analyses, we obtain approximations for the dynamic bifurcations, often called

Figure 1: (LEFT) The bifurcation diagram for (1) showing upper and lower equilibrium branches (solid lines) and the unstable middle branch (dash-dotted line). The NS static fold bifurcation is at $(0,0)$ (blue *); the smooth fold bifurcation is at $(1,1)$ (red o). The numerical solution (blue dotted line) to (1) is for $A = 0$ and $\epsilon = .05$. (RIGHT). Simulations of (1), superimposed on the static bifurcation curve (black lines). Diamonds: analytical predictions μ_{tip} for the DB/TP for $\lambda \leq 1$ (simulation in red and green for $A = 2$ and $\lambda = .7, 1$, respectively, and in blue for $A = 5$ and $\lambda = .7$); circle o: analytical prediction of μ_{sv} , (simulation in magenta for $A = 2$, $\lambda = 2$)

tipping points (DB/TP), with and without the oscillatory forcing. Here x follows the lower equilibrium branch $x < 0$ as μ decreases. Using the multiple scales expansion $x(t, T) = -\epsilon^\lambda A \cos T + \epsilon^{q_1} y_1(t, T) + \dots \epsilon^{q_2} y_2(t, T) + \dots$ for $1 \ll \Omega = \epsilon^{-\lambda}$ and $T = \Omega t$, we obtain the DB/TP

$$A \neq 0, \quad 0 < \lambda \lesssim 1 \quad \mu_{\text{tip}} = \left(\frac{\epsilon^2}{\Omega} \right)^{1/3} \left(\frac{\pi |A|}{2} \right)^{1/3} \xi_r + \frac{4|A|}{\pi \Omega} \quad \text{Ai}(\xi_r) = 0 \text{ for } \xi_r = -2.33811 \dots \quad (2)$$

$$A = 0, \quad 0 < \lambda \quad \mu_{\text{sv}} \sim \frac{1}{2} \epsilon \log(\epsilon). \quad (\text{Ai is the Airy function}) \quad (3)$$

Fig. 2 compares the analytical and numerical results for these DB/TP's. For small frequencies the NS DB/TP is advanced relative to the static $\mu = 0$, while for larger frequencies (larger λ or smaller A/Ω), the DB/TP is positive, with its asymptote at μ_{sv} corresponding to $A = 0$. Note that μ_{tip} depends on the ratio A/Ω . Figs. 1 and 2 illustrate advanced DB/TP for larger A/Ω and lagged DB/TP for smaller A/Ω . We contrast these results with the DB/TP for the canonical smooth dynamic fold bifurcation studied in [1]-[2], $x'(t) = a(\epsilon t) - x^2$, $a = a_0 - \epsilon t$ for $\epsilon \ll 1$. For $A \neq 0$, in both smooth and NS cases, the DB/TP's are the sum of two contributions, one negative contribution which corresponds to a lag due to slowly varying μ , and a second positive contribution corresponding to an advance in tipping due to the oscillations. Thus we have a competition between influences generating advances and lags, with different parametric dependencies. Analogous to the NS case, the DS/TP value of a in the smooth case depends on A/Ω and ϵ , but with a different functional dependency. For example, the asymptote for small A/Ω in the smooth case is $0 > a_{\text{sv}} = O(\epsilon^{2/3})$, in contrast to $\mu_{\text{sv}} = O(\epsilon \log \epsilon)$. Thus the lag in the DB/TP is larger in the smooth case, as shown Fig. 2 LEFT.

Figure 2: LEFT: For $A = 5$, $\epsilon = .03$. comparison of the critical value μ_{tip} (black solid line) valid for $\lambda \lesssim 1$ and the limiting μ_{sv} for larger λ (blue dotted line). Red stars indicate tipping in the numerical solution to (1), corresponding to the value of μ at which x reaches 1. The red dash-dotted line is the analogous results for the smooth fold bifurcation analyzed in [2], for comparison. CENTER: The tipping value for μ_{sv} approximated by (3) (solid red line) and compared with the numerical result from (1) (black dots) with $A = 0$, taking $x_{tip} = 1$. RIGHT: Same as LEFT, but for (4).

Applications in larger systems

We apply a similar approach in higher DOF models, illustrated via the non-dimensionalized Stommel box model for thermohaline ocean circulation [3],

$$\begin{aligned} \dot{V} &= \eta_1 - \eta_2 + \eta_3(T - V) - T - V|V| + A \sin(\Omega t), & \dot{\eta}_2 &= -\epsilon \\ \dot{T} &= \eta_1 - T(1 + |V|) + B \sin(\Omega t), & T(0) &= T_i, \quad V(0) < 0, \quad \eta_2(0) = \eta_{2i} > \eta_1 \eta_3. \end{aligned} \quad (4)$$

Here V is the difference between non-dimensional temperature T and salinity S , with underlying static bifurcation structure of V vs. η_2 similar to that of (1) in Fig. 1. Then the equilibrium branches for $V > 0$ ($V < 0$) corresponds to a temperature (salinity)-dominated state. There is slow variation in time for $\epsilon \ll 1$ of the bifurcation parameter η_2 and high frequency oscillations $\Omega \gg \epsilon^{-\lambda}$ for $\lambda > 0$ with amplitudes A and B . Model parameters η_1 and η_3 are positive constants. The varying parameter η_2 is related to the freshwater flux, as also studied in Roberts [4]. Variations in (η_1, η_3) are captured by nonzero A, B , analogous to observed behavior in Huybers [5]. Using the approaches developed for (1), we obtain approximations for the DB/TP η_{2tip} as shown in Fig. 2 RIGHT for the NS dynamic bifurcation, capturing the transition from solutions near the salinity-dominated branch for $V < 0$. Note, as in Fig. 2 LEFT, an advanced DB/TP relative to the static bifurcation point $\eta_{2c} \approx 1.5$ occurs for larger values of A/Ω . Lagged DB/TP occurs for smaller A/Ω , with an asymptote to the lag corresponding to slow variation of η_2 and $A = 0$.

Potential influence of coherence resonance in non-smooth dynamic bifurcations

For the model (4) forced by white noise rather than oscillatory forcing, there is the potential for a coherence-resonance (CR)-driven advance of the tipping point. A linear analysis of the salinity-dominated branch for $V < 0$, with static NS bifurcation at $\eta_2 = \eta_{2c}$, shows that the corresponding eigenvalues can be either real or complex. This behavior is in contrast to a smooth fold bifurcation with real eigenvalues of its near-by linearized system, e.g. as is the case for the temperature-dominated branch of (4) for $V > 0$. For the salinity-dominated branch of (4) for $V < 0$, the eigenvalues are typically complex as η_2 approaches η_{2c} , allowing for CR in which noise excites the frequency corresponding to the complex part of the eigenvalues, even if the real part is negative. Using a measure of CR based on the power spectral density of the fluctuations about the attracting salinity-dominated branch, we identify parameter ranges for which this CR produces a large probability of advanced tipping to the temperature-dominated state. (This is also joint work with Ziming Yin, now a co-op at Scotiabank in Toronto, CA.)

Conclusions

Via multiple scale analyses we capture the different parametric dependencies of dynamic bifurcations, i.e. tipping points, in forced systems with smooth and non-smooth (NS) dynamic fold bifurcations. For $O(1)$ forcing amplitude with high frequency oscillations, the advance in the tipping point is larger in the NS case, since the contributions from the lag due to slow variation of parameters is reduced relative to the smooth case. Furthermore, we find that coherence resonance-driven tipping can advance NS fold bifurcations since switching surfaces rather than loss of local attraction to the equilibrium state generates the bifurcation. Then the eigenvalues describing the local behavior near the NS fold bifurcation may be complex, so that the noise can excite frequencies corresponding to the imaginary part of these eigenvalues.

Summary. This study proposes to investigate the effects of dry friction on the behaviour of a parametrically excited nonlinear oscillator using a pendulum as example. A harmonic balance method and time integration simulations are used to respectively compute and validate the solutions of the problem and their stability. The effects of dry friction on the behaviour of the system are discussed.

Context

The parametric resonance phenomenon comes from the excitation of a dynamical system through the modulation of one of its parameter and can be simply described by the Mathieu's equation [1]. This phenomenon has been widely used to enhance the dynamical behaviour of systems for energy harvesting or parametric amplification [2, 3]. Usually it occurs for a forcing frequency different from the resonance of the excited system and results in infinite amplitude of oscillation if no non linearities are present. The latter are thus necessary to stabilize the system motion and obtain a finite amplitude of oscillation. An example of such a system is given by the Mathieu-Duffing's equation. When adding viscous damping, a forcing amplitude threshold depending on the damping coefficient must be overcome to initiate parametric oscillations. Although dry friction is also a common source of damping, few studies deal with this kind of problems [4]. The present study proposes to investigate the effects of dry friction on the behaviour of a parametrically excited nonlinear oscillator. The governing equation is given and the example of the pendulum is used as illustration. A harmonic balance method is used to compute theoretical solutions of the problem. Time integration simulations are compared to these solutions to validate the model and its stability. The effects of dry friction on the behaviour of the pendulum and on its forcing amplitude threshold are discussed.

Theoretical motion of a parametric nonlinear oscillator with dry friction

Governing equation

The Mathieu-Duffing's equation including viscous and dry friction damping terms reads

$$\ddot{\theta} + \mu_1 \dot{\theta} + f_0(\dot{\theta}) + (\omega_0^2 - \delta 4\Omega^2 \cos(2\Omega t)) \theta - \gamma \theta^3 = 0. \quad (1)$$

This equation is the governing equation of a pendulum parametrically excited with a vertical displacement. In this case, θ is the angular displacement of the pendulum and \bullet denotes a derivative relative to time t . $\omega_0^2 = g/l$ is the resonance angular frequency of the system with g the gravitational acceleration and l the length of the pendulum. δ and 2Ω are respectively the amplitude and the angular frequency of the forcing. A factor 2 is joined to Ω since the parametric resonance occurs at half of the excitation frequency in the case of the pendulum. The factor $4\Omega^2$ appears due to the double derivative relative to time of the forcing displacement term. The nonlinear coefficient γ comes from the linearisation of the \sin term describing the motion of the pendulum. The viscous damping coefficient is μ_1 and the dry friction term is described by the non-smooth function $f_0(\dot{\theta}) = \mu_0 \text{sign}(\dot{\theta})$ if $\dot{\theta} \neq 0$ and $f_0(\dot{\theta}) \in [-\mu_0, \mu_0]$ if $\dot{\theta} = 0$, with μ_0 the dry friction coefficient.

Harmonic balance approach

The harmonic balance method (HBM) is used to find the solutions of Equation (1) using a Fourier series expansion of the angular displacement with only one harmonic :

$$\theta(t) = a(t) \cos(\Omega t + \beta(t)) \quad (2)$$

Substituting (2) in (1), considering the expansion of the dry friction function as a one term Fourier series and equating each harmonics in Ω and 3Ω with zero results in a system of four equations named \mathcal{S} . Equating all time derivatives of \mathcal{S} with zero and neglecting harmonics higher than the first order, one finds that the amplitude of fixed points can be obtained solving the following equation :

$$\frac{9}{16} \gamma^2 a^6 - \frac{3}{2} \gamma (\omega_0^2 - \Omega^2) a^4 + [(\omega_0^2 - \Omega^2)^2 + \Omega^2 \mu_1^2 - 4\Omega^4 \delta^2] a^2 + \frac{8}{\pi} \Omega \mu_0 \mu_1 a + \frac{16}{\pi^2} \mu_0^2 = 0 \quad (3)$$

The amplitude a is numerically computed to find the non trivial solutions of the pendulum motion. Then, the phase β of the angular displacement is computed such as

$$\tan(2\beta) = \frac{(\Omega \mu_1 a + \frac{4}{\pi} \mu_0)}{(\frac{3}{4} \gamma a^3 - (\omega_0^2 - \Omega^2) a)} \quad (4)$$

It is worth mentioning that the trivial solutions $a = 0$ cannot be found with Equation (3) even if these solutions obviously exist according to experiments. The stability of solutions is computed using the method of varying amplitude [5]. The Jacobian \mathcal{J} of the system \mathcal{S} is first calculated. Then, the stability of the solutions is evaluated using the sign of its trace and determinant. Assuming $\mu_1 > 0$, the trace of \mathcal{J} is found to be negative. Thus, the condition for stability is achieved when the determinant of \mathcal{J} is positive.

Time integration approach

Time integration simulations of Equation (1) are used to (i) validate the solutions found using the HBM, (ii) study the trivial solutions of the system when $\mu_0 \neq 0$ and (iii) validate the solution stability computed with the method of varying amplitude. Simulations are computed using the ode45 solver from Matlab (MathWorks, Natick, USA). To avoid numerical issues due to the discontinuities brought by the dry friction term, the switch model proposed in [6] is used. Thus, the dry friction function is not regularized but replaced by a function including a transition phase in addition to the usual stick and slip phases. Backward and forward frequency sweeps are done to obtain the trivial and periodic solutions.

Results

Figure 1 presents solutions of Equation (1) computed with the HBM and time integration simulations. The black dot-

Figure 1: Solutions of Equation (1) computed with the harmonic balance method (lines) and time integration simulations (circle markers) for $\omega_0 = 1$, $\gamma = 1/6$, $\delta = 0.07$, $\mu_1 = 0.1$ and $\mu_0 = 0$ (red) or $\mu_0 = 0.015$ (blue). Plain and dashed lines correspond respectively to stable and unstable solutions. The black dotted line is the conservative solution of the system ($\delta = 0$, $\mu_1 = 0$, $\mu_0 = 0$). The blue cross corresponds to the birth of the isola.

ted line is the backbone curve of the system computed using the HBM. Red lines are the well-known solutions of the parametric pendulum without dry friction whose behaviour is softening. The trivial solution is unstable between the two bifurcation points of the periodic orbits. In this region, the pendulum necessarily jumps on the stable non trivial solution branch when the forcing amplitude is larger than the critical value given by the HBM $\delta_{cr} = \mu_1/2\Omega$. Blue lines are the solutions of the parametric pendulum with dry friction. In this case, non trivial solutions are disconnected from the trivial ones which are always stable according to time integration simulations. According to HBM, the birth of the resulting isola does not occur from a zero amplitude but from a point represented by the blue cross in Figure 1. It is worth mentioning that the HBM does not predict this birth point onto but nearby the backbone curve. The critical forcing amplitude needed to give birth to the isola depends on both the viscous and dry friction coefficient. However, the HBM does not allow the computation of an analytical value for this threshold.

Conclusion and perspectives

A Mathieu-Duffing's equation including a dry friction term was investigated to describe the dynamical behaviour of a parametrically excited oscillator. The example of the pendulum was used to illustrate this problem. Solutions and their stability were respectively computed using a harmonic balance approach and the method of varying amplitude. Results were validated using time integration simulations. The dry friction gave birth to isolated solutions. To further investigate these solutions, the energy principle method detailed in [7] will be used to analytically derive the critical forcing amplitude needed to give birth to the isola. The influence of other parameters like initial conditions on the existence of non trivial solutions will be also discussed.

Experimental Verification of Stability Theory for a Planar Rigid Body with Two Unilateral Frictional Contacts

Yizhar Or*, Peter L. Varkonyi**

*Faculty of Mechanical Engineering, Technion - Israel Institute of Technology, Haifa, Israel.

**Department of Mechanical Materials and Structures, Budapest University of Technology and Economics, H-1111 Budapest, Hungary.

Summary. Stability of equilibrium states in mechanical systems with multiple unilateral frictional contacts is an important practical requirement, with high relevance for robotic applications. In our previous work, we theoretically analyzed finite-time Lyapunov stability for a minimal model of planar rigid body with two frictional point contacts. Assuming inelastic impacts and Coulomb friction, conditions for stability and instability of an equilibrium configuration have been derived. In this work, we present for the first time an experimental demonstration of this stability theory, using a variable-structure rigid "biped" with frictional footpads on an inclined plane. By changing the biped's center-of-mass location, we attain different equilibrium states, which respond to small perturbations by divergence or convergence, showing remarkable agreement with the predictions of the stability theory. Using high-speed recording of video movies, good quantitative agreement between experiments and numerical simulations is obtained, and limitations of the rigid-body model and inelastic impact assumptions are also studied. The results prove the utility and practical value of our stability theory.

Many robotic systems are based on establishing contacts between bodies, for performing tasks of object manipulation or locomotion. Several characteristic types of contact-based robotic motion exist. In robotic grasping, contacts are typically used to enforce kinematic constraints that immobilize an object with zero relative motion, so contacts are maintained persistent. On the other hand, dynamic tasks such as object juggling and rapid legged locomotion involve intermittent contacts where impacts induce non-smooth transitions in contact states. An intermediate regime uses *quasistatic* manipulation and locomotion tasks with non-prehensile contacts. Such motion often relies on unilateral contacts that are maintained in persistent no-slip state imposed by equilibrating forces that satisfy frictional contact constraints. A common example is quasistatic legged locomotion on rough terrain where gravitational load is resisted by contact forces at the feet's supports.

In the regime of quasistatic motion with unilateral contacts, it is of practical importance to consider *stability* of multi-contact equilibrium states under disturbances caused by model uncertainties, joint coordination inaccuracies, irregular contact surfaces, and more. Common approaches consider robustness of the solution for equilibrium contact forces under disturbances such as localized elastic deformations at contacts or margins of potential energy. A main limitation of these approaches is assuming persistent contacts without accounting for dynamics under small initial perturbations about equilibrium, that do not necessarily maintain contact constraints. This is close in spirit to the well-known concept of *Lyapunov stability* in dynamical systems theory. Analysis of this type of dynamic stability in multi-contact systems is challenging, since any small initial perturbation of displacements and velocities immediately induce response governed by hybrid dynamics involving non-smooth transitions between contact states and impacts. Such systems often involve complicated phenomena such as solutions with *Zeno behavior* and more rarely, *Painlevé paradox* where friction-dominated solution is either indeterminate or inconsistent.

Our recent joint work [1] presented theoretical analysis of finite-time Lyapunov stability for a planar rigid body with two frictional contacts and frictional inelastic impacts. The analysis in [1] reduced the hybrid dynamics of the system in close vicinity of an equilibrium state to a scalar Poincaré map R and scalar magnitude-growth function G , which together encompass the entire response and contact state transitions. Under specific restrictions called *persistent equilibrium*, the work [1] derived theoretical conditions for stability and instability of frictional two-contact equilibria based on properties of the semi-analytic functions R and G , and showed how stability can depend on structural parameters such as friction coefficients and center-of-mass location relative to contact positions.

The goal of this work is to present, for the first time, an experimental demonstration of our stability theory from [1]. Our experimental setup consists of a rigid "biped" with variable structure, which is perturbed from frictional two-contact equilibrium state on an inclined plane. We first present extension of our theoretical analysis in [1] to account for a relaxed notion called *weakly-persistent equilibria* and also derive a simpler stability condition. Both modifications cover cases which are relevant to actual properties of our experimental biped and contact geometry. Upon shifting the biped's variable center-of-mass, our theoretical predictions indicate changes between the two instability mechanisms towards stability. These stability transitions are demonstrated experimentally, and high-speed camera recording enables tracking the biped's motion for quantitative comparison with theoretical simulations, as well as assessing the validity of our rigid-body model assumptions. We find excellent qualitative and good quantitative agreement between the theoretical predictions and experimental measurements, and conclude that our model slightly underestimates stability, where discrepancies are mainly due to added energy dissipation caused by damped elastic vibrations and footpads' compression during impacts. The results demonstrate the utility and practical value of our stability theory. Our present work is based on our recently submitted paper [2].

Figure 1: Our experimental setup of a biped on a slope, with variable center-of-mass (COM) and unequal friction on both footpads. The biped is given slight initial perturbation from equilibrium and its response is a sequence of impacts and contact states. Stability and instability can be changed by shifting the biped's COM.

Figure 2: Plot of the biped's COM locations in (x, z) plane, where p_1, p_2 denote the footpads' contacts. Colored areas denote COM regions where our theoretical analysis predicts stability, instability, ambiguous equilibrium and no equilibrium. The grid of markers denote experimental results:
 '•' – no equilibrium
 '+' – ambiguous equilibrium
 'x' – unstable equilibrium
 '*' – stable equilibrium

Summary. We present a novel equation of motion for a nonlinear gradient elasticity model. Thereby, higher-order gradient terms are introduced to capture the effect of small-scale soil heterogeneity/micro-structure. Using a newly established finite difference scheme, corresponding solutions including stationary waves are determined. In comparison with a commonly used model for nonlinear seismic waves, which has leading derivatives of second order, the solutions of the novel equations are much smoother. This allows much more accurate numerical computations as well as more realistic predictions of the seismic waves.

Introduction

In order to predict the response of the top soil layers of the earth - the so-called seismic site response- induced by seismic waves, the so-called equivalent linear scheme is used very often. Thereby, soil stiffness and damping are modeled taking a shear modulus and material damping ratio, which are constant in time [1]. However, for high maximum strain levels in the soil layers, the equivalent linear scheme with constant shear modulus and material damping can not adequately represent the behavior of a seismic event over its entire duration, since the strains in the soil layers vary significantly. In order to account for the variation of shear modulus and damping ratio in this case, a nonlinear time domain solution is usually used, e.g. [2].

Actual research in nonlinear modeling for seismic site response is mostly focused on the development of advanced constitutive models, which capture important features of the soil behavior like anisotropy, pore water pressure generation and dilation [3]. In this work, we determine specific solutions including stationary waves in the subsurface, whereby the constitutive behavior is governed by the hyperbolic soil model. Here, the (secant) shear modulus is strain dependent with a non-polynomial nonlinearity. In order to capture the effects of small-scale heterogeneity/ micro-structure, we extend the classical wave equation to a nonlinear gradient elasticity model. This is sometimes also called a higher-order gradient continuum or a micro-structured solid. Compared to the classical continuum, higher-order gradient terms are introduced into the equation of motion, which lead to dispersive effects particularly for shorter waves [4]. These higher-order gradient terms are usually obtained using asymptotic homogenization techniques for periodically inhomogeneous media [4]. Since localized stationary waves exist only because of the balance between dispersive and nonlinear effects, their influence on the behavior of stationary solutions is significant and allows them to propagate without distortion. Since the dispersion prohibits the formation of jumps, physically realizable solutions are obtained.

In this work, the effects of the higher-order gradient terms and the corresponding dispersion are investigated. Thereby, specific solutions of the corresponding equations of motion are presented and compared. It is observed that the classical wave equation contains solutions which have non-physical discontinuities (in the strain) and which vanish in the presence of the higher-order terms.

The structure of this work is as follows: First, we derive the equation of motion of the classical and nonlinear gradient elasticity model, respectively. The derivation is based on Newton's second law and Eringen's general strain-stress relation [5]. Then, an ordinary differential equation is derived, from which stationary solutions for the nonlinear gradient elasticity model are obtained. Afterwards, a numerical scheme for the computation of the derived nonlinear equations of motion in time and space is presented. Using this scheme, solutions of the classical and nonlinear gradient elasticity model are compared. Finally, this work ends with a conclusion.

Model

In this section, a classical and an advanced constitutive model are described in order to capture important features of the soil behavior, respectively. In both cases, the constitutive behavior is governed by the hyperbolic soil model, which results in a strain-dependent shear modulus. As the classical model has non-physical discontinuous solutions, a nonlinear gradient elasticity model is employed.

The classical continuum model

In order to derive the equation of motion, Newton's second law is applied. Let x be the horizontal direction, z the vertical direction and t the time. For transverse waves propagating in the direction of z and considering the one-dimensional situation, it reads [6]

$$\rho \frac{\partial^2 u}{\partial t^2} = \frac{\partial \sigma_{zx}}{\partial z}. \quad (1)$$

Thereby, $u(z, t)$ is the displacement in x , σ_{zx} is the shear stress and ρ is the material density. The corresponding strain can be calculated from the displacement by [6]

$$\varepsilon_{zx} = \frac{1}{2} \frac{\partial u}{\partial z}. \quad (2)$$

In this study, the constitutive behavior is governed by the hyperbolic soil model, which is typically employed for the seismic site response analysis. Here, the strain-dependent shear modulus [7]

$$G(\gamma) = \frac{G_0}{1 + (\gamma/\gamma_{\text{ref}})^\beta} \quad \text{with} \quad \gamma = \sqrt{3}|\varepsilon_{zx}| = \frac{\sqrt{3}}{2} \left| \frac{\partial u}{\partial z} \right| \quad (3)$$

is used, whereby γ_{ref} denotes the reference shear strain and $0 < \beta < 1$ is a dimensionless constant. Applying the stress-strain relationship

$$\sigma_{zx} = 2G(\gamma)\varepsilon_{zx}, \quad (4)$$

Eq. (1) results in

$$\rho \frac{\partial^2 u}{\partial t^2} = \frac{\partial}{\partial z} \left(G(\gamma) \frac{\partial u}{\partial z} \right). \quad (5)$$

This is the wave equation for the classical continuum model.

The nonlinear gradient elasticity model

In order to capture the effects of small-scale soil heterogeneity/micro-structure, the stress strain relationship of Eq. (4) is extended by including higher-order gradient terms. In a nonlinear system, the stress-strain relation can generally be written as [5]

$$\sigma_{zx}(z, t) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} g(z - \zeta, t - \tau, \gamma(\zeta, \tau)) \varepsilon_{zx}(\zeta, \tau) d\zeta d\tau, \quad (6)$$

whereby the kernel function $g(z, t, \gamma)$ contains the specific nonlocality and history dependence. In order to compute the soil behavior using a partial differential equation instead of an integro-differential equation, the kernel function is taken as a combination of Dirac delta functions $\delta(\dots)$. This results in [8]

$$g(z - \zeta, t - \tau, \gamma) = 2(G(\gamma)\delta(z - \zeta)\delta(t - \tau) - L^2 G^{(L)}(\gamma)\delta_{,\zeta\zeta}(z - \zeta)\delta(t - \tau) + T^2 G^{(T)}(\gamma)\delta(z - \zeta)\delta_{,\tau\tau}(t - \tau)). \quad (7)$$

Thereby, $(\dots)_{,\zeta\zeta}$ and $(\dots)_{,\tau\tau}$ denote double partial differentiation with respect to ζ and τ , respectively. Apart from the conventional strain-dependent shear modulus $G(\gamma)$, the kernel function g contains additional strain-dependent elastic moduli $G^{(L)}(\gamma)$ and $G^{(T)}(\gamma)$, respectively. Finally, L and T are time and length scales which specify the nonlocality and history dependence of the medium, respectively.

Without loss of generality, the scales T and L are interrelated in this work by $T^2 = L^2/c_0^2$, whereby $c_0 = \sqrt{G_0/\rho}$ is the shear wave speed corresponding to the small-strain shear modulus G_0 from linear elasticity.

For simplicity, the additional elastic moduli are related to the conventional strain-dependent shear modulus $G(\gamma)$ by

$$G^{(L)}(\gamma) = B_1 G(\gamma), \quad G^{(T)}(\gamma) = B_2 G(\gamma). \quad (8)$$

Thereby, B_1 and B_2 are dimensionless constants. Inserting Eqs. (2), (6), (7) and (8) into (1) results into

$$\rho \frac{\partial^2 u}{\partial t^2} = \frac{\partial}{\partial z} \left(G(\gamma) \frac{\partial u}{\partial z} - B_1 L^2 \frac{\partial^2}{\partial z^2} \left(G(\gamma) \frac{\partial u}{\partial z} \right) + B_2 \frac{\rho L^2}{G_0} \frac{\partial^2}{\partial t^2} \left(G(\gamma) \frac{\partial u}{\partial z} \right) \right). \quad (9)$$

This is the equation of motion of the nonlinear gradient elasticity model used in this work. A comparison of Eq. (9) with Eq. (5) shows that the effects of small-scale soil heterogeneity/micro-structure are accounted for by the higher-order gradient terms multiplied with B_1 and B_2 , respectively.

In this work, the hyperbolic soil model $G(\gamma)$ given in Eq. (3) is also used for the nonlinear gradient elasticity model.

Stationary wave solution

In the following, the influence of the higher-order gradient terms on the behavior of numerical solutions is considered. Thereby, stationary solutions of Eq. (9) are taken considered. These solutions can be determined by assuming that they propagate with constant speed $c \in \mathbb{R}$ through the nonlinear medium while not changing their shape [8]. Applying the transformation $\xi = x - ct$ and assuming stationarity, this results in

$$u_{,tt} = u_{,\xi\xi}c^2, \quad u_{,ztt} = u_{,\xi\xi\xi}c^2, \quad u_{,zt} = -u_{,\xi\xi}c, \quad \frac{\partial}{\partial z} = \frac{\partial}{\partial \xi}. \quad (10)$$

Computing the derivatives of $G(\gamma)u_{,\xi}$ with respect to ξ , we get for $y := u_{,\xi}$ [8]

$$y_{,\xi\xi} = \frac{1}{1 - \beta \left(\frac{\sqrt{3}|y|}{2\gamma_{\text{ref}}} \right)^\beta \left(1 + \left(\frac{\sqrt{3}|y|}{2\gamma_{\text{ref}}} \right)^\beta \right)^{-1}} \left\{ \frac{\rho c^2 \left(1 + \left(\frac{\sqrt{3}|y|}{2\gamma_{\text{ref}}} \right)^\beta \right) - G_0}{B_2 c^2 \rho L^2 - G_0 B_1 L^2} y - \frac{\sqrt{3} \operatorname{sgn}(y)}{2\gamma_{\text{ref}}} \left[2\beta^2 \left(\frac{\sqrt{3}|y|}{2\gamma_{\text{ref}}} \right)^{2\beta-1} \left(1 + \left(\frac{\sqrt{3}|y|}{2\gamma_{\text{ref}}} \right)^\beta \right)^{-2} - (\beta + \beta^2) \left(\frac{\sqrt{3}|y|}{2\gamma_{\text{ref}}} \right)^{\beta-1} \left(1 + \left(\frac{\sqrt{3}|y|}{2\gamma_{\text{ref}}} \right)^\beta \right)^{-1} \right] y_{,\xi}^2 \right\}. \quad (11)$$

Solving this nonlinear second-order ordinary differential equation, stationary wave solutions of Eq. (9) can be computed.

Numerical scheme for the nonlinear gradient elasticity model

In order to compute the corresponding numerical solutions $u(z, t)$ of Eqn. (5) and (9), a numerical scheme based on finite-difference approximations is used. This scheme has been developed by Dostal et al. [8] and solves partial differential equations of the form

$$\rho \frac{\partial^2 u}{\partial t^2} = \frac{\partial}{\partial z} \left(G \left(\frac{\partial u}{\partial z} \right) \frac{\partial u}{\partial z} - B_1 L^2 \frac{\partial^2}{\partial z^2} \left(G \left(\frac{\partial u}{\partial z} \right) \frac{\partial u}{\partial z} \right) + B_2 \frac{\rho L^2}{G_0} \frac{\partial^2}{\partial t^2} \left(G \left(\frac{\partial u}{\partial z} \right) \frac{\partial u}{\partial z} \right) \right). \quad (12)$$

Thereby, $G \left(\frac{\partial u}{\partial z} \right)$ is an arbitrary function depending on $\frac{\partial u}{\partial z}$. If $G \left(\frac{\partial u}{\partial z} \right)$ is chosen as in Eq. (3), Eq. (12) reduces to Eq. (9). If furthermore B_1 and B_2 are set to zero, Eq. (12) becomes Eq. (5). Since all numerical results presented in the next section are based on the scheme developed in [8], we briefly outline it here.

It is assumed that the analytical solution $u(z, t)$ of Eq. (12) exists in space $z \in [Z_\ell, Z_h]$ and time $t \in [0, \mathbb{T}]$. Therefore, a grid in space

$$Z_\ell = z_0 < z_1 < \dots < z_M = Z_h, \quad z_i = i\Delta z \text{ for } i = 0, \dots, M, \quad \Delta z = \frac{Z_h - Z_\ell}{M}, \quad (13)$$

and time

$$0 = t_0 < t_1 < \dots < t_N = \mathbb{T}, \quad t_n = n\Delta t \text{ for } n = 0, \dots, N, \quad \Delta t = \frac{\mathbb{T}}{N}, \quad (14)$$

is introduced, respectively. Defining

$$h(u_{,z}) := G(u_{,z}) u_{,z}, \quad (15)$$

Eq. (12) becomes

$$\rho u_{,tt} = h_{,z} - B_1 L^2 h_{,zzz} + B_2 \frac{\rho L^2}{G_0} h_{,ttz}. \quad (16)$$

In this way, the structure of the considered partial differential equation is exploited. As will be seen later, this simplifies the calculation of the spatial finite difference approximations.

In order to approximate the derivatives with respect to time, it is assumed that the solution is known at the timepoints t_{n-1} and t_n . Let u_i^n be a grid function, which approximates the analytical solution u at space z_i and time t_n , i. e. $u_i^n \approx u(z_i, t_n)$. Furthermore, let $u_{i,z}^n$ be a grid function approximating $u_{,z}(z_i, t_n)$. Replacing the time derivative with a finite difference approximation, Eq. (12) yields

$$\mathbf{f}(\mathbf{u}^{n+1}) = \mathbf{0} \text{ with } \mathbf{u}^{n+1} := [u_0^{n+1}, u_1^{n+1}, \dots, u_M^{n+1}]^T, \quad (17)$$

whereby

$$f_i(\mathbf{u}^{n+1}) := \rho \frac{u_i^{n+1} - 2u_i^n + u_i^{n-1}}{\Delta t^2} - \frac{h_{,z}(u_{i,z}^{n+1}) + 2h_{,z}(u_{i,z}^n) + h_{,z}(u_{i,z}^{n-1})}{4} + B_1 L^2 \frac{h_{,zzz}(u_{i,z}^{n+1}) + 2h_{,zzz}(u_{i,z}^n) + h_{,zzz}(u_{i,z}^{n-1})}{4} - B_2 \frac{\rho L^2}{G_0} \frac{h_{,z}(u_{i,z}^{n+1}) - 2h_{,z}(u_{i,z}^n) + h_{,z}(u_{i,z}^{n-1})}{\Delta t^2}. \quad (18)$$

A solution of Eq. (18) approximates the corresponding exact solution of Eq. (12) up to an accuracy of $\mathcal{O}(\Delta t^2)$.

Next, the space derivatives $h_{,z}(u_{i,z})$ and $h_{,zzz}(u_{i,z})$ at location $z = z_i$ are approximated. Thereby, the following standard finite differences are used, which have all an accuracy of $\mathcal{O}(\Delta z^2)$:

$$u_{i,z} = \frac{u_{i+1} - u_{i-1}}{2\Delta z} + \mathcal{O}(\Delta z^2), \quad h_{,z}(u_{i,z}) = \frac{h(u_{i+1,z}) - h(u_{i-1,z})}{2\Delta z} + \mathcal{O}(\Delta z^2), \quad (19)$$

$$h_{,zzz}(u_{i,z}) = \frac{h(u_{i+2,z}) - 2h(u_{i+1,z}) + 2h(u_{i-1,z}) - h(u_{i-2,z})}{2\Delta z^3} + \mathcal{O}(\Delta z^2).$$

In order to simplify the notation, the time index n is omitted. If the hyperbolic soil model $G(u, z)$ from Eq. (3) is used, we get for $h_{,z}$:

$$\begin{aligned} h_{,z}(u_{i,z}) &= \frac{h(u_{i+1,z}) - h(u_{i-1,z})}{2\Delta z} + \mathcal{O}(\Delta z^2) \\ &= \frac{1}{2\Delta z} \left\{ \frac{G_0}{1 + \left(\frac{\sqrt{3}}{2} \frac{|u_{i+2} - u_i|}{2\Delta z \gamma_{\text{ref}}} \right)^\beta} \frac{u_{i+2} - u_i}{2\Delta z} - \frac{G_0}{1 + \left(\frac{\sqrt{3}}{2} \frac{|u_i - u_{i-2}|}{2\Delta z \gamma_{\text{ref}}} \right)^\beta} \frac{u_i - u_{i-2}}{2\Delta z} \right\} + \mathcal{O}(\Delta z^2). \end{aligned} \quad (20)$$

The approximation of $h_{,zzz}$ follows analogously.

Now the advantage of the presented numerical scheme can be seen: In Eq. (12), the third-order space derivative of $G(u, z)$ has to be computed. However, since the hyperbolic soil model defined in Eq. (3) contains the absolute value function $k(x) = |x|$, the function $G(u, z)$ is only one time weakly differentiable. By introducing the function h , the problem of the missing differentiability is circumvented.

With this, the solution \mathbf{u}^{n+1} of $\mathbf{f}(\mathbf{u}^{n+1}) = \mathbf{0}$ can be computed solving a nonlinear system of equations. This can be done iteratively using Newton's method, for example.

Numerical results

In this section, numerical results for the nonlinear Eqs. (5) and (9) are shown. Corresponding results are compared in order to investigate the effects of the higher-order gradient terms. Thereby, the parameters from Table 1 are used. While the values of G_0 , ρ , β and γ_{ref} have been chosen to represent soil, the values of B_1 and B_2 are similar to the ones used in [4].

Table 1: Medium parameter values.

G_0 [Pa]	ρ [kg m ⁻³]	β [-]	γ_{ref} [-]	B_1 [-]	B_2 [-]	L [m]
$111.86 \cdot 10^6$	2009.8	0.91	10^{-3}	1	1.78	0.2

Solutions of a Gaussian pulse

First of all, the effects of the higher-order gradient terms are studied for a specific solution, where as initial condition a Gaussian pulse is used:

$$u(z, t = 0) = u_0 \exp\left(-\frac{z^2}{2\sigma^2}\right). \quad (21)$$

Here, the amplitude of the pulse is set to $u_0 = 0.0016$ m and the standard deviation is set to $\sigma = 1$ m. In accordance with [2], these values are chosen to obtain a relatively high strain level. The temporal evolution of the numerical solution is computed using the scheme described in the last section, whereby absorbing boundary conditions are applied. Thereby, an additional initial condition u^{-1} at time t_{-1} has to be chosen. In this study, $u^{-1} = u^0$ is used, which results in a solution with no initial velocity.

The resulting solution of Eq. (5) can be seen in Fig. 1. It is observed that the initial pulse divides into two parts, which travel in opposite directions. Furthermore, the numerical solution of the classical model is non-smooth due to the sharp edges (one at the top of the wave and the other at the bottom behind it). This makes the strain discontinuous at those locations, which is not physically admissible. In contrast to this, Fig. 2 shows the corresponding solution of Eq. (9), where the effect of higher-order gradient terms are taken into account. Again, a solution is shown where the initial pulse is divided into two parts. However, the shape of the solution is smoother and does not contain sharp edges. Instead of sharp edges, small oscillations are observed behind the wave, which is consistent with the findings in [4]. This can also be seen in Fig. 3, which shows the corresponding solutions at the end of the simulation time together with the used initial condition. By introducing dispersion, the higher-order gradient terms lead to a solution where sharp edges do not occur and therefore lead to a physically admissible behavior.

Moreover, Fig. 3 shows that after division, both solutions travel with the same speed. Furthermore, a negative displacement is observed at $z = 0$ m after the initial pulse has departed. This could be caused by the combination of the hyperbolic soil model with the Gaussian pulse that has non-zero content at zero wavenumber. However, this shift in negative direction decreases for increasing time. This is shown in Fig. 4, which shows the solution at $z = 0$ m over time.

Stationary solution of the nonlinear gradient elasticity model

Next, the effects of the higher-order gradient terms on the stationary solution of Eq. (9) are investigated. For this, Eq. (11) is computed for the velocity $c = 100$ m/s. Since the numerical scheme of the last section needs an additional initial condition u^{-1} at t_{-1} , the corresponding value has to be calculated. As the stationary solution propagates with speed c , the value of u^{-1} is computed by shifting u^0 in space by $c t_{-1}$. Since the solution of Eq. (11) is periodic in space, periodic boundary conditions are used to calculate the temporal evolution of the solutions of Eqs. (9) and (5), respectively.

From Eq. (11), the corresponding phase portrait for u_ξ and $u_{\xi\xi}$ can be obtained. In the following, we study solutions where the trajectories approximate the homoclinic orbit. Using the solution of Eq. (11) as initial condition, the resulting

Figure 1: Numerical solution of Eq. (5) for the classical model. Thereby, a Gaussian pulse is chosen as initial condition. The solution is shown from two different perspectives.

Figure 2: Numerical solution of Eq. (9) for the higher-order elasticity model. Thereby, a Gaussian pulse is chosen as initial condition. The solution is shown from two different perspectives.

Figure 3: Comparison of the numerical solutions of Eqn. (5) and (9) at the end of the simulation time. In both cases, the Gaussian pulse is used as initial condition. The solution is shown for (a) $z \in [-200 \text{ m}, 200 \text{ m}]$ and (b) $z \in [120 \text{ m}, 200 \text{ m}]$, respectively.

solution of Eq. (9) is shown in Fig. 5. It is shown that the solution consists of two plateaus with different heights, which are alternating in space. As the shape of the solution is not changing in time, this is truly a stationary solution.

In order to investigate the effects of the higher-order gradient terms on the stationary solution, Fig. 6 shows the solution of Eq. (5). Thereby, the same initial condition as in Fig. 5 is used. It can be seen that high disturbances are introduced into the temporal evolution of the solution. These disturbances have their spatial origin in the transition area between the two plateaus of the initial condition, where high derivatives occur. They move in the opposite direction to the corresponding stationary solution.

Moreover, Fig. 7 compares the corresponding solutions at the end of the simulation time. It is observed that the higher-order-gradient terms and the disturbance shown in Fig. 6 change the shape of the solution. This shows that the dispersive effects influence the behavior of localized stationary solutions significantly, as they only exist exactly due to the balance

Figure 4: Comparison of the numerical solutions of Eqn. (5) and (9) at $z = 0$ m. In both cases, the Gaussian pulse is used as initial condition.

of nonlinear and dispersive effects. Once the dispersive terms are removed, the stationary solution can no longer exist. It has to be noted that oscillations of very small wavelength occur in the solution of Eq. (5). These are arising due to the large values of the derivatives, which lead to numerical inaccuracies. However, these inaccuracies have such a small effect on the solution behavior that they do not destroy the structure of the solution.

Figure 5: Numerical solution of Eq. (9) for the higher-order elasticity model. Thereby, the stationary solution of Eq. (11) is chosen as initial condition. The solution is shown from two different perspectives.

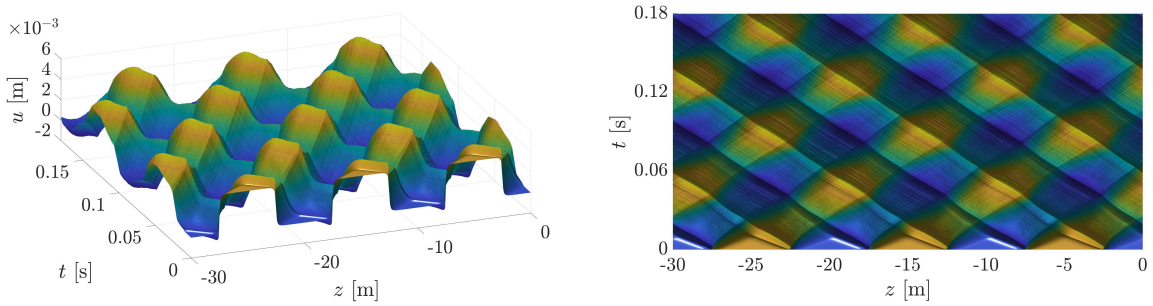

Figure 6: Numerical solution of Eq. (5) for the classical model. Thereby, the stationary solution of Eq. (11) is chosen as initial condition. The solution is shown from two different perspectives.

Figure 7: Comparison of the numerical solutions resulting from Eqn. (5) and (9) at the end of the simulation time. In both cases, the stationary solution of Eq. (11) is used as initial condition.

Conclusions

The response of the top layers of the earth induced by seismic waves is investigated. In this study, the constitutive behavior is governed by the hyperbolic soil model, whereby the shear modulus is strain dependent. The effects of small-scale heterogeneity/micro-structure is captured by considering higher-order gradient terms, which introduce dispersive effects. These effects are investigated in this work. For this, the corresponding equations of motion are solved using a numerical scheme, which has been introduced in Dostal et al. [8]. This scheme exploits the structure of the equation of motion and provides an accuracy of $\mathcal{O}(\Delta t^2 + \Delta z^2)$ in time and space.

Having applied this scheme using the Gaussian pulse as initial condition, it is shown that the higher-order gradient terms prohibit the formation of jumps. In this way, they lead to physically realizable solutions.

Moreover, the effects of the higher-order gradient terms are studied for the stationary solution of the equation of motion. Here, it is shown that the dispersive effects influence the behavior of localized stationary solutions significantly, as they only exist exactly due to the balance of nonlinear and dispersive effects. Once the dispersive terms are removed, the stationary solution can no longer exist.

In conclusion, this work shows that the proposed nonlinear gradient elasticity model provides physically realizable solutions. The introduced higher-order gradient terms are necessary and have significant influence on the corresponding solutions.

Summary. We explore the breather propagation in a damped oscillatory chain with substantially nonlinear (non-linearizable) nearest-neighbour coupling. It is demonstrated that the combination of the damping and substantially nonlinear coupling leads to rather unusual two-stage pattern of the breather propagation. The first stage occurs at a finite fragment of the chain and is characterized by power-law decay of the breather amplitude. The second stage is featured by extremely small breather amplitudes that decay hyper-exponentially. Thus, one can speak about finite penetration depth of the breather – breather arrest. Specific models considered are the chains of damped linear oscillators with Hertzian or purely cubic nonlinear contact between the nearest neighbours. The effect of the initial excitation and of the viscous damping on the breather penetration depth is explored and approximate scaling relationships between these two parameters are established. These results are then rationalized by considering a simplified model of two damped linear oscillators coupled by strongly nonlinear springs. By using an approximate analytic procedure, we demonstrate that the initial excitation of one of these oscillators results in a finite number of beating cycles in the system. Then, the beating cycle in this system of two coupled oscillators is associated with the passage of the discrete breather between the neighbouring sites in the chain. Somewhat surprisingly, this simplified model reliably predicts the main features of the breather arrest in the chain of oscillators. Generalization for arbitrary coupling function and effect of pre-compression are also discussed.

Phenomenon of the breather arrest

We consider a chain of linear forced-damped oscillators coupled by essentially nonlinear springs the model is demonstrated in Figure 1.

Figure 1. Sketch of the system

The presence of local damping with impulsive forcing inevitably leads to the energy dissipation and therefore decay of the amplitude of the breather propagating along the chain. In the case of linear viscous damping, one intuitively expects that this amplitude decay will be exponential, thus defining characteristic space scale of the decay. However, if the coupling between the neighbours is essentially nonlinear (i.e. non-linearizable), then, due to peculiar interaction between these two factors (essential nonlinearity and damping) one observes an interesting phenomenon of *breather arrest* (BA). The latter is defined as abrupt switch from power-law to hyper-exponential decay of the maximum breather amplitude, leading to a negligibly small amplitude after penetration to *finite* depth in the lattice. Typical dependence of the breather amplitude on the site number (for the case of Hertzian contacts) is presented in Figure 2.

Figure 2. Typical dependence of the breather amplitude on the site.

Numerical simulations demonstrate that the breather penetration depth n_{arrest} scales with initial velocity A and damping coefficient λ according to the approximate relationship:

$$n_{\text{arrest}} \approx A^k \lambda^l \quad (1)$$

In the case of Hertzian contact, one obtains $k = 0.466$ and $l = -0.931$.

Reduced-order model

To assess the BA phenomenon from theoretical viewpoint, and to rationalize the numeric findings, we consider a simplified model that mimics the breather propagation in the chain with strongly nonlinear coupling. This simplification seems to be viable due to extreme localization of the breather in this specific chain. Therefore, it is possible to adopt, in the crudest approximation, that the breather propagation can be understood as a sequence of energy transfers between subsequent particles. Moreover, due to the strong localization, it is possible to assume that each such transfer involves only two neighbouring particles. Thus, the simplified model will consist of two identical oscillators, grounded through pairs of linear springs and viscous dampers, and with essentially nonlinear coupling, as presented in Figure 3.

Figure 3. Sketch of the simplified model.

When one of the particles is excited with sufficient amplitude, the beating motion occurs. Each beat is associated with the propagation of the breather by one particle. It is possible to demonstrate that the number of such beats will be finite, due to the strong nonlinearity of the coupling. Then, one can obtain the following estimations for the breather penetration depth, and for the dependence of the breather amplitude on the site number before the arrest:

$$n_{\text{arrest}} \approx \frac{A^{\varepsilon-1}}{\lambda}, \quad A_{\text{max}}(n) \approx A \left(1 - \frac{n}{n_{\text{arrest}}}\right)^{\frac{1}{\varepsilon-1}} \quad (2)$$

Here ε is the power of the substantially nonlinear power-law force. These estimations are in good correspondence with numeric findings. If initial pre-compression exists, the asymptotic evaluations (2) are no more valid, but the two-stage pattern of the breather propagation preserves itself, as demonstrated in Figure 4.

Figure 4 Two-stage breather propagation in granular chain with pre-compression.

These results point on generic character of the observed propagation patterns in damped systems with substantially nonlinear coupling

Summary. The free propagation of nonlinear harmonic waves in acoustic metamaterials with inertia amplification is investigated. A Lagrangian model is formulated to describe the nonlinear dynamics of a periodic chain of elastically coupled point masses (atoms), realizing a minimal 1D acoustic metamaterial with local inertia-amplifying oscillators. First, the nonlinear equations of motion governing the free undamped oscillations of the tetra-atomic periodic cell are formulated, and the linear dispersion properties governing the small-amplitude range of wave propagation are determined. Second, the harmonically-periodic solutions characterizing the high-amplitude range of wave oscillations are investigated, by employing the method of nonlinear maps. Some non-standard methodological tools are introduced to consistently apply the map approach to the implicit function characterizing the nonlinear difference equations.

Introduction

The band structure of microstructured periodic media has long been attracting the scientific interest of researchers in linear and nonlinear dynamics. In the last years, a renewed attention has been devoted to the parametric and computational design of phononic microstructured materials, targeted at fine-tuning the periodic microstructure to achieve unconventional, superior of functional dispersion properties [1]. In this respect, the pressing technological demand for light-weight materials serving as mechanical low-frequency filters or isolators has favoured the rapid diffusion and success of acoustic metamaterials [2]. Indeed, the free propagation of elastic waves in acoustic metamaterials can be inhibited – even in the absence of dissipation – by the linear mechanism of *local resonance*, which allows the opening, shifting and widening of spectral band gaps by properly tuning the natural frequency of auxiliary periodic oscillators (*resonators*), locally coupled to the cellular microstructure. From the physical viewpoint, low-frequency resonators tend to combine high flexibility with large inertial masses, conflicting with the requirement of material lightness. In order to circumvent this conundrum, proper solutions of inertia amplification can be adopted by introducing pantographic mechanisms, exploiting levered masses coupled in parallel with elastic stiffnesses [3]. In this framework of extreme mechanical solutions, the combination of high microstructural flexibility, pantographically-amplified oscillations and null or minimal dissipation can be the natural scenario for the development of important nonlinear dynamic phenomena.

Lagrangian model of the acoustic metamaterial

A Lagrangian model is formulated to describe the nonlinear dynamics of a periodic chain of undamped oscillators (Figure 1), in which only linear forces of attraction/repulsion are exchanged between any pair of adjacent point masses (*primary atoms*). The atomic chain represents a minimal physical realization of a 1D acoustic metamaterial with inertia-amplifying auxiliary oscillators (*secondary atoms*), rigidly connected to the primary atoms by a pantographic mechanism.

Equations of motion

Collecting the nondimensional displacement variables $u = U_1/L$, $w = (U_3 - U_1)/L$, $u_\ell = U_\ell/L$ and $u_r = U_r/L$ in the vector $\mathbf{u} = (u, w, u_\ell, u_r)$, the exact nonlinear equation governing the motion of the generic cell can be formulated. Expanding in Taylor series around the rest position $\mathbf{u} = \mathbf{0}$ and retaining terms up to the third order, the equation reads

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{K}\mathbf{u} + \mathbf{m}_2(\dot{\mathbf{u}}, \dot{\mathbf{u}}) + \mathbf{n}_2(\ddot{\mathbf{u}}, \mathbf{u}) + \mathbf{m}_3(\mathbf{u}, \dot{\mathbf{u}}, \dot{\mathbf{u}}) + \mathbf{n}_3(\ddot{\mathbf{u}}, \mathbf{u}, \mathbf{u}) = \mathbf{0} \quad (1)$$

The quasi-static equilibrium at the cell boundary nodes is instead governed by the linear equation $\mathbf{K}_p \mathbf{u} = \mathbf{f}_p$, where the external forces $\mathbf{f}_p = (f_\ell, f_r)$ can easily be related to the internal stresses $\boldsymbol{\sigma} = (\sigma_\ell, \sigma_r)$. Partitioning the displacement vector \mathbf{u} , the inner and outer displacement subvectors read $\mathbf{u}_a = (u, w)$ and $\mathbf{u}_p = (u_\ell, u_r)$, respectively. Collecting all the outer variables in the vector $\mathbf{v} = (u_\ell, u_r, \sigma_\ell, \sigma_r)$, the quasi-static equilibrium equations can be inverted to obtain the static condensation rule $\mathbf{u}_a = \mathbf{S}\mathbf{v}$. After condensation, the nonlinear equations of motion reads

$$\mathbf{M}\ddot{\mathbf{v}} + \mathbf{K}\mathbf{v} + \mathbf{p}_2(\dot{\mathbf{v}}, \dot{\mathbf{v}}) + \mathbf{q}_2(\ddot{\mathbf{v}}, \mathbf{v}) + \mathbf{p}_3(\mathbf{v}, \dot{\mathbf{v}}, \dot{\mathbf{v}}) + \mathbf{q}_3(\ddot{\mathbf{v}}, \mathbf{v}, \mathbf{v}) = \mathbf{0} \quad (2)$$

Focusing the analysis on the only periodic solutions in the nondimensional τ -time domain, the real-valued unknown $\mathbf{v}(\tau)$ can conveniently be expressed in Fourier series (truncated to account for the first harmonic terms)

$$\mathbf{v}(\tau) = \sum_{k=-\infty}^{\infty} \mathbf{a}_k e^{ik\omega\tau} \simeq \mathbf{a} e^{i\omega\tau} + \bar{\mathbf{a}} e^{-i\omega\tau}, \quad \text{with } k \in \mathbb{Z} \quad (3)$$

where the Fourier coefficient $\mathbf{a} = (A_\ell, A_r, B_\ell, B_r)$ serves as (unknown) amplitude of the first harmonic component and bar indicates complex conjugate. The nondimensional parameter ω plays the role of circular frequency for the harmonic motion.

Figure 1: Acoustic metamaterial: (a) tetra-atomic crystal structure, (b) periodic cell of the lagrangian model, (c) mechanical properties.

Nonlinear map approach

The nonlinear equations of motion (2) can be linearized in the small-amplitude oscillation range. Therefore, the linear dispersion functions $\omega(\beta)$ relating the frequency ω to the nondimensional wavenumber β can be determined by applying either the Floquet-Bloch theory [4] or the map approach [5]. The latter technique employs the formal analogy between the wave periodicity (in the β -space) and the Lyapunov stability (in the τ -space) for discrete systems. The map approach can be applied to nonlinear systems governed by explicit equations $\dot{\mathbf{y}} = \mathbf{f}(\mathbf{y})$ to analyze the periodic solutions in the high-amplitude range of wave oscillations [6].

However, the nonlinear equations (2) can be manipulated to achieve only the implicit form $\mathbf{g}(\dot{\mathbf{y}}, \mathbf{y}) = \mathbf{0}$, which may require a different mathematical treatment [7]. Specifically, according to the most general definition of discrete implicit map, \mathbf{y}_0 is a p -periodic point of the implicit dynamic system $\mathbf{g}(\dot{\mathbf{y}}, \mathbf{y}, \alpha) = \mathbf{0}$ if

$$\begin{cases} \mathbf{g}(\mathbf{y}_0, \mathbf{y}_1, \alpha) = \mathbf{0} \\ \mathbf{g}(\mathbf{y}_1, \mathbf{y}_2, \alpha) = \mathbf{0} \\ \dots \\ \mathbf{g}(\mathbf{y}_{p-2}, \mathbf{y}_{p-1}, \alpha) = \mathbf{0} \\ \mathbf{g}(\mathbf{y}_{p-1}, \mathbf{y}_0, \alpha) = \mathbf{0} \end{cases} \quad (4)$$

Therefore, the \mathbf{y}_0 stability can be analysed by introducing bifurcation conditions in order to assess the critical values of the parameter set α . The periodic points can be searched for the nonlinear system under investigation by setting $\dot{\mathbf{y}} = (A_r, B_r, \bar{A}_r, \bar{B}_r)$ and $\mathbf{y} = (A_\ell, B_\ell, \bar{A}_\ell, \bar{B}_\ell)$ and assuming ω as control parameter in the α -set.

Equations (4) can be stated and solved for particular p -cases ($p = 1, 2$), giving solutions $\omega(\mathbf{y}_0, \mathbf{y}_1)$ corresponding to $\beta = 2\pi/p$. Using polar representations $A_\ell = a_\ell e^{i\phi}$ and $B_\ell = b_\ell e^{i\varphi}$, Figure 2 shows the amplitude-dependent frequency solutions $\omega(a_\ell)$ or $\omega(b_\ell)$, as obtained by setting $\mathbf{y}_1 = \mathbf{y}_0 e^{i2\pi/p}$. The amplitude-dependent frequency curves have dominant softening behaviour for small amplitudes, as expected for inertial nonlinearities [8], and originate from the linear spectrum for null amplitudes. The softening behaviour tends to enlarge the amplitude-dependent stop bandwidth (green region).

Figure 2: Linear spectrum (blue curves) and amplitude dependent frequency functions (red curves)

Conclusions

Nonlinear periodic solutions for the free wave propagation have been determined for a 1D acoustic metamaterial waveguide with inertia amplification. The nonlinear mapping approach has been employed, as it applies to discrete implicit maps. Amplitude-dependent frequency functions have been determined for particular oscillation periodicities.

Nonlinear dynamics of topological lattices

Rajesh Chaunsali and Georgios Theocharis

LAUM, CNRS, Le Mans Université, Avenue Olivier Messiaen, 72085 Le Mans, France

Summary. Due to the recent discovery of topological insulators in condensed matter physics, a new notion of topology has emerged in association with the intrinsic wave dispersion of a structure. It has led to several mechanical designs with robust localization of energy in space—potentially offering novel applications in energy harvesting, vibration isolation, and structure health monitoring. The framework of topology fundamentally rests on the linear dynamics of the system. In this work, we present our recent efforts to understand the interplay between nonlinearity and topology in mechanical systems. Our system obeys the dynamics that is governed by a second-order differential equation akin to electronic circuits. In particular, we study one-dimensional nonlinear lattices of both Fermi–Pasta–Ulam–Tsingou and Klein-Gordon types and discuss linear stability of topological states, soliton formation, and nonlinearity-induced topological transition. The findings highlight the effect of nonlinearity on the characteristics of topologically-robust edge states and the role of topology in interpreting purely nonlinear states.

Introduction

It is well-known that a periodic arrangement of structural constituents or properties possesses band gaps, and thus, can filter a range of frequencies from propagating in the medium. Recently, the topological characterization of such systems has enabled researchers to see them in a new light. Two periodic systems showing similar band gaps can still be different on topological grounds. This difference is quantified in terms of the topological invariant calculated from band dispersion. At the physical level, the difference manifests as robust edge/surface states in topologically-nontrivial systems. Such modes are “topologically protected” as small impurities in the system do not affect their presence [1].

The majority of studies on the topological mechanical lattices have so far relied on linear wave dynamics. Some open questions in the area are: What is the effect of nonlinearity on the characteristics of topologically-robust edge states? How can the topological framework be used as a novel tool to interpret purely nonlinear states? Along these lines, in this work, using analytical and numerical tools, we examine three particular aspects of the interplay between topology and nonlinearity in mechanical systems shown next.

Linear stability of topological states

As shown in Fig. 1(a), we take a 1D chain that consists of equal masses and two interconnecting linear springs of stiffness coefficients $1 + \gamma$ and $1 - \gamma$. Each mass is grounded with a nonlinear spring of cubic nonlinearity, such that the force (F)-deformation(x) profile is $F = \gamma_0 x + \Gamma x^3$, where γ_0 is the linearized ground stiffness and Γ is the parameter for nonlinearity. In the linear limit ($\Gamma = 0$), this lattice possesses a band gap due to nonzero γ . Depending on the sign of γ , the system makes a topological transition from a trivial to nontrivial state [2]. Consequently, the topologically-nontrivial system supports a robust edge state with frequency inside the band gap. We examine how the onsite nonlinearity affects the form and stability of such a state. In Figs. 1(b) and 1(c), we show the nonlinear edge states (obtained through the continuation of the linear edge state) and their long-time dynamics for the chain with *softening* ($\Gamma < 0$) and *stiffening* ($\Gamma > 0$) types of nonlinearity, respectively. We find that the topological edge states are generally unstable due to oscillatory instabilities, leading to the delocalization of energy into the bulk of the chain. However, we find a frequency regime in the case of the *stiffening* nonlinearity that can support linearly stable edge states. This could potentially be useful in confining high-amplitude vibrations at the edges of structures for a long duration.

Moving Dirac soliton excites topological states

In Fig. 1(d), we take another chain similar to previous chain in the linearized limit; however, it has cubic nonlinearity in interconnecting springs. The force (F)-deformation(dx) profile of two alternating springs is $F = (1 - \gamma)dx + \Gamma dx^3$ and $F = (1 + \gamma)dx + \Gamma dx^3$. Depending on the sign of γ , the system again supports a topological edge state in the linear limit. The frequency of the state lies inside the band gap. Due to nonlinearity, it is possible to find spatially localized solutions that lie in the bulk of the periodic lattice with their frequency inside the band gap. Therefore, for a small band gap ($\gamma \ll 1$) and nonlinearity ($\Gamma \ll 1$), we employ the continuum approximation and find Dirac solitons residing inside the band gap. A stationary soliton is shown in Fig. 1(e). We also find a family of moving solitons in the lattice. We demonstrate numerically in Fig. 1(f) that such moving solitons can be used to excite edge states in lattices from far distances without actually placing the vibration source on the edge of the lattice.

Self-induced topological state by nonlinearity management

To achieve a topological transition in a mechanical lattice using nonlinearity, we take a 1D chain that consists of equal masses and two types of nonlinear springs, a *stiffening* and a *softening* spring, periodically alternating along the chain as shown in Fig. 1(g). We choose force (F)-deformation (dx) profiles for two springs as $F = (1 - \gamma)dx + \Gamma dx^3$ and $F = (1 + \gamma)dx - \Gamma dx^3$. In the linear limit ($\Gamma = 0$) the system supports a band gap; however, the system is in a

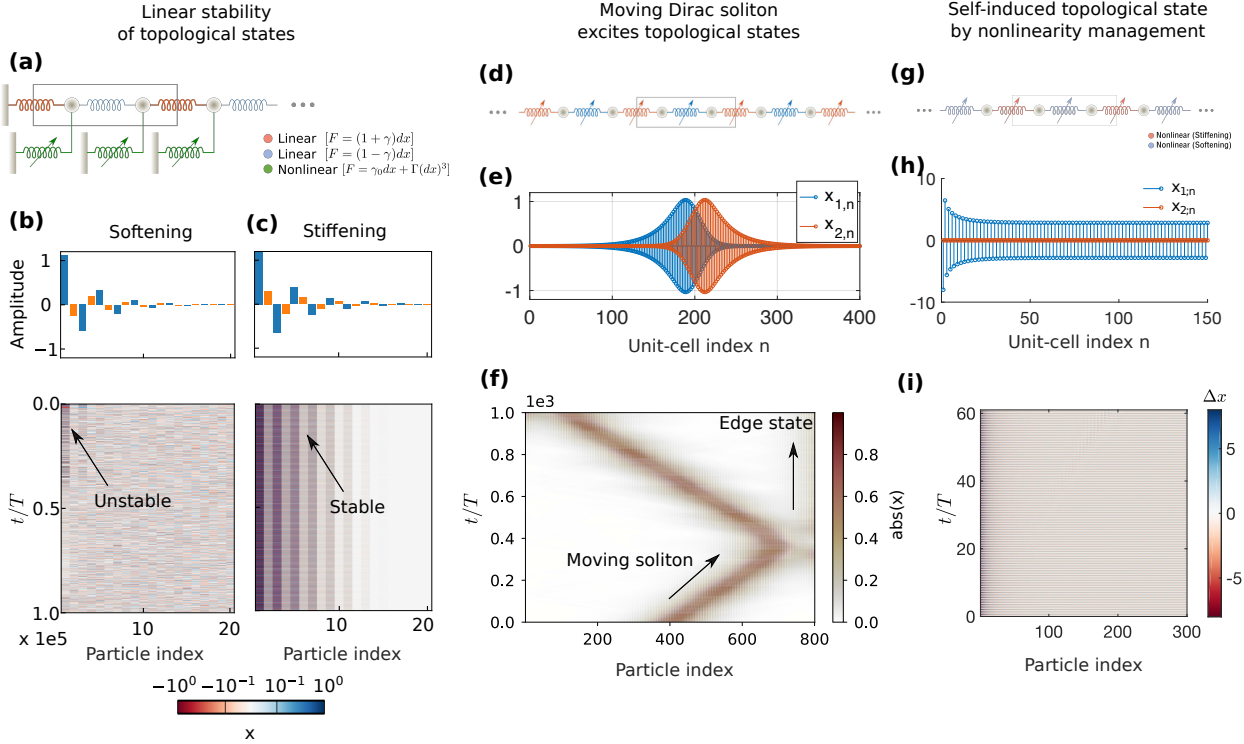

Figure 1: (a) A 1D chain with two linear springs alternating along the length and onsite nonlinearity. (b) One of the nonlinear edge states for *softening* nonlinearity. Below is its spatiotemporal diagram verifying instability. (c) One of the nonlinear edge states for *stiffening* nonlinearity. Below is its spatiotemporal diagram verifying linear stability. (d) A 1D chain with two nonlinear springs alternating along the length. (e) Dirac soliton residing inside the band gap. (f) Spatiotemporal diagram showing a moving Dirac soliton the excites an edge state localized on the right boundary of the lattice. (g) A 1D chain with two types of nonlinear springs (one *stiffening* and another *softening*) alternating along the length. (h) Analytically-obtained edge state in the lattice as a result of the amplitude-dependent topological transition. (i) Spatiotemporal diagram verifying the existence of such a solution in the lattice.

topologically trivial state with no state localized on the edges of the chain. For a system with a small band gap ($\gamma \ll 1$) and nonlinearity ($\Gamma \ll 1$), when the amplitude is increased, we witness an effective closure and reopening of the band gap. This leads to an amplitude-dependent topological transition, and we observe the emergence of a self-induced edge state in the system. We show an analytically obtained profile in Fig. 1(h). We note that this has a unique profile different from the ones seen in linear systems. Instead of the amplitude decaying to zero farther away from the edge, we note that it saturates to a nonzero amplitude [3]. We then verify the existence of this solution by performing full numerical simulations for the lattice. We take the nonlinear solution shown in Fig. 1(h) as initial conditions and obtain the spatiotemporal strain diagram in Figs. 1(i). We do not observe any significant scattering for a short time duration, which verifies the existence of the edge state in the system. This study, therefore, highlights novel ways to tailor nonlinearity in mechanical lattices to achieve a topological transition and localize spontaneously some energy at the edges of the system.

Conclusions

In this work, we discuss three different aspects of studying the nonlinear dynamics of topological lattices. First, we find that nonlinearity can generally make a topological edge state linearly unstable. However, depending on the details of nonlinearity, it is possible to find high-amplitude edge states that are linearly stable. Second, nonlinearity makes it possible to achieve spatial localization of energy in defect-free lattices. These solutions, e.g., moving soliton in our case, can be used to excite topological edge states in the lattices from farther distances. And third, an amplitude-dependent topological transition can be achieved by nonlinearity management in mechanical lattices, such that exotic nonlinear states emerge spontaneously on the edges.

Optimal Controller Gain for the Control Based Continuation of a Duffing-Oscillator

Gleb Kleyma, Sebastian Tatzko, Jörg Wallaschek

Institute of Dynamics and Vibration Research, Leibniz University Hannover, Germany

Summary. In the context of control based continuation for the experimental identification of nonlinear dynamic systems a PD-controller is usually exploited to stabilize the unstable branches of so called S-curves. The literature often refers to a simple trial-and-error method in order to determine the controller gains. In this paper the optimal controller gains for a Duffing-oscillator are determined analytically by applying the Harmonic Balance Method (HBM) to obtain a nonlinear algebraic approximation. However, the generalized methodology can be easily extended to any kind of nonlinear dynamic system.

Introduction

Experimental or Control-Based Continuation (CBC) is a promising method for the bifurcation analysis in real life nonlinear experiments. Exploiting the CBC method, it is possible to track a branch of periodic solutions through a fold bifurcation where they become unstable and continue them up to a second bifurcation point where they become stable again. A typical example for such behavior is the frequency response of vibrating structures featuring nonlinear stiffness, [1]. Typically, thin structures tend to behave like this, as they become geometrically nonlinear when excited to vibration amplitudes in the order of their thickness. In particular, it can be shown that the nonlinear restoring force of thin shell elements can be described by quadratic and cubic stiffness terms, [2, 3]. Considering a modal approach, in the more specific case of a transversely loaded hinged-hinged beam, a Duffing-type differential equation can be assumed, [4]. Here, the stiffness term is cubic, but depends on the mode-shape and type of support.

Experimental characterization of nonlinear oscillating systems is a challenging task. There are only few methods that will identify a nonparametric model of the structure, [5]. CBC is one of these methods. The goal of CBC is to estimate the nonlinear frequency response curves (NLFR). Originally, CBC was proposed by [6] as a tool for the bifurcation analysis of a dry-friction oscillator. However, since then the application of CBC has already been experimentally demonstrated on various systems, such as a parameter excited pendulum [7], an electromagnetic and piezoelectric energy harvesting device [8, 9, 10], a nonlinear tuned mass damper (NTMD) [11], a beam with a locally attached nonlinear spring [12], an impact oscillator [13], a Duffing-oscillator, and frictionally coupled beams [14]. There are also several publications that deal with different extensions and improvements compared to the original method. For instance, the adaption of CBC for tracking of backbone-curves [15, 16], increased robustness against measurement noise [17] and the application of FIR-filters to speed up the measurement time [18]. Even the stability of periodic orbits can be assessed during a CBC experiment, as described in [11] and [19].

A main concern in CBC is the applied control strategy. A feedback control is essential to stabilize the unstable periodic orbits of the system in order to trace them through the bifurcation points. Typically, a PD-controller, corresponding to figure 2 is exploited. After finding suitable controller gains, the amplitude \hat{x}_{ref} of the reference signal is swept (or stepped) and the corresponding force is measured. By means of Newtons method (full CBC), fixed point iteration or an adaptive FIR-filter (simplified CBC), the controller is constrained to be stabilizing but non-invasive with respect to the system dynamics. For the determination of the controller gains, literature often refers to a trial-and-error procedure. However, this can be very time-consuming if at least approximate values are unforeseen. Besides the trial-and-error procedure, in [20], stability maps were created for an impact oscillator by varying the controller gains and evaluating the resulting control error. In that way the optimal settings for this specific experiment were found. Unfortunately, these findings can not be generalized for different types of systems. An application of adaptive control strategies to CBC was presented in [21]. Although the authors approach is formulated for linear systems, they have showed that the method can be successfully applied to nonlinear examples as well. However, the mathematical derivation of the controller equation is very challenging and a generalized proof of concept for nonlinear systems is still pending. This is why we feel like the major control problem is not yet fully solved.

This paper deals with an analytical approximate solution of critical controller gains for a Duffing-type oscillator in a CBC experiment. The Harmonic Balance Method is applied on the closed-loop system in order to determine stabilizing gains of the PD-controller. The results are validated on an experimental single-degree-of-freedom nonlinear oscillator. The concept can be adapted to other systems including the initially mentioned geometrically nonlinear structures. With the developed formula one is capable of predicting the critical controller gains, which can be considered as lower limits, where stabilization is granted. It will be shown, that for polynomial nonlinearities only the polynomial degree and not the coefficients are essential. This makes it very easy to estimate the necessary structural parameters.

Figure 1: Manifold of a single degree of freedom Duffing-oscillator. White: Nonlinear frequency response curve (NLFR), Black: S-curve, Red lines: Unstable branches, Red dots: Fold bifurcation

Figure 1 shows the displacement amplitude of a stiffening Duffing-oscillator as a three-dimensional manifold plotted versus the excitation frequency and excitation force. The white curve is the nonlinear frequency response (NLFR) of the system. The red dots mark bifurcation points and the red curves are unstable periodic solutions. The black curve can be interpreted as the load-displacement characteristic of the system at a constant excitation frequency. Due to the particular shape, it is referred to as a S-curve in literature. Both types of curves (NLFRs and S-curves) are projections of the same manifold to different parameter spaces. Accordingly, an experimental characterization of such systems can be performed in two different ways: A continuation of the NLFRs varying two parameters at a time (frequency and displacement) like proposed by [20] (full CBC) or tracing the S-curves at constant frequency (simplified CBC). Due to the unique correlation between displacement and forcing amplitude in many systems, the latter approach can be considered as the simpler method. The continuation parameter reduces then to a single variable, which is the displacement amplitude. Either way (full or simplified CBC) a feedback controller is essential to stabilize the unstable periodic orbits.

We will focus on the simplified CBC in this paper. Here, each frequency corresponds to a measurement run and so the control parameters can be adjusted between the runs, if necessary. For a detailed description of the CBC method, please refer to the previously mentioned literature. An application of CBC to the experimental Duffing-oscillator presented within this paper is also found in [14].

Figure 2: Feedback control loop utilized for control-based continuation.

Condition for a Stabilizing Controller

The equation of motion (EOM) of the forced Duffing-oscillator reads:

$$m\ddot{x} + d\dot{x} + kx + \alpha x^3 = f. \quad (1)$$

Here f is the excitation force and x is the displacement. Harmonically excited at certain frequencies, in open-loop condition, the system features two stable and one unstable periodic solution, as shown in figure 1. The goal is to stabilize the system by a feedback controller such that for a given reference displacement x_{ref} the unstable branch is accessible. A simple PD-controller, corresponding to figure 2, is exploited for this purpose. In closed-loop the excitation force can be expressed in terms of the controller gains (K_p , K_d) and displacements (x , x_{ref}):

$$f = K_p(x_{\text{ref}} - x) + K_d(\dot{x}_{\text{ref}} - \dot{x}). \quad (2)$$

Inserting equation 2 into 1 the EOM of the feedback-controlled system becomes:

$$m\ddot{x} + (d + K_d)\dot{x} + (k + K_p)x + \alpha x^3 = K_p x_{\text{ref}} + K_d \dot{x}_{\text{ref}}. \quad (3)$$

The simplified CBC exploits the unique parametrization of S-curves, which many nonlinear systems hold to. Varying x , the S-curves can be traced at constant excitation frequencies. In the closed-loop experiment the displacement is controlled by the reference signal x_{ref} . The excitation force settles automatically according to equation 2. Therefore, in an experiment the amplitude of the reference signal is increased while the resulting force is measured and the S-curves are

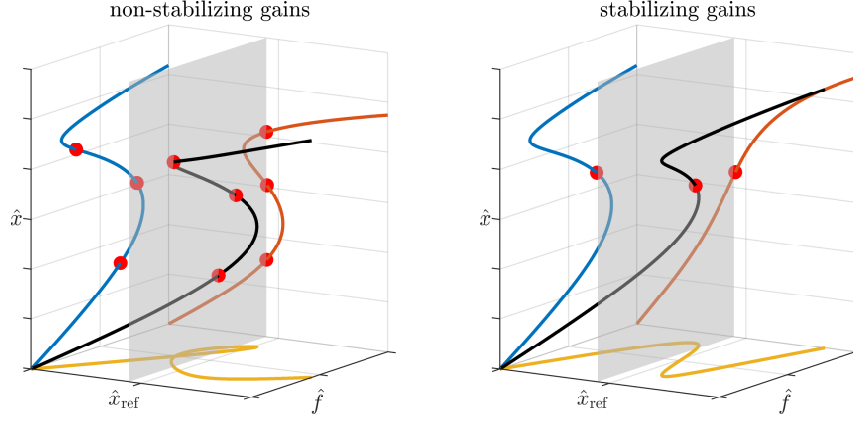

Figure 3: Comparison of the $\hat{x}(\hat{x}_{\text{ref}})$ -parametrization for a set of stabilizing and non-stabilizing controller gains (at a constant frequency).

reconstructed from the amplitude values of x and f . In figure 3, the correlations of the amplitudes \hat{x}, \hat{f} and \hat{x}_{ref} for two sets of controller gains are given as 3-dimensional curves. These curves result from the solution of equation 3 under the assumption of harmonic oscillations (Harmonic Balance Method). The gain settings are chosen for a non-stabilizing effect in the left panel and a stabilizing effect in the right panel. The blue, red and yellow curves are projections into different parameter spaces. The blue curves are the already discussed S-curves. S-curves are exploited to characterize the system and therefore this curves must remain independent of the controller settings. Trying to measure the S-curve with inappropriate controller settings can result in cutting of the extreme points (i.e. the bifurcation points), as shown in section Experimental Validation. The red curves map the reference amplitudes \hat{x}_{ref} to corresponding values of \hat{x} . These shapes are parameterized differently for the two sets of controller gains. For stabilizing control, it is desired that the correlation of \hat{x}_{ref} and \hat{x} becomes unique. This means that for any value of \hat{x}_{ref} there should be only one corresponding value of \hat{x} . This is, what the gray section plane, which runs along a constant value of \hat{x}_{ref} , indicates. If there is only a single solution (operation point), oscillation on the unstable branch of the S-curve can be tuned specifying a certain reference amplitude \hat{x}_{ref} . If there are multiple intersections, the system will automatically settle to a stable solution. From this theoretical considerations, one can claim that the required constraint for a stabilizing control in CBC is the following: *the control gains are optimally set, when the parameterization of \hat{x} and \hat{x}_{ref} becomes unique.*

Derivation of Optimal Control Gains

In order to find the desired control settings for the Duffing-oscillator, the corresponding $\hat{x}_{\text{ref}}(\hat{x})$ -curve is studied analytically. However, the general workflow can be applied to any other nonlinear system, although it may be necessary to extend the principle to a semi-analytical or numerical approach. First, the reference signal is defined to be harmonic and it is assumed that the fundamental harmonic dominates the system response while higher harmonics can be neglected. This approach is known as Harmonic Linearization or Harmonic Balance Method (HBM):

$$\begin{aligned} x &\approx \tilde{x} = \hat{x} \sin(\Omega t), & \dot{\tilde{x}} &= \Omega \hat{x} \cos(\Omega t), & \ddot{\tilde{x}} &= -\Omega^2 \hat{x} \sin(\Omega t) \\ x_{\text{ref}} &= \hat{x}_{\text{ref},s} \sin(\Omega t) + \hat{x}_{\text{ref},c} \cos(\Omega t), & \dot{x}_{\text{ref}} &= \Omega (\hat{x}_{\text{ref},s} \cos(\Omega t) - \hat{x}_{\text{ref},c} \sin(\Omega t)). \end{aligned} \quad (4)$$

The varying phase relation between excitation and response is expressed by splitting the reference signal into sine and cosine components but can also be described by complex numbers, [22]. Next, the nonlinear restoring force is approximated in terms of its Fourier series considering the fundamental harmonic Ω :

$$\alpha \hat{x}^3 = \alpha \hat{x}^3 \sin^3(\Omega t) \approx \frac{a_0}{2} + a_1 \cos(\Omega t) + b_1 \sin(\Omega t), \quad (5)$$

where a_0 , a_1 and b_1 are defined as:

$$a_0 = \frac{1}{\pi} \int_{-\pi}^{\pi} f_{\text{nl}} d\varphi, \quad a_1 = \frac{1}{\pi} \int_{-\pi}^{\pi} f_{\text{nl}} \cos(\varphi) d\varphi, \quad b_1 = \frac{1}{\pi} \int_{-\pi}^{\pi} f_{\text{nl}} \sin(\varphi) d\varphi \quad (6)$$

With $\varphi = \Omega t$. From eq.6 it follows that in the present example $a_0 = a_1 = 0$. Thus, equation 5 turns into:

$$\alpha \hat{x}^3 \sin^3(\Omega t) \approx \alpha \frac{3}{4} \hat{x}^3 \sin(\Omega t). \quad (7)$$

Combing equations 3, 4 and 7 gives:

$$\begin{aligned} &\hat{x} \left(-m\Omega^2 + k + K_p + \alpha \frac{3}{4} \hat{x}^2 \right) \sin(\Omega t) + \hat{x} (d + K_d) \Omega \cos(\Omega t) \\ &= (K_p \hat{x}_{\text{ref},s} - \Omega K_d \hat{x}_{\text{ref},c}) \sin(\Omega t) + (K_p \hat{x}_{\text{ref},c} + \Omega K_d \hat{x}_{\text{ref},s}) \cos(\Omega t). \end{aligned} \quad (8)$$

Because sine and cosine are orthogonal to each other, equation 8 can be further split into terms which contain only sine or cosine components:

$$\begin{aligned}\hat{x}_{\text{ref},c} &= \frac{\Omega}{K_p} ((d + K_d)\hat{x} - K_d\hat{x}_{\text{ref},s}), \\ \hat{x}_{\text{ref},s} &= \frac{\hat{x} (K_d\Omega^2 (d + K_d) + K_p (-m\Omega^2 + k + K_d + \alpha\frac{3}{4}\hat{x}^2))}{K_d^2\Omega^2 + K_p^2}.\end{aligned}\quad (9)$$

It can now be solved for the reference amplitude \hat{x}_{ref} and the $\hat{x}_{\text{ref}}(\hat{x})$ -curve can be derived as a function of the controller gains:

$$\hat{x}_{\text{ref}}(K_p, K_d, \hat{x}) = \sqrt{\hat{x}_{\text{ref},c}^2 + \hat{x}_{\text{ref},s}^2} = \frac{\hat{x} \sqrt{\Omega^2 (d + K_d)^2 + (-m\Omega^2 + k + K_p + \alpha\frac{3}{4}\hat{x}^2)^2}}{\sqrt{K_d^2\Omega^2 + K_p^2}}. \quad (10)$$

Equation 10 is visualized in the left panel of figure 4 for a set of non-stabilizing, critical and stabilizing controller gains. In the right panel of figure 4 the gradient of equation 10 for the same gain settings is given. It is obvious that in order to achieve the desired unique parametrization of $\hat{x}_{\text{ref}}(\hat{x})$, the curve must be monotonous. That means the gradient \hat{x}'_{ref} must remain positive for all values of \hat{x} . For critical gains the two extreme points of $\hat{x}_{\text{ref}}(\hat{x})$ (blue curve) merge into a single saddle point (red curve). Here the $\hat{x}_{\text{ref}}(\hat{x})$ -curve has a horizontal tangent, which means the gradient has only a single zero point. This is why, for gains above this values the closed-loop system becomes stable.

Figure 4: Comparison of the $\hat{x}_{\text{ref}}(\hat{x})$ -curve for a set of stabilizing and non-stabilizing and critical controller gains (at a constant frequency).

First, the special case of a differential controller ($K_p = 0$) is studied. The D-component is sufficient to stabilize most systems featuring nonlinear stiffness. With a differential controller the derivative of equation 10 can be analytically expressed as:

$$\begin{aligned}\hat{x}'_{\text{ref}} &= \frac{d\hat{x}_{\text{ref}}}{d\hat{x}} = \frac{1}{K_d\Omega} \left(\gamma + \frac{\gamma'}{2\gamma} \right) \\ \text{where } \gamma &= \sqrt{\Omega^2 (d + K_d)^2 + \left(m\Omega^2 - k - \alpha\frac{3}{4}\hat{x}^2 \right)^2} \\ \text{and } \gamma' &= \left(\frac{9}{4}\alpha^2\hat{x}^4 + 3(k - \Omega^2 m)\alpha\hat{x}^2 \right)\end{aligned}\quad (11)$$

In order to find the critical value $K_{d,\text{crit}}$, the gradient \hat{x}'_{ref} is set equal to zero, from which follows:

$$2\gamma^2 + \gamma' = 0. \quad (12)$$

Equation 12 can be rewritten as monic polynomial:

$$\hat{x}^4 + \underbrace{\frac{16}{9\alpha} (k - \Omega^2 m)}_p \hat{x}^2 + \underbrace{\frac{16}{27\alpha^2} \left((d + K_d)^2 \Omega^2 + (k - \Omega^2 m)^2 \right)}_q = 0. \quad (13)$$

Solutions of equation 13 for \hat{x} are extreme points of $\hat{x}_{\text{ref}}(\hat{x})$. However, the condition for the critical gain is that the extreme points merge into a saddle point, which means that equation 13 will have only one solution. Substituting $z = \hat{x}^2$

the solution can be expressed as:

$$z = -\frac{p}{2} \pm \sqrt{\frac{1}{4}p^2 - q}. \quad (14)$$

There is only one condition under which equation 14 has zero points at $z = -\frac{p}{2}$:

$$\frac{1}{4}p^2 = q. \quad (15)$$

Solving equation 15 leads to the critical gain $K_{d,crit}$, which is a function of the oscillation frequency Ω and the mass, damping and stiffness coefficients of the system:

$$K_{d,crit} = \pm(k - \Omega^2 m) \frac{1}{\sqrt{3}\Omega} - d \quad (16)$$

Note, that although both solutions (negative and positive) are mathematically correct, only the negative is practically relevant. Equation 16 also reveals that the critical gain is independent of the nonlinear coefficient α . That means, it is only necessary to determine the structural parameter of the underlying linear system for optimal controller settings. In most cases this can be easily done performing a linear experimental modal analysis at low level oscillations.

The critical proportional gain $K_{p,crit}$ can be derived in an analogous way, setting $K_d = 0$ in equation 10. The proportional gain $K_{p,crit}$ becomes:

$$K_{p,crit} = \pm\sqrt{3}d\Omega + m\Omega^2 - k. \quad (17)$$

Here, again the solution has mathematically a positive and a negative sign. However, the negative solution is the only valid one. Note, that for $K_p \neq 0$, K_p becomes part of the solution z in equation 14, which means increasing K_p also increases the displacement amplitude \hat{x} where the saddle point occurs. That means, that the proportional gain alters the general shape of the $\hat{x}_{ref}(\hat{x})$ -parametrization. This fact can be exploited to increase the spatial resolution of the measured curves at some intervals. Although the single proportional-controller has a stabilizing effect in theory, experience shows that in practice this case is rather irrelevant. In real-life applications always a PD-controller should be chosen over a pure P-controller. Without a D-component, the system very slowly approaches a steady state. A PD-controller significantly reduces the settling time.

Figure 5: Critical controller gains for different excitation frequencies.

Figure 5 shows the curves corresponding to equations 16 and 17 for the experimental system from section Experimental Validation in the relevant range of frequencies. The linear natural frequency (LNF) of the system is just below 30 Hz. For frequencies higher than this, stabilization is necessary because the NLFR has a significant overhang, see figure 1. It can be seen, that the critical gains increase almost linearly with the frequency starting at the LNF. At 31 Hz the displacement became so high that the upper bifurcation point could not be reached with the used displacement sensor. However, from the equations it is evident, that both values continue to grow for higher frequencies.

It can be seen that the critical P-gain is about two orders of magnitude above the critical D-gain. Accordingly, considering a displacement and a velocity signal with the same signal to noise ratio, the measurement noise is amplified many times more by a stabilizing P-controller than by a pure D-controller. Therefore, in a practical implementation it depends on the measured variable and signal quality, whether the D-component or the P-component should be weighted more, as several combinations will equally stabilize the system. If a PD-controller is employed, the critical gains are reduced because both values contribute to stabilization. This can be mathematically derived performing the calculation from equations 11 to 15 for both, $K_p \neq 0$ and $K_d \neq 0$. The critical differential gain $K_{d,crit}$ is then a function of the proportional gain K_p :

$$K_{d,crit} = -\frac{1}{\sqrt{3}\Omega} (k + K_p) + \frac{1}{\sqrt{3}}m\Omega - d. \quad (18)$$

m	k	d	α
0.1964 kg	6926 $\frac{\text{N}}{\text{m}}$	0.1046 $\frac{\text{Ns}}{\text{m}}$	$5.27 \cdot 10^7 \frac{\text{N}}{\text{m}^3}$

Table 1: Parameter of the Duffing-oscillator.

From equation 18 it can be concluded, that $K_{d,\text{crit}}$ decreases linearly with K_p but still increases with Ω . Following equation 18 stability maps can be constructed, compare figure 6. Here, the critical gains from equation 16 and 17 are intersections of the curves with the vertical and horizontal axes. The curves themselves are defined by equation 18. These maps are intended to find proper controller gains for different frequencies. Both components can be weighted as preferred by the user. As long as the values lie above the curves, the feedback-control has the desired stabilizing effect on the system.

Figure 6: Stability map for the Duffing-oscillator with system parameters from section Experimental Validation. The lines indicate the stability margin for different excitation frequencies.

Experimental Validation

The theoretical considerations are experimentally validated. Hereby, the focus lies on the hypothesis from equation 10, and the resulting critical controller gains according to figures 5 and 6. The experimental setup is a single-degree-of-freedom oscillator, which has already been investigated in [14] and [23]. Figure 7 shows a picture and a schematic representation of the system. The main components are the fixed frame ①, the voice-coil actuator (VCA) ② and the mass ③. The mass is suspended by guitar strings in the middle of the frame. It is excited by the VCA and moves out of the frame plane as illustrated by the schematic view. The VCA is actuated by a power amplifier for electrodynamic shakers made by TIRA. The amplifier supports a current-mode which enables to control the output current directly. The velocity and displacement of the mass is measured at position ④. Due to the geometric nonlinearity between mass displacement and strain of the guitar strings the oscillator exhibits a significant nonlinear stiffness. Following figure 7 the restoring force can be formulated as:

$$F_k = 8k_s \left(1 + \frac{l_v - l_g}{\sqrt{l_g^2 + x^2}} \right). \quad (19)$$

Here k_s is the axial stiffness of the strings, l_v is the elongation due to the preload force, l_g is the free length from mass to corner and x is the displacement. Approximating equation 19 by its truncated Taylor series the nonlinear EOM of the forced system can be written in analogy to equation 1 as:

$$m\ddot{x} + d\dot{x} + \underbrace{8\frac{k_s l_v}{l_g}}_k x + 4\frac{k_s(l_g - l_v)}{l_g^3} x^3 = f. \quad (20)$$

It can be seen, that this particular system can be well described by a Duffing-oscillator. In order to find the appropriate model parameters, a two-step procedure was conducted. First, the parameters of the underlying linear system (m, d, k) were determined by sweeping through the resonance frequency at a low level excitation (0.02 N from 29 – 31 Hz). The frequency response was observed and the modal parameters were extracted, which already correspond to the physical parameters in the case of a single-degree-of-freedom system. The excitation force was reverse calculated from the measured current flowing through the VCA, because both are proportional. In the second step, the system was excited with a significantly larger force of about 0.1 N. Here during the sweep-up the system showed a jump phenomenon. Assuming the EOM from equation 20 is accurate, the nonlinear coefficient α was determined by an optimization algorithm based on Newton's

method. For this purpose, the measured time-domain data was matched with a time step simulation until the residuum (difference between the envelopes of both signals) became minimal. As an input signal for the time step integration the actually measured force resp. current signal was used. Figure 8 shows a comparison between the measured velocity and the envelope of the model output after optimization. The estimated system parameters are summarized in table 1. In the following the linear part was used to calculate critical gains corresponding to figures 5 and 6. Three different excitation frequencies were chosen to validate the formulas from equation 10, 16 and 18. The critical differential gains $K_{d,crit}$ for these frequencies are given in table 2.

Figure 8: Comparison between measurement and model of the Duffing-oscillator.

After parametric characterization, the CBC procedure was applied to the test-rig. For each CBC run the controller gains were varied around the calculated critical values. The reference amplitude was increased in 0.2 mm steps. First, a pure differential controller was investigated, therefore the P-component was set to zero. In figure 9 the estimated results are shown in comparison with the theoretical curves (black), given by equation 10. On the top panels the $\hat{x}_{ref}(\hat{x})$ -curves are shown for different settings of controller gains and on the bottom panels the corresponding S-curves are plotted. The blue markers indicate values close to the critical gains, see table 2. The red and green markers represent gains below and above the critical values. All measured curves are in good agreement with the theoretical results. Here, especially the red curves illustrate the negative effect of a poorly chosen controller gain. As those curves are not monotonous, at some point the system suddenly transits from one stable solution branch to the other stable solution branch (from A to B on the upper graph). Therefore, a whole interval of displacement amplitudes is missing on this measurements and the upper bifurcation point is skipped. Similar results were achieved for all three frequencies. The gains with the blue markers are chosen to be close to the critical values. Here, the bifurcation regions are sampled quite well. Best results are achieved for controller gains 30 – 50 % above the critical values (yellow markers).

The more common case of a PD-controller was also investigated. Therefore, K_d was set to a constant value and K_p was

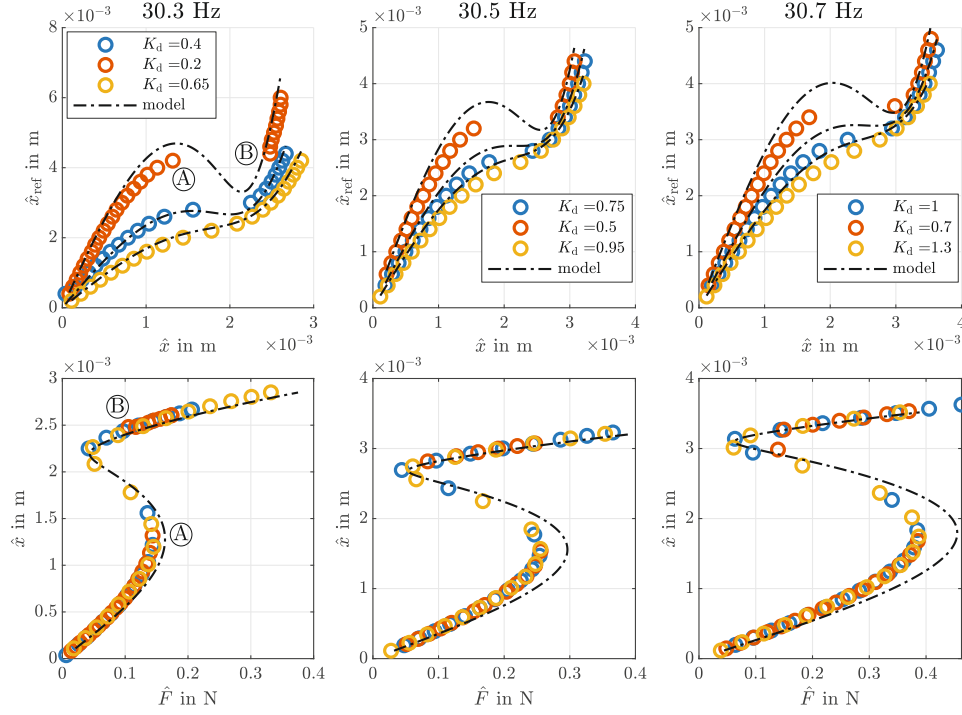

Figure 9: Comparison between measured $\hat{x}_{\text{ref}}(\hat{x})$ -curves resp. S-curves and theoretical curves. For all curves applies $K_p = 0$.

varied. The aim of this experiment was to validate the stability map from figure 6. The results for three different settings of K_d and totally seven pairs of gain settings are shown in figure 10. The graph on the upper left side shows the distribution of the control gains and the remaining three graphs represent the corresponding S-curves. All curves are captured at 33.3 Hz. The crosses correspond to values close to the theoretical stability margin, which is highlighted as the dotted black line, while circles are values within the instability area. It can be seen, that for all unstable gain settings (circles) the S-curves are not entirely captured. Parts of the unstable branches are skipped. However, for values just above the stability margin the s-curves are sampled well, although $\hat{x}_{\text{ref}}(\hat{x})$ has been incremented by the same step size in all experiments. For $K_d = 0.3$ a third measurement was performed, which is represented by the red stars. Here, the proportional gain was chosen significantly higher than in the other two cases. It appears that featuring a higher P-component, the unstable branch is sampled at a finer spatial resolution. This has been predicted in section already. The reason is that the proportional gain shifts the turning point of the $\hat{x}_{\text{ref}}(\hat{x})$ -curve towards higher amplitudes. As a result the $\hat{x}_{\text{ref}}(\hat{x})$ -curve is unfolded to a more parabolic shape and so the spacing between two adjacent \hat{x} -values becomes smaller, as figure 11 illustrates. The marker style and color in figure 11 correspond to those from figure 10. Depending on the controller setting it is possible to trade of between a finer resolution of the lower stable branch or the unstable and upper branch. For either setting the controller is stabilizing. No significant drop of signal quality by the higher proportional gain ($K_d = 0.3$ and $K_p = 61$ compared to $K_d = 0.3$ and $K_p = 142$) was observed. However, measurement noise could be amplified by higher gains and thus decrease signal quality or even lead to instability of the closed loop system. Therefore, controller gains should not be set too high. Critical gains are good starting points for a manual optimization.

To confirm this, a proportional gain of $K_p = 500$ and a differential gain of $K_d = 1.5$ for the final analysis of the system dynamics was chosen. According to figure 6 this gain settings are stabilizing up to 32 Hz. As at 30.9 Hz the displacement amplitude corresponding to the upper bifurcation point became too large for the sensor, only S-curves from 29.6 Hz to 30.9 Hz in 0.1 Hz are studied in figure 12. As it can be seen, all S-curves have an excellent spatial resolution of the unstable branch. Note, that these are raw results, no filtering or averaging has been applied to the fundamental Fourier coefficients. The scattered measurement data points (black) have been interpolated by cubic splines. This is represented by the gray manifold, similar to figure 1. The red curves in the upper graph of figure 12 are the contour plots of this manifold at specific forcing amplitudes. These NLFR-curves are shown in the bottom graph in detail. Due to the chosen interpolation type they appear noisy, here a higher frequency resolution would have been beneficial. Nevertheless, the NLFR-curves give a better understanding of the system response near resonance, including two stable and one unstable branch, than a sweep test like in figure 8. Conclusively it can be stated, that the theoretical considerations from section Derivation of Optimal Control Gains, led to an analytical formula for the critical gains and enabled a significant speed up of the CBC measurement compared to previous studies, [14]. The time consuming part of finding stabilizing controller gains by trial and error could be omitted and was replaced by an efficient preliminary analysis of the examined system. The Duffing-oscillator approximation for the investigated single-degree-of-freedom system is in good agreement with measurements in terms of $\hat{x}_{\text{ref}}(\hat{x})$ - and S-curves.

Conclusion

In this paper an analytical formula has been derived to find critical controller gains for the stabilizing control of a Duffing-oscillator exploiting a PD-controller. Critical gains are described as the minimum necessary gains to stabilize the unstable periodic orbits of the system. The main application is intended to be the control based continuation of systems that can be approximated by a Duffing-oscillator model. For the formula the structural parameters of the underlying linear system are needed, which can be extracted from experimental modal analysis at low level excitation. The prefactor of the nonlinear cubic term is not required. Although in this paper the derivation has been conducted and validated for the single-degree-of-freedom Duffing-oscillator only, the workflow can be generalized and applied to any nonlinear system. The process incorporates the following steps:

- Find an approximate model for the nonlinear system
- Include controller rule in the equation of motion
- Apply Harmonic Balance to solve for $\hat{x}_{ref}(\hat{x})$
- Investigate $\hat{x}_{ref}(\hat{x})$ (or its derivative)
- Critical gains are those values which unfold $\hat{x}_{ref}(\hat{x})$ so that the curve becomes unique

Nonlinear localisation in a cyclic system with unilateral contact

Björn NIEDERGESÄß*, Aurélien GROLET† and Norbert HOFFMANN *

* *Hamburg University of Technology, Hamburg, Germany*

† *LISPEN, ENSAM Lille, Lille, France*

Summary. The following abstract presents a cyclic structure subjected to unilateral contact in order to investigate nonlinear localisation of vibration. After a brief description of the system, a reduced-order model is derived for numerical analysis. Subsequently, the experimental setup is introduced and the system response to harmonic excitation is depicted. In the nonlinear regime vibration localisation is observed with a high amplitude ratio regarding the beam elements of the structure.

Introduction

Localisation of vibration corresponds to states where the vibration energy is spatially localised to a section of the system so that only this section vibrates in high amplitude. It has been observed in a vast variety of systems either numerically, e.g. for coupled Duffing oscillators [1] and coupled beams [2], or experimentally, e.g. for a microbeam array [3] and a macro mass-spring system [4]. The localisation arises from nonlinear modal interaction, such as 1:1 internal resonances [5]. In this work experimental measurements of localised vibration states are reported in a cyclic structure subjected to unilateral contact.

Presentation of the system and reduced-order model

Presentation of the system

The structure investigated in this paper consists of three clamped-free beams with attached tip masses ordered in a cyclic fashion and coupled through slender connections as depicted in Fig.1. When vibrating in the transverse direction the beams are subjected to unilateral contact enforced at a level between the slender connection and the tip mass. Since the mass of the beams is small compared to the attached tip masses it can be neglected and the system can be regarded as three coupled nonlinear oscillators.

Figure 1: First three linear mode shapes of the considered structure. Note that, due to the symmetry, the first two modes have the same eigen-frequency

Reduced-order model

Based on the FEM mode shapes, a lumped mass model with three degrees of freedom can be derived for numerical analysis. The contact nonlinearity for the i -th oscillator is modeled by a bi-linear force $g(u_i)$: in small amplitude, the beam is not in contact so that the force is zero. When the tip displacement reaches a threshold u_g the effective stiffness increases and tends toward one of a beam with "pinned" boundary condition at the position of the contact. The force can be expressed as a bi-linear function of the tip displacement:

$$g(u_i) = \begin{cases} 0 & \text{if } u_i \leq u_g \\ K(u_i - u_g) & \text{if } u_i \geq u_g, \end{cases} \quad (1)$$

where K is the contact stiffness and u_g is the tip displacement at the moment of contact. In order to find periodic solutions to the equations of motion, the harmonic balance method (HBM) is applied. The solution is searched for a truncated Fourier series and the coefficients are obtained by solving a system of nonlinear algebraic equation. This system will be solved by the asymptotic numeric method (ANM). Both methods (HBM and ANM) are implemented in a common framework in the MANLAB package, along with the stability computation of the periodic solutions [6]. The equations of motion are written in a quadratic form for MANLAB and the required regularisation function g_{reg} of the unilateral contact force is obtained over a hyperbola branch which is defined by the following quadratic equation:

$$g_{reg}[g_{reg} - K(u_i - u_g)] = \epsilon, \quad (2)$$

where a smaller regularisation parameter ϵ indicates a hyperbola closer to the piecewise curve.

Experimental setup and results

Description of the experiment

In the experimental setup the structure depicted in Fig 1 and a contact disk share a common base, which is mounted on two slender plates. The base is excited by a shaker (TIRA TV 51140-M) and vibrates harmonically due to the mode of the supporting plates. Therefore a harmonic excitation signal is fed in the shaker in open loop, processed by an ADwin-Gold control box with a sampling frequency of 4kHz. To measure the response of the system accelerometers are glued to the base, as well as to the three tip masses. When the system is excited close to the first eigenfrequency of the structure the coupled beams start touching the contact disk.

Results

Fig. 2 depicts the measured response of the base and the three tip masses m_i of the structure while excited with a frequency of 11.35 Hz. At this excitation level the structure gets in unilateral contact with the disk which amounts in a disturbance of the harmonic excitation depicted in Panel (a). The nonlinear localisation of the structure is depicted in Panel (b) where the amplitude ratio A_1/A_3 is ~ 9.56 ($A_1/A_2 \sim 7.32$ respectively).

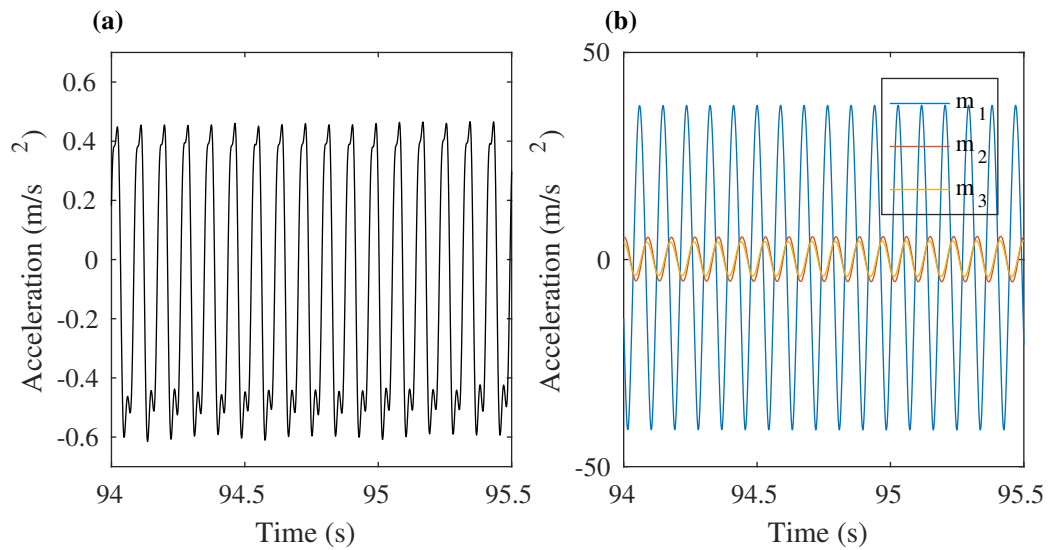

Figure 2: Nonlinear localisation at 11.35Hz : a) Base excitation; b) Response at the tip mass m_i of the structure. m_2 and m_3 vibrate in low amplitude while m_1 vibrates in high amplitude

Conclusions

The abstract considers nonlinear vibrations of a cyclic system subjected to contact nonlinearity. The investigated system can be regarded as a simple qualitative model of more complex structures such as bladed disk in airplane engines. Numerical results based on a reduced-order model indicate that homogeneous solutions can lose their stability to lead to localised states of vibration. The nonlinear localisation is observed in the experimental investigation of the structure.

Summary. Flexible, one-dimensional structures such as slender beams and cables are capable of undergoing highly nonlinear vibrations in extremely large amplitudes. A novel method for computing the behavior and, in particular, the nonlinear modes is here presented based on a geometrically exact finite element beam model that is solved using the continuation software MANLAB. An experimental setup is also described which utilizes a vibration table and Digital Image Correlation to physically observe the extreme amplitude vibration of the flexible cantilever beam.

Figure 1 (Left): Four snapshots of preliminary experiments depicting the first nonlinear mode of a cantilever beam in extreme amplitude, achievable due to the bending capabilities of the flexible structure. Figure 1 (Right): Numerical computation of the first nonlinear mode of the cantilever beam, obtained using the path-following continuation solver, MANLAB [2, 3, 4].

Introduction

Although the field of nonlinear dynamics is vast and dense, nonlinear models of highly flexible structures are a subject of continuing research. Wires, cables, rods and hoses are examples of such flexible structures, as their slender, one-dimensional geometry and corresponding mechanical stiffness allow for extreme bending capabilities, especially when resonance conditions are considered. While several methods already exist for the computation of flexible systems, they are often limited, due to either the amount of required computation time or the limited range of applicability. Current strategies for simulation of nonlinear dynamics often utilize direct time integration schemes to solve the equations of motion. While often adequate for many purposes, these strategies can potentially encounter certain limitations, such as in detecting multiple solutions (if present) or bifurcation points. Additionally, further extensions to existing models are needed to capture the behavior of highly nonlinear dynamical systems, such as the present case of extreme amplitude vibration. For this reason, we here propose a custom continuation algorithm for the periodic solution of geometrically exact finite element beam models undergoing extreme amplitude vibrations. Numerical results are then compared with vibration experiments involving slender beam specimens as seen in Fig. 1 (Left).

Numerical model

A geometrically exact finite element discretization is performed for a cantilever beam geometry using Timoshenko-theory beam elements and a total Lagrangian nonlinear formulation [1]. The model is derived from the weak form variational formulation of the equation of motion of a cantilever beam rooted in the principle of virtual work and is traditionally written, for all time t ,

$$\mathbf{M}\ddot{\mathbf{q}} + \mathbf{D}\dot{\mathbf{q}} + \mathbf{f}_{\text{int}}(\mathbf{q}) = \mathbf{f}_{\text{ext}} \quad (1)$$

where \mathbf{q} is a vector of size $3N$ that gathers nodal displacements u_i , w_i and θ_i representing the axial displacement, transverse displacement and cross section rotation of the i th finite element node, respectively, for N nodes: $\mathbf{q} = [u_1 w_1 \theta_1 \dots u_N w_N \theta_N]^T$. \mathbf{M} and \mathbf{D} are the mass and damping matrices, respectively, each of size $3N \times 3N$; \mathbf{f}_{ext} is

the vector of applied external forces and $\mathbf{f}_{\text{int}}(\mathbf{q})$ is the nonlinear internal force vector, both of length $3N$, which is a nonlinear function of \mathbf{q} based on the geometrical nonlinearities. The details of the finite element model can be found in Appendix 2 of [1].

Numerical solution

The geometrically exact finite element model described in (1) is then solved numerically using MANLAB, an interactive path-following solver rooted in MATLAB. Given harmonic forcing imposed on the cantilever beam, the resulting motion of the structure is sought periodic. The MANLAB solver employs a unique continuation scheme for periodic solutions, combining the Harmonic Balance Method (HBM) with the Asymptotic Numerical Method (ANM) continuation technique [2]. Traditionally, the principle of the HBM is to decompose a periodic function into a Fourier series truncated to a certain number of harmonics. However, in the present case of a geometrically exact cantilever beam, sine and cosine nonlinearities of the degrees of freedom are involved in the system. To reconcile these nonlinearities and others that may be present in any original system, the solution technique implemented in MANLAB proposes a quadratic recast of the original equation into a new system containing only polynomial nonlinearities of quadratic order or less. Following the quadratic recast, the derivation of the corresponding algebraic system for the Fourier coefficients is rather straightforward [2, 3]. The ANM continuation technique, which uses a pseudo-arc length parameterization, is then applied to yield the path-following solution that is visualized in MANLAB [4].

The combination of HBM and ANM has been shown to be both highly efficient and yet applicable to a broad set of systems containing non-polynomial nonlinearities [3, 4]. Recently, extensions to the method and, therefore, the MANLAB solver, allow for the stability analysis of the various branches of the periodic solution [4]. Using this solver, the computation time for the solution to (1) is greatly reduced and enables a numerical solution for the cantilever structure subject to extreme amplitude vibration (see Fig. 1 (Right)). In the case under study, the nonlinear modes of (1) are computed with periodic solutions of the unforced system, with $\mathbf{f}_{\text{ext}} = 0$, as explained in [4].

Experiments

In order to compare with the aforementioned numerical simulations, an experimental strategy has been designed to recreate the extreme amplitude vibrations of flexible specimens using a Long Stroke Shaker vibration table. The experimental strategy here described utilizes a Phase-Locked Loop (PLL) controller, which, for a harmonic excitation $F(t) = F \sin(\Omega t + \phi)$, changes the frequency Ω so that a given phase lag between the phase ϕ of the force signal and that of the system response is induced [5]. Adjustment of the amplitude of excitation with the desired phase lag set to $\pi/2$ provides a robust method for measuring the backbone curve of the system, equivalent to its nonlinear modes. A long and thin stainless steel beam is prepared for the experiments and is fixed at the base to the vibration table to recreate the cantilever condition under investigation. The table vibrates at the selected amplitude F and frequency Ω , thereby exciting the cantilever beam specimen. Preliminary experiments are able to demonstrate the extreme amplitude vibrations using reflective points along the beam (Fig. 1 (Left)). The displacement field along the beam is measured based on differences in the illuminated points through a series of images captured with a rapid motion camera in a technique known as Digital Image Correlation (DIC). The results of the DIC are then compared with numerical results obtained from MANLAB.

Conclusions

In this paper, numerical and experimental extensions to existing strategies for calculation of nonlinear modes of cantilever beams in large amplitude vibrations are presented. A geometrically exact finite element numerical model of the equation of motion is developed and implemented into the MANLAB continuation solver for periodic solutions. The solver is able to describe the motion of highly flexible structures even at extreme amplitudes, which is then compared with experimental results obtained from vibration tests integrating a Phase-Locked Loop for robust calculation of the nonlinear modes. In conclusion, the procedure outlined in this paper presents a novel and efficient method for the calculation and simulation of highly geometrically nonlinear beam structures, even at extreme amplitudes of vibration.

Summary. This study reports some experimental results of a beam-slider vibration system which is often called the self-adaptive resonator. It is said to increase the efficient frequency bandwidth of a vibration-based energy harvester. In this study, excitation experiments were carried out focusing on the interaction between the vibrating beam and the slider. The experimental results show that a certain mode of the beam resonates as a result of the slider moving along the beam under excitation at a certain frequency. Some of the results also show the effect of nonlinear modal interactions through the slider movement.

Introduction

A self-adaptive resonator consisting of a beam and a slider was introduced to the field of vibration energy harvesting by Miller[1] as a solution to the problem of narrow resonance frequency range. The proposed system is said to achieve resonance at multiple frequencies, thanks to the slider which, under the condition of excitation, moves along the beam to such a position that the beam will resonate. To discuss the dynamics of the system, we must mention that behaviors of a vibrating beam-slider structure was studied well before it was incorporated to energy harvesting. Recent studies by Lyu[2] report that the adaptive behavior of the system is influenced by the geometrical nonlinearity of the vibrating beam. In this study we conducted some experiments to find out the important factors to explain the motion of the beam and the slider.

Analytical Studies

Governing equations

Figure 1 shows the image of the analytical model. The horizontal position is denoted by x , and the vertical beam displacement at each position is denoted by W . s stands for the position of the slider, which would be a factor that changes the natural frequency and the beam shape. Hence W is a function of time t , x and s , and the equation of the beam and sliders motion can be described as follows[1].

$$\rho A(\ddot{W} + \ddot{W}_o) + EI \frac{d^4 W}{dx^4} + \ddot{W}_o + M \left(\ddot{W} + \ddot{W}_o + \dot{s} \frac{dW}{dx} + 2\dot{s} \frac{d\dot{W}}{dx} + \dot{s}^2 \frac{d^2 W}{dx^2} \right) \delta(x-s) = 0 \quad (1)$$

$$M \ddot{s} + M \left[\left(\ddot{W} + \ddot{W}_o + \dot{s} \frac{dW}{dx} + 2\dot{s} \frac{d\dot{W}}{dx} + \dot{s}^2 \frac{d^2 W}{dx^2} \right) \frac{dW}{dx} \right]_{x=s} = 0 \quad (2)$$

M is the slider's mass, W_o is the excitation term, ρ , A , E and I are the density, cross-sectional area, Young's modulus and second moment of inertia of the beam, respectively.

Theory

In early studies, Thomsen[3] assumed that the slider's mass was light compared to the beam, hence neglected the change of the beam shape. This assumption provides a tendency in the slider's motion, that the slider would move toward the antinode of one of the modes which stands out the most. However, experimental studies report that the self-adaptive behaviors ideal to energy harvesting can be observed mostly when the slider's mass is relatively large. This results in not only the change of the beam shape, but also some unnatural motions of the slider, possibly due to linear and nonlinear couplings between the modes or between the beam and the slider.

Before we move on to the experimental study, we must introduce the dependencies of the natural frequency of the first and second mode for a fixed-fixed beam with a fixed additional mass. Figure 2 shows an example of those relationships with a shared horizontal axis indicating the mass position, with the additional mass being slightly heavier than the beam. According to this figure, depending on the position of the slider, the natural frequency ratio of these two modes may become an integer ratio such as 1 to 2, which may cause nonlinear coupling between the modes..

Figure 1: Analytical Model of the beam-slider system.

Figure 2: The left figure shows the natural frequencies of the two modes depending on the position of the mass. The right figure shows the corresponding mode shape for a decentered mass.

Figure 3: Picture of the experimental system of the beam-slider structure and its separated parts.

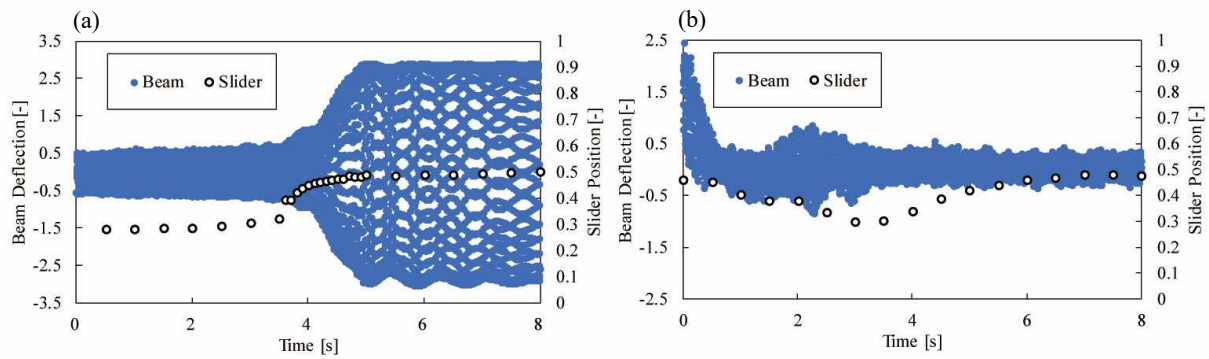

Figure 4: Time histories of slider displacements and beam deflection. The left vertical axis is normalized with the excitation amplitude, while the right vertical axis is normalized with the beam length. The beam deflection was measured at 0.75 according to the right vertical axis. The excitation frequencies were (a)20 Hz and (b)53 Hz while the excitation amplitudes were (a)0.148 mm and (b)0.524 mm.

Experimental Study

Figure 3 shows the parts and the setup of the experimental system. A stainless-steel beam was fixed at both ends to a shaker. In order to make the slider motion as smooth as possible, a pair of plastic bearings were used as the main parts of the slider which interacts with the beam. The gap was small to prevent the slider to rattle or bounce on the beam, but large enough for the slider to move. The slider to beam mass ratio was 1.24, and the first natural frequency of the fixed-fixed beam without the slider was 44 Hz.

Figure 4 shows two of the results obtained by the experiment. (a) is the example of when the system achieved resonance of the first mode. This is caused through the movement of the slider. In the example (b), the slider moved from the center of the beam toward the outer region, then started to move back to the center when it reached a certain position. This motion is difficult to explain when only the second mode with constant mode shape is considered.

Though we have found much more about the beam-slider motion through this experiment, this extended abstract can only provide two examples of the results due to page limitations. Nevertheless, even the two examples alone show that interactions between the vibration modes of the beam are the key to understand the nature of this system.

Conclusion

Experiments were conducted to verify the key aspects to analyze the self-adaptive resonator. The results exhibited the effect of nonlinear modal interactions and therefore theoretical studies ranging to nonlinear analysis of multiple degrees of freedom are essential to truly understand the system.

Measuring nonlinear localisation and isolated curve of solutions in a system of two coupled beams

Aurélien GROLET*, Zein A. SHAMI* and Olivier THOMAS *

* *LISPEN, ENSAM Lille, Lille, France*

Summary. This work presents experimental measurement of nonlinear localisation in a system of two coupled beams. In this system, localisation correspond to vibrations states where the symmetry is broken, and where the energy is mainly localised to one of the two beam only, see e.g. [1]. Using a two degrees of freedom reduced order model, one can show that the localised states arise from a 1:1 internal resonance between two particular linear modes [2]. In the case of forced response, for particular conditions, the localised solution can be depicted under the form of an isolated closed curves (isola) in the amplitude-frequency diagram [3]. Experimental measurements showing nonlinear localisation are presented and compared to the numerical solution, showing good agreement.

Presentation of the system

The system considered here consists of a circular plate that has been machined in order to create two parallel beams as indicated on Fig. 1. The body of the circular plate provides a coupling between the beams, and it also restrains the axial displacement of the beams ends, so that non-linearity occurs due to a coupling between axial and transverse motions. We consider two particular eigen-modes of the structure depicted on Fig. 1. For those modes, the beams vibrate over a first bending mode shape (in phase or out of phase). The structure has been designed such that both modes interact non-linearly to give a localized mode. Indeed, looking at the mid-beam displacement, the modes can be described with the shape $\phi_1 = (1, 1)$ and $\phi_2 = (1, -1)$. Localisation arise due to a modal interaction of the form $q_1(t)\phi_1 + q_2(t)\phi_2$, where q_1 and q_2 are (in-phase) modal amplitudes, leading to a shape of the form $(a_1 + a_2, a_1 - a_2)$, which eventually tends to the localised shape $(1, \epsilon)$ as the amplitude of the first mode a_1 tends to the amplitude of the second mode a_2 .

Figure 1: Linear mode shape of interest. Left: in phase mode ($f_1 = 364$ Hz); Right: out-of-phase mode ($f_2 = 367.5$ Hz)

Reduced order model and Numerical solutions

In order to simplify the analysis, a reduced order model is derived using the so called STEP method, particularised to the case of planar structure (see e.g. [4]). Only the two modes of interest are kept in the reduced order model and the reduced set of equation have the following form:

$$\ddot{q}_1 + 2\xi_1\omega_1\dot{q}_1 + \omega_1^2q_1 + G_1q_1^3 + Cq_1q_2^2 = f_1 \sin(\Omega t) \quad (1)$$

$$\ddot{q}_2 + 2\xi_2\omega_2\dot{q}_2 + \omega_2^2q_2 + Cq_1^2q_2 + G_2q_2^3 = f_2 \sin(\Omega t) \quad (2)$$

where q_i is the modal amplitude of the i -th transverse mode ($i = 1$: in phase mode, $i = 2$ out of phase mode, see Fig.1), ξ_i 's are the modal damping ratio, ω_i 's are the natural frequencies, f_i 's are the modal forces amplitude and Ω is the excitation frequency. G_1, G_2 and C are the non-linear coefficients obtained through the reduced order model procedure. Approximated solutions to the system in Eq.(1) are obtained using the Harmonic Balance Method (HBM), coupled with a numerical continuation procedure based on the Asymptotic Numeric Method (ANM) [5].

When the system is forced on the first mode ($f_2 = 0$), if the forcing amplitude is sufficient, it can be observed that the localised solution can be depicted under the form of a closed curve solution in the Amplitude-Frequency diagram (isola), see the left panel of fig.2. When the system is forced on the second mode ($f_1 = 0$), if the amplitude is sufficient, it can be observed that the localised solution stems from the principal resonance curve through a branching point bifurcation, see the right panel of fig.2.

Experimental setup and results

The structure has been machined out of a stainless steel plate using wire cutting. For the experiments, the structure is hanged, which allows to be close to free boundary conditions. The experimental setup is depicted on fig.3.

A magnet and a coil is used to provides excitation to the structure without having an actual physical contact between the structure and the excitation device. To keep the symmetry of the system, another magnet (without coil) is positioned on the opposite side of the plate (see fig.3). The amplitude of the force is controlled by the intensity of the current

Figure 2: Numerical forced response. Left: force on the first mode, localised states appear as closed curve solution. Right: force on the second mode, localised states arise from the homogeneous (out-of-phase) solution through a branching point bifurcation

sent to the coil, which is monitored using a current clamp. Velocity measurements are carried out using a laser vibrometer.

Example of stepped sine measurements (for a force exciting mainly the second mode) are given on the right panel of fig.3. For low amplitude of forcing, the behaviour of the structure is linear, and both beams vibrates with the same amplitude. When the amplitude increases, the non-linearity starts to be activated and the hardening property of the structure can be observed. Finally, for higher force amplitude, when the displacement amplitude reach a threshold, there is a break of symmetry in the vibration shape of the structure, both beams clearly vibrates with different amplitude. For the highest excitation current (black curve on Fig.3), one can see that the first beam vibrates with an amplitude 7 times greater than the second beam.

Figure 3: a) Picture of the experimental setup; b) Measurement of localised states when forcing over the second mode (mid-beam amplitude versus frequency of excitation)

Conclusions

This study presents numerical and experimental results about nonlinear localisation in a system of two coupled beams. Experimental measurements using swept sine excitation demonstrate that the localisation can be observed in practice. The numerical and the experimental results agree very well, showing that the reduced order model procedure is able to generate a good representation of the physical system with only a few degrees of freedom.

Summary. We present some new results obtained in experimental nonlinear dynamics analysis of a beam supporting a rotating machine. Two phenomena were detected in our research work. First, the effect of large axial compressive forces on the geometric stiffness of the beam and, consequently, on its free undamped vibration frequencies. The larger these forces are, the smaller the measured frequencies up to a certain point, when strong nonlinearities reverse this trend. Second, the Sommerfeld effect of low power machines getting stuck at resonance and possible occurrence of jump phenomena.

Introduction

We present an experimental study of the effects of geometric nonlinearities on vibrations of rotating machines support structures. Dynamic characteristics of structures depend on their stiffness, damping and mass. The initial stiffness of a structure, computed in its unloaded state, is affected by the applied forces, the so-called geometric stiffness. Compressive forces reduce the stiffness and the frequencies and may lead to buckling, for zero frequencies. In bases of machines excited by the supported equipment, vibrations may affect the structures but, in general, they may generate damage to the suspended equipment and the quality of the production. Although machine support structures are, as a rule, very bulky, little affected by geometric stiffness considerations, the tendency of modern structural engineering, especially in aerospace applications, is towards slender members, due to more efficient materials and powerful analysis tools. Here we study these effects via experimental methods designed to evaluate previous mathematical models. Our model is a metal beam under compression supporting a DC motor. We suppose the original design provided natural frequencies away from the excitation frequency. Nevertheless, the presence of large axial compressive force will reduce the beam stiffness and natural frequencies leading to unexpected, potentially dangerous resonance states. Experimental imperfections led to observation of interesting phenomena not predicted in our previous theoretical and numerical studies. We also observe, as expected, occurrence of the so called Sommerfeld Effect, when underpowered excitation sources get their rotation regime stuck at resonances. Earlier mathematical and numerical work is to be found in [1-3].

Experimental setup

The model beam

Figure 1 displays the experimental setup: a rectangular section steel bar mounted in a calibrated manual hydraulic press intended to apply large axial compressive forces in order to change its geometric stiffness. A small DC electric motor is fixed with PVC fixtures to the beam central section. Unbalanced forces are generated by wooden flywheels with attached small point masses. Several end conditions were studied: embedded ball point, simply cut etc.

Figure 1: The experimental setup

Instrumentation

Data acquisition was carried out by an 8 channels automatic system coupled to a PC computer, with FFT capabilities. The sensor system comprises: piezoelectric accelerometers to pick up vibrations; strain gauges for strain and bending moments measurement; optical tachometer to access the motor rotation speed; an *ad hoc* designed power control and measurement digital electronic circuit, coupled to a DC supply.

Results and discussion

The effect of large compressive axial forces applied to the beam on the geometric stiffness and 1st free undamped vibration frequency was detected, as displayed in Fig. 2. Frequencies get smaller as the compressive axial force grows, up to a point, where large nonlinearities reverse the trend. Effect of end conditions were also studied and presented in Fig. 2.

Figure 2: First vibration frequency as function of axial compressive force and end conditions

By controlling the amount of power available to the DC motor, the Sommerfeld effect was also observed, of getting stuck in resonance and occurrence of the jump phenomenon. Figure 3 displays measured forced vibrations accelerations as power is varied linearly from zero through resonance, for a certain value of axial compressive force. Motor angular velocity, measured by the tachometer, is also shown.

Figure 3: Accelerations and motor rotation speed as power is increased through resonance

Conclusions

An experimental research was carried out on the nonlinear dynamics of a beam supporting a unbalanced rotating machine. The effect of large compressive axial forces upon the geometric stiffness and free undamped vibration frequencies was detected. Further, for underpowered machines, the Sommerfeld effect was also observed, of getting stuck in resonance and occurrence of jump phenomena. Effect of several end conditions was also studied. We acknowledge support by FAPESP and CNPq, both Brazilian research funding agencies.

Summary. Applying a novel analysis we study targeted energy transfer (TET) in a non-smooth vibro-impact system (VI), comprising a ball freely moving within a frictionless slot made within a harmonically excited large mass. Both the ball and the mass can move independently between inelastic collisions. The proposed semi-analytical approach allows analyzing TET in the discontinuous piecewise linear systems exactly, in contrast with previous studies via approximations related to a specific state. We obtain parameter ranges for the impact pair to effectively transfer energy to it from the base excited system via a series of impacts.

Problem statement

Targeted energy transfer may be viewed as an extension of a classical linear tuned mass damper (TMD) theory, where a second mass-spring system is added to an original single-degree-of-freedom (SDOF) oscillator to avoid a high-amplitude response near its resonance frequency [1, 2]. The parameters of the resulting two DOF (TDOF) system are selected so achieve a low energy state in the original system, while the added mass-spring subsystem stores the energy of the entire TDOF system. While TMD is a standard approach for vibrational mitigation and energy transfer, used by engineers for over 100 years, it has no direct analogy for nonlinear systems. Without an exact analytical solution for the classical nonlinear TDOF system there is no “obvious” way to choose the systems’ parameters for transferring energy from a forced oscillator to a nonlinear energy sink via nonlinear coupling, see [3, 4] and references therein. Analyses are generally based on weakly nonlinear approximations or model reductions. Parametric studies are then limited requiring simulations for explorations of the full nonlinear behavior.

Alternatively, we note that energy transfer in continuous nonlinear systems is a special case of more general nonlinear systems, which can be non-smooth and discontinuous. Considering TET via persistent vibro-impact motion (e.g. as in [5, 6]) we focus on the non-smooth impact pair as in [5, 7], with a small mass ball traveling freely within a slot of length $2b$ made in the large excited mass. The dynamics of the displacements q_1, q_2 of the large and small masses with mass M and m respectively, complemented by the impact conditions at $|q_1 - q_2| = b$, is described by the following equations:

$$M\ddot{q}_1 + c\dot{q}_1 + kq_1 = kE \sin(\omega t + \phi) + c\omega E \cos(\omega t + \phi) \quad \ddot{q}_2 = 0 \quad (1)$$

$$(q_1^+ - q_2^+) = -r(q_1^- - q_2^-) \quad M\dot{q}_1^+ + m\dot{q}_2^+ = M\dot{q}_1^- + m\dot{q}_2^-, \quad -^{(+)} \text{ before (after) impact} \quad (2)$$

where k is the elastic spring coefficient, E, ω, ϕ are the excitation amplitude, frequency, and initial phase, r is the restitution coefficient, t is the time, the dot indicates derivatives with respect to time. The instantaneous impact conditions (2) capture the two-way energy exchange between the masses, in contrast to the extensive literature on bouncing ball dynamics, where the mass of the ball is typically assumed as negligible [8].

Analytical approach

Within a non-dimensionalized framework, with parameters $\mu = \frac{m}{M}$, $A = \frac{E}{b}$, $\omega_0 = \sqrt{\frac{k}{M}}$, $\Omega = \frac{\omega}{\omega_0}$, $\lambda = \frac{c}{M\omega_0}$, state variables $x_1 = \frac{q_1}{b}$, $x_2 = \frac{q_2}{b}$ and rescaled time $\hat{t} = \omega_0 t$, and dropping \wedge 's for the remainder, we integrate the equations of motion (1), and apply the impact conditions (2) when the ball impacts either end of the cavity. This yields the map of the state from the previous impact time t_{k-1} to the next impact time t_k in terms of all system parameters

$$\begin{aligned} x_{1,k} &= a_1 e^{\frac{-\lambda t_k}{2}} \sin(\gamma t_k) + a_2 e^{\frac{-\lambda t_k}{2}} \cos(\gamma t_k) + b_1 \sin(\Omega t_k + \phi) + b_2 \cos(\Omega t_k + \phi) \\ \dot{x}_{1,k} &= a_1 e^{\frac{-\lambda t_k}{2}} \left(-\frac{\lambda}{2} \sin(\gamma t_k) + \gamma \cos(\gamma t_k) \right) + a_2 e^{\frac{-\lambda t_k}{2}} \left(-\frac{\lambda}{2} \cos(\gamma t_k) - \gamma \sin(\gamma t_k) \right) + b_1 \Omega \cos(\Omega t_k + \phi) \\ &\quad - b_2 \Omega \sin(\Omega t_k + \phi), \\ x_{2,k} &= x_{2,k-1} + \left(\frac{1+r}{1+\mu} \dot{x}_{1,k-1} + \frac{\mu-r}{1+\mu} \dot{x}_{2,k-1} \right) \cdot (t_k - t_{k-1}) \\ \dot{x}_{2,k} &= \frac{1+r}{1+\mu} \dot{x}_{1,k-1} + \frac{\mu-r}{1+\mu} \dot{x}_{2,k-1} \end{aligned} \quad (3)$$

Here the conditions are in terms of $x_{j,k}, \dot{x}_{j,k}$ the displacements and velocities at the impact time t_k , corresponding to the end of each sub-interval of continuous motion, so that the superscript $-$ as in (2) can be dropped without loss of generality. The coefficients a_l, b_l are functions (not given here) of the previous time t_{k-1} and states $\dot{x}_{j,k-1}, x_{j,k-1}$. Taking $|x_{1,k-1} - x_{2,k-1}| = 1$ and $|x_{1,k} - x_{2,k}| = -1$ yields the map P_1 for the motion from left to right in the capsule. Similarly

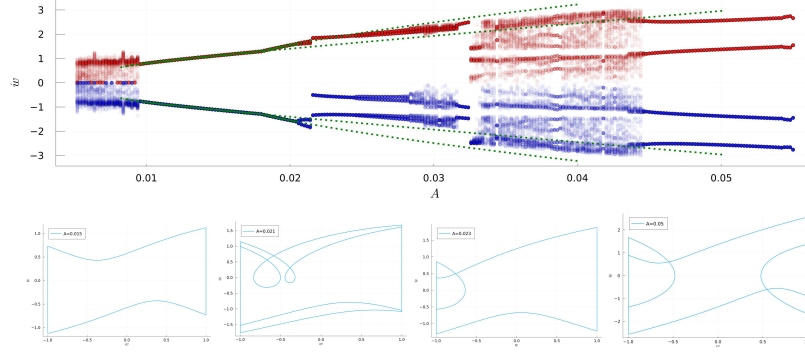

Figure 1: Upper: Bifurcation diagram of relative impact velocity \dot{w} for (red (blue) is left (right) impact obtained numerically) vs. forcing amplitude A ; Green solid (dotted) lines are stable (unstable) 1:1 solutions obtained analytically. Lower: Phase planes with \dot{w} vs w at $A = .015, .021, .023$ and $.05$ showing 1:1, 1:1/2T, 2:1, and 2:2 periodic solutions, respectively.

we determine maps for the other motions, e.g. P_2 right to left, and P_3 (P_4) for successive impacts on left (right). Thus it is possible to construct a sequence of maps describing the different periodic motions, whether successive impacts occur on the same or different ends of the slot. We use the notation $n:m/pT$ corresponding to pT -periodic solutions with n (m) impacts on the left (right) of the capsule, given an external forcing with period T on the large mass. Then 1:1 solutions, the simpler case where the ball has alternating impacts on either end of the capsule, are determined from the system (3) given by the composition $P_1 \circ P_2$ together with the periodicity condition. Similarly 2:1 solutions are obtained from the combined equations from the composition $P_3 \circ P_1 \circ P_2$ plus periodicity, and so on for other $n:m$ behaviors. From these compositions plus periodic conditions we obtain the period solution in terms of state vectors $\mathbf{H}_k^* = (\phi_k, \dot{x}_{1,k}, \dot{x}_{2,k}, x_{1,k})$, where the phase shift ϕ_k of the impact is relative to the forcing. Based on these analytical results for the periodic solution, we can also study their linear stability [9], and thus identify analytically both traditional bifurcations such as period doubling and discontinuity-induced bifurcations. The procedure described in this section is also applied to obtain semi-analytical solutions of a soft impact model and are used to analyse the compliant system dynamics.

Comparison of Numerical and Analytical results

Figure 1 shows the numerically obtained bifurcation structure of the relative impact velocity $\dot{w} = \dot{x}_{1k} - \dot{x}_{2k}$ vs. forcing amplitude A , illustrating 1:1, 1:1/2T, 2:1, and 2:2 solutions, as well as chaotic behavior occurring for different A . Stable and unstable 1:1 solutions obtained analytically are shown, indicating good agreement between analytical and numerical results for the stable 1:1 periodic solutions, as well as the regions for instability. From the results we can calculate performance based on energy transfer efficiency, for example, kinetic energy transferred relative to work done by the excitation. This measure (not shown) indicates improved performance via 1:1 type periodic solutions, with some reduced performance at non-smooth bifurcations such as 1:1 to 2:1 transitions.

Conclusions

We study targeted energy transfer in a VI system by expressing the inter-interval dynamics as a sequence of maps. We capture physically-relevant motions via the derived semi-analytical approach that reveal critical parameter dependencies of the dynamics and energy transfer. Developing this approach within the instantaneous (hard) impact condition allows us to generalize to compliant impact conditions.

Energy harvesting from vortex induced vibration in MEMS devices using magnetic interaction

Amal Nambiar*, Manoj Pandey†

† *Department of Mechanical Engineering, Indian Institute of Technology Madras, Tamil Nadu, India*

Summary. Energy harvesting from the environment is an emerging field and a better alternative to battery-operated systems such as wireless sensors, IoT and lower power electronic devices. Linear energy harvester has maximum power output near its natural frequency, which restricts its operation in narrow bandwidth. To improve the bandwidth and the power output, a pair of magnets with same polarity is used to induce non-linearity in a cantilever beam subjected to vortex induced vibration. This increases the complexity of the problem in FEA softwares as it will be coupled electrical-fluid-mechanical-magnetic problem. Thus, the magnetic force is replaced with nonlinear spring in ABAQUS and the Fluid Structure Interaction is carried out by reducing the complexity to electrical-fluid-mechanical problem. The magnets are placed at a certain distance so that the beam operates as a bistable system. The analysis was carried out for beam with different natural frequencies by changing the tip mass. Using the pair of repulsive magnets, we have found that the energy harvested in non-linear system is higher than the linear energy harvester.

Keywords: Energy harvesting; Fluid Structure Interaction; MEMS; Nonlinear Dynamics; Vortex Induced Vibration

Introduction

With the rapid development of technology in the field of sensors, IoT more emphasis is made on low power based devices. Wireless Sensor Networks(WSNs), IoT applications demand for low-energy wireless nodes typically powered by non-renewable energy storage units(batteries). But the battery have limited lifetime and it is difficult and expensive to replace them. An energy harvester(EH) operated along with a battery could potentially increase the lifetime of the node and eliminate the need to replace the battery. MEMS devices could be easily integrated with the circuit but the process to develop MEMS devices is complex, time consuming and expensive. Thus, FEA simulation allows to analyze or redesign the harvester according to the need. But FEA packages cannot handle complicated coupled problems which are common in non-linear EH. The major problem to analyze a vortex induced vibration based nonlinear EH involving magnets includes the complexity to solve the electrical-fluid-mechanical-magnetic problem. The magnetic force between two cylindrical magnets used in the MEMS cantilever beam is modeled as a nonlinear spring which has the same behavior as the repulsive magnets. The FE model of cantilever nonlinear EH with nonlinear springs is validated with the theoretical model. Application of phase space, bifurcation diagram, Poincaré maps were used to study the nonlinearity effects to enhance the energy harvested.

Analysis

The axial force and lateral forces between two cylindrical magnets [2] is given in Figure 5 (2a). This nonlinear magnetic force is approximated using piecewise linear segments and given as an input in ABAQUS. The beam with nonlinear spring is simulated in ABAQUS with an acceleration of 2 m/s^2 (20 Hz) and validated with the theoretical model using equations shown in Figure 5 (1c and 2c)

Figure 1: Voltage time history of FEA and theoretical results

Figure 2: FFT of voltage from theoretical and FE results

Set up

The setup consists of a 2mm cylindrical bluff body and a beam ($5\text{mm} \times 0.3\text{mm} \times 9\mu\text{m}$) which is placed at a distance of 6mm from the center of the bluff body. The magnets(NdFeB N35 grade) have dimension $\phi 0.1 \times 0.1\text{mm}$ placed at a distance of 0.4mm from each other. Beam is subjected to a uniform input velocity of 2m/s having vortex shedding frequency of 217Hz. The beam operates in a bistable system, for distance less than 0.4mm as shown in Figure 4.

Figure 3: Magnetic force between magnets at different distances

Figure 4: Potential Energy for different magnet distance

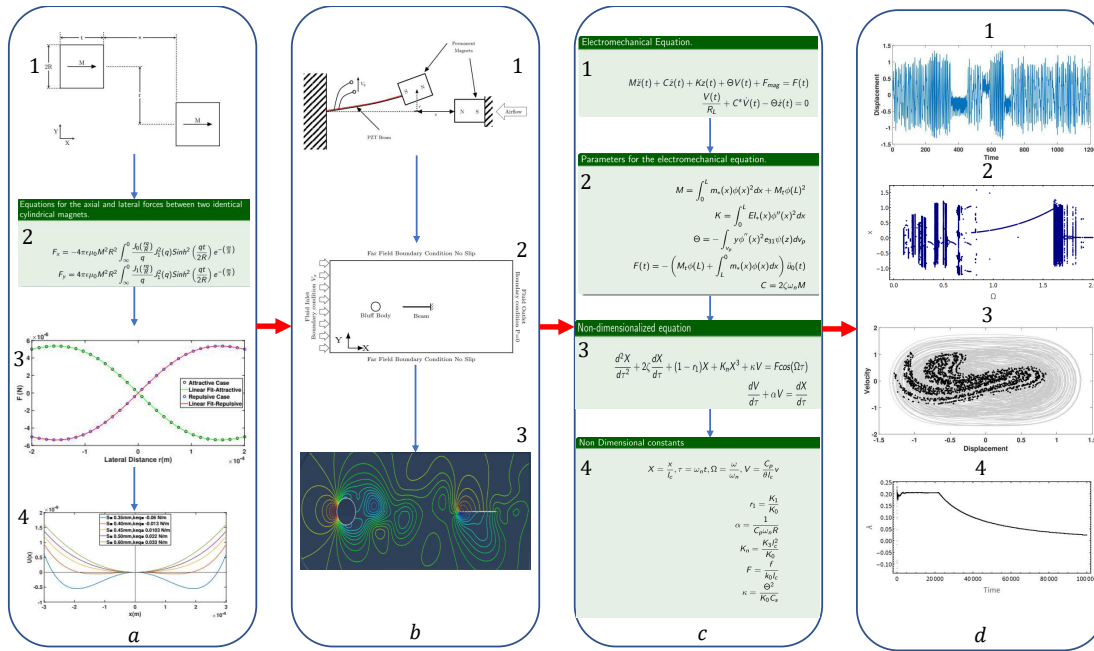

Figure 5: (a) Magnet Design (b) FSI Setup (c) Coupled electromechanical Equation (d) (1) Time history (2) Bifurcation Diagram (3) Phase space (4) Maximum Lyapunov exponents for time series at 131 Hz

The coupled non-dimensionalized equation can be represented as Figure 5 (3c). For beam with natural frequency 131 Hz ($\Omega = 1.65$) operates in chaotic range for $\zeta = 0.0275$ as shown in Figure 5 (d)

Discussion

The magnetic force equation was derived with the assumption that the cylindrical magnets are placed axially and there exists uniform magnetization in each magnet. Also, the rotation of the magnet is neglected while simulating magnetic force with nonlinear spring as the rotation of the magnet will be typically below 10° for low base excitation used in energy harvesting applications. Piezoelectric materials are anisotropic by nature. But for our analysis, we have considered both substrate and Piezoelectric material as a linear elastic material model as the strain in the substrate is well below the elastic limit. In HVAC systems airflow is usually unidirectional with operating speeds from 1.8 m/s to 5 m/s. Care must be taken while designing for a bistable system, as adequate forcing is required for the beam to cross the potential barrier.

Conclusion

In this work, we analyzed the nonlinear EH operating as a bistable system using pair of permanent magnets. The bistability causes the beam to cross from one potential to another, thereby increasing velocity and in turn power output. The beam acts as a linear EH when the distance between the magnets is very large. Nonlinear energy harvesters generate more power compared to linear counterparts except at resonance. Beam operating in the chaotic range have higher power output but there is an additional need to design efficient energy harvesting circuit. The system is chaotic for particular values of amplitude, forcing frequency and damping value.

Frequency-Energy Plot of Unsymmetrical Nonlinear Energy Sink

Mohammad A. AL-Shudeifat

Department of Aerospace Engineering, Khalifa University of Science and Technology, Abu Dhabi, United Arab Emirates

Summary. Studying the nonlinear energy sink (NES) attachment with a linear dynamical oscillator (LO) on the frequency-energy plot (FEP) reveals the underlying nonlinear dynamical behavior of the LO-NES system. In addition, the FEP reveals different kinds of periodic motions on NNMs backbone branches. The unsymmetrical force nonlinear energy sink (UNES) incorporates a cubic stiffness element at one side of its equilibrium position where a weak linear restoring coupling stiffness acts in both directions. The obtained FEP has revealed several unsymmetrical backbones of 1:1 resonance between the UNES and the LO periodic oscillations at different nonlinear frequency levels.

Introduction

The frequency energy plots (FEPs) analysis has a significant impact on revealing the underlying nonlinear dynamics of the structure-NES nonlinear motion. The periodic motion of stiffness-based structure-NES systems have been extensively studied on harmonic NNM backbone curves and their associated branches/tongues of subharmonic and super harmonic periodic motions in the FEPs. The FEPs accompanied with the superimposed wavelet frequency spectrum content have confirmed the existence of different kinds of resonance captures between the primary system and the NES oscillations at the backbones and their associated subharmonic branches and tongues. The resonance captures on the FEPs have explained the rapid and passive targeted energy transfer (TET) from the primary system into the NES attachment [1–5].

UNES Description

The UNES attachment with the LO in [6] is shown in Figure 1 where the UNES mass is coupled with the LO by a cubic stiffness element that acts only to the left-side of the equilibrium position. In addition, the UNES incorporates a weak linear restoring spring that acts in both directions as shown. The physical parameters in [6] are used here for generating the frequency energy plot of the Hamiltonian version of the LO-UNES system (i.e., $\lambda_1 = \lambda_2 = 0$). The other parameters are; LO mass of $M = 1$ kg, LO coefficients of stiffness of $k_1 = 1$ N/m, NES mass of $m = 0.05$ kg, NES coefficients of cubic nonlinear stiffness of $k_{nl} = 1$ N/m³, and the UNES coefficient of weak linear restoring stiffness $k_{res} = 0.03$ N/m.

Figure 1: Unsymmetrical NES attachment with a linear oscillator

Frequency Energy Plot of the LO-UNES System

The FEP backbones are generated here by applying the numerical continuation method in [4, 5] with the considered LO-UNES system in Figure 1. The free-response of the Hamiltonian equations of motion of the system is obtained at the given physical parameters in the previous section for zero velocities and nonzero displacements. Therefore, the underlying nonlinear dynamical behaviour due to the influence of the unsymmetrical coupling stiffness force is investigated on the obtained FEP. Accordingly, seven backbone curves (*A1*, *A2*, *B1*, *B2*, *C*, *D* and *E*) are obtained in the FEP as shown in Figure 2. The backbones are named according to the ratio of the frequency content in the oscillation response between the LO and UNES masses. Therefore, $U11\pm$ denotes to an unsymmetrical NNM periodic motion at which the NNM does not pass through the origin in the NNM configuration space where the $+$ and $-$ indices indicate to the in and out of phase periodic motions, respectively. $U11+$ -branch of the backbone indicates to 1:1 resonance frequency ratio of the in phase periodic motion between the LO and UNES masses. As shown from the FEP, the backbones, *A2*, *B1*, *B2*, and *C*, approach 1, 1/2, 1/3 and 1/4 of the natural frequency of the LO at high energy levels. Unlike other kinds of NESs, all backbones are at 1:1 resonance for different values of the nonlinear frequency.

The NNM, the related periodic time response of the UNES mass and the associated mass of the LO, and the corresponding nonlinear UNES coupling force are plotted for selected data points a and b , respectively, as shown in Figure 3. For the data point a , the NNM does not pass through the origin where this NNM is located at the $U11$ –backbone $A1$. Therefore a 1:1 out of phase resonance takes place between the UNES and LO periodic motions. The data point b is located $U11$ –backbone $B1$. For this data point, also 1:1 out of phase resonance takes place between the UNES and LO periodic motions. In Figures 3c and 3f, the strong nonlinear effect to the right-side of the equilibrium position of the UNES and the weak linear coupling effect in the left-side are shown.

Figure 1: The obtained unsymmetrical backbone curves of the FEP of the LO-UNES system.

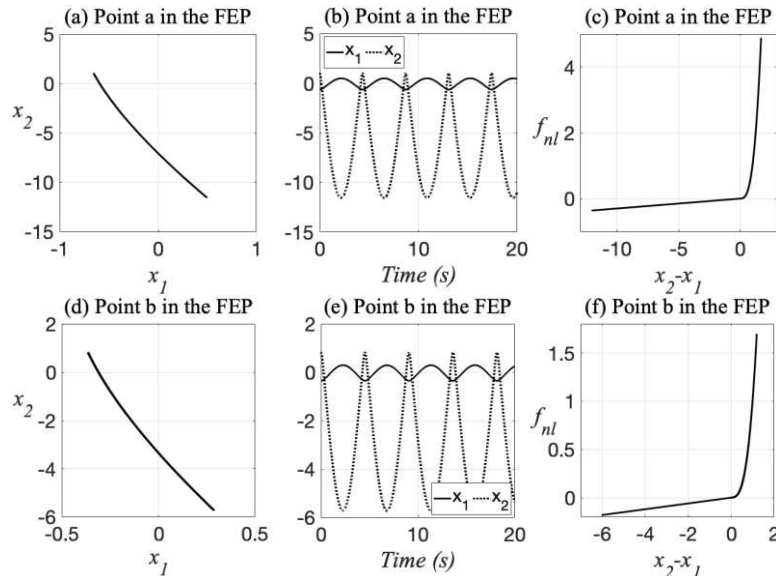

Figure 3: The NNMs in (a) and (d), their corresponding oscillation displacements in (b) and (e), and the corresponding nonlinear coupling forces in (c) and (f) for the data points a and b in the FEP.

Conclusions

In this study, the frequency energy-dependence of LO-UNES system is studied on the frequency energy plot. The underlying nonlinear dynamical behavior of the LO-UNES is revealed on the FEP. Unlike other existing NESs, the UNES is found to be associated with several backbones of unsymmetrical NNMs of 1:1 in phase and out of phase resonance between the UNES and LO oscillations for wide range of nonlinear frequency levels. The UNES shows a unique capability of functioning at 1:1 resonance at a broadband frequency-energy fashion.

Escape of two-DOF dynamical system from the potential well

A.Engel^{*}, T. Ezra^{*}, O.V.Gendelman^{*}, A.Fidlin^{**}

^{*} *Technion—Israel Institute of Technology, Israel*

^{**} *Karlsruhe Institute of Technology*

Summary. The escape of initially excited dynamical system with two degrees of freedom from three different one-dimensional benchmark potential wells is considered. Main challenge is revealing the basic mechanisms that govern the escape in different regions of the parametric space, and constructing appropriate asymptotic approximations for analytic treatment of these mechanisms. In this study numerical and analytical tools are used in order to classify and map the different escape mechanisms for a variety of initial conditions, and to offer the analytic criteria predicting the system's behavior for those cases.

Introduction

Escape from a potential well is a classic problem, relevant in many branches of physics, chemistry and engineering. Among many examples of possible applications, one encounters dynamics of molecules and absorbed particles, celestial mechanics and gravitational collapse [1,2], energy harvesting [3] responses of Josephson junctions [4], various aspects of capture into and escape from the resonance [5], as well as the capsizing of ships [6]. Even more profound, and widely explored manifestation of the escape phenomenon is a dynamic pull-in in microelectromechanical systems (MEMS) [7,8]. In this current study, we will expand the discussion and analyze two DOF systems. For a better understanding of the problem and a more reliable model in our work, three one-dimensional examples of potentials are considered: inverse hyperbolic potential, cubic potential and biquadratic potential. General setting explored in the present work can be presented as two equal particles attached to each other by a spring, and imbedded into the potential well (Fig 1).

Figure 1: sketch of the general setting

Main challenge is revealing the basic mechanisms that govern the escape in different regions of the parametric space, and constructing appropriate asymptotic approximations for analytic treatment of these mechanisms.

Results

In this study numerical and analytical tools, such as Poincare maps and grid classification, are used in order to classify and map the different escape mechanisms for various initial conditions. Further investigation was performed on two different sets of initial conditions. For the first set of conditions, only one of the particles was excited by a nonzero initial velocity. For the second set of conditions, both particles were excited. For convenience, in this case other coordinates were used: center of mass R and interparticle displacement W . When only W coordinate is excited, one can reveal an additional escape mechanism - dissociation, in which the distance between the particles eventually diverges. In order to investigate the classic escape mechanisms in which both particles escape in the same direction, we add minor disturbance to the center of mass velocity \dot{R} .

$$\text{set I} \quad q_1(0) = q_2(0) = \dot{q}_2(0) = 0 ; \dot{q}_1(0) = v_0$$

$$\text{set II} \quad R(0) = W(0) = 0 ; \dot{W}(0) = v_0 ; \dot{R}(0) = 0 / \dot{R}(0) = \delta$$

Variety of analytical and dynamical methods were used to derive the dependence between the minimum energy required for different escape mechanisms of the system and the spring stiffness ε . The resulting relations were validated by the numerical results, as presented in (Fig 2).

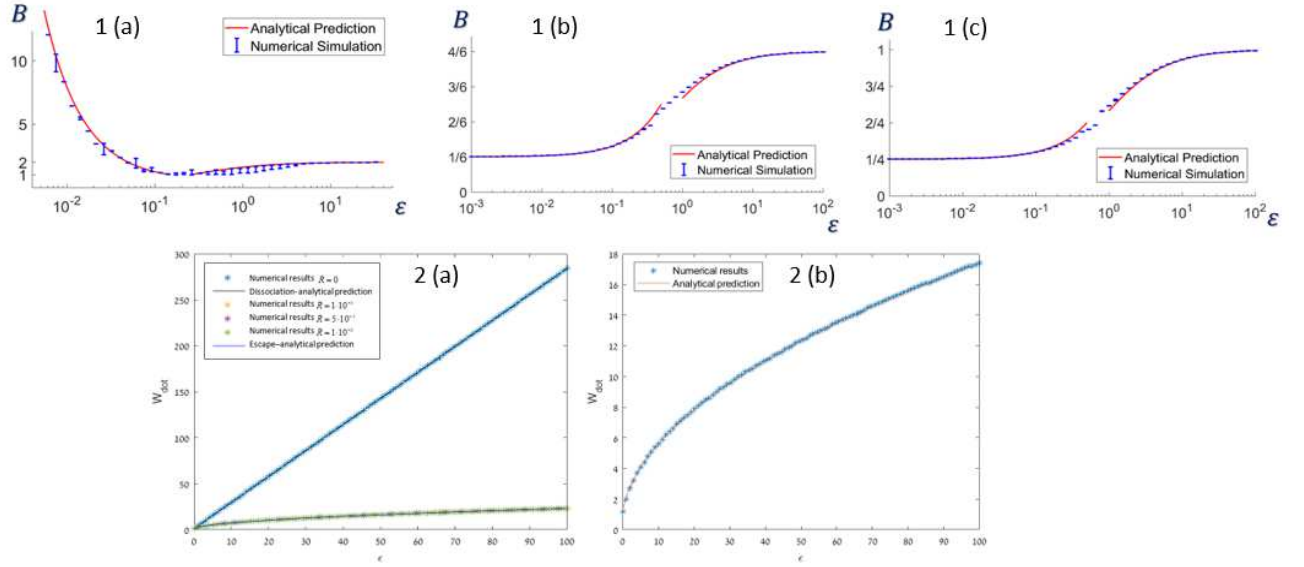

Figure 2: the analytical prediction and numerical results for the different cases (1) set I, minimum energy required to escape as a function of the spring stiffness (a) inverse hyperbolic potential (b) cubic potential (c) biquadratic potential. (2) set II, minimal separation velocity \dot{W} required for each escape mechanism as a function of the spring stiffness (a) biquadratic potential (b) cubic potential

Discussion

For the case of the single particle excitation, a clear distinction between the cases of weak and strong coupling has been revealed. For the small coupling, the escape is achieved when the excited particle has enough energy to pull the remaining particle from the well. For the case of the strong coupling, one can separate the timescale of fast interparticle oscillations; appropriate averaging delivers the modified effective potential for relatively slow evolution of the center of masses. Interestingly, two aforementioned limiting cases faithfully cover almost all space of parameters. To explore the chaotic responses, Lyapunov exponents were calculated, as presented in (Fig 3).

Figure 3: Lyapunov exponents as a function of the spring stiffness (a) Cubic potential (b) Biquadratic potential (c) Hyperbolic potential

Only the inverse hyperbolic potential has shown characteristics of chaotic behavior, mainly for low values of the spring stiffness, while the cubic and biquadratic potentials have not exhibited the chaos-governed escape dynamics. For the other set of initial conditions, a new escape mechanism – dissociation, derived from the symmetry of the initial conditions and the biquadratic potential, was recognized. Along with an additional escape mechanism, related to a parametrically driven acceleration of the center of masses. Those two mechanisms introduced in (Fig 2.2.a)), the dissociation mechanism occurs for higher energy levels while the other is described by lower levels. For those cases no separation of the parameters plane was needed and the same regime described the system for all ranges of the stiffness.

Summary. Slender and highly flexible structures quite often take place in systems designed to meet high to extreme performances. Hence cables, ropes, yarns, hoses and pipelines, which are essential parts of such structures, play a relevant role in practically every engineering field. In mechanical and automotive engineering, large amplitude motions of thin rods can be exploited to design nonlinear vibration absorbers for the reduction of torsional vibrations of drivelines; in assembly and disassembly phases and in system operation, reliable models are needed to predict and analyze the behavior of cables and wiring harnesses, taking also into account effective material properties; accurate structural models of wire ropes are required to study the behavior of rope-ways and cranes on the system level. In aerospace engineering, compact, flexible and slender aerals and booms to be deployed in space are typically used to minimize the room needed to store satellites in launching phases. In textile engineering, complicate interactions among hundreds of yarns have to be controlled to obtain the desired final layout. In biomedical engineering, medical endoscopes characterized by a multilayer structure must be accurately modeled, since they exhibit highly deformed configurations while moving inside narrow curved tubes within the human body. In offshore engineering, floaters, mooring lines, and others structural components of floating wind farms, are subject to structural fatigue and various sources of damping and power cables show complex cross-sectional properties. In civil engineering, estimates of the structural properties from response data coming from non-destructive procedures is critically empowered by a deeper understanding of beam-like structures. However, despite of their ubiquity, slender structures in real operating conditions exhibit responses often too complicated for current modeling tools. In this respect there is a continuous need for reliable models. In this area, this contribution considers a beam model equipped with non-standard constitutive laws and in particular it is aimed at deriving approximate solutions of the equations of motion via asymptotic multiple scale expansion.

Introduction

We consider a geometrically exact beam model deduced by stipulating a relation between one- and three-dimensional formulations for initially straight beams undergoing planar and twist-less deformed states. Using comma notation for derivatives, the equations of motion derived in [1], to which we refer for any further detail, are written as

$$m_0 u_{,tt} - m_1(\theta_{,t}^2 \sin \theta - \theta_{,tt} \cos \theta) + c_0 u_{,t} + c_1 \theta_{,t} \cos \theta = \left(N(1 + u_{,x})\sqrt{2\varepsilon + 1} - \frac{T v_{,x}}{\sqrt{2\varepsilon + 1}} \right)_{,x} + q_1, \quad (1)$$

$$m_0 v_{,tt} - m_1(\theta_{,t}^2 \cos \theta + \theta_{,tt} \sin \theta) + c_0 v_{,t} - c_1 \theta_{,t} \sin \theta = \left(N v_{,x}\sqrt{2\varepsilon + 1} + \frac{T(1 + u_{,x})}{\sqrt{2\varepsilon + 1}} \right)_{,x} + q_2, \quad (2)$$

$$m_1(u_{,tt} \cos \theta - v_{,tt} \sin \theta) + m_2 \theta_{,tt} + c_1(u_{,t} \cos \theta - v_{,t} \sin \theta) + c_2 \theta_{,t} = M_{,x} - T\sqrt{2\varepsilon + 1} + q_3, \quad (3)$$

where $u(x, t)$ and $v(x, t)$ stand for the axial and transverse displacements of the beam axis, $\theta(x, t)$ is the cross-sectional rotation, $N(x, t)$, $T(x, t)$ and $M(x, t)$ are axial, transverse and bending generalized stresses. These are related to the axial strain ε , the shear angle γ and the Lagrangian bending curvature κ , all nonlinear functions of u , v , and θ , by the nonstandard constitutive assumptions

$$N = \frac{\sin^2 \gamma}{\sqrt{2\varepsilon + 1}} K_S + \frac{\varepsilon}{\sqrt{2\varepsilon + 1}} K_0 + \cos \gamma \left(\frac{3\varepsilon + 1}{2\varepsilon + 1} \right) \kappa K_1 + \frac{1 + 2 \cos^2 \gamma}{2\sqrt{2\varepsilon + 1}} \kappa^2 K_2 + \frac{\cos \gamma}{2(2\varepsilon + 1)} \kappa^3 K_3, \quad (4)$$

$$T = \sqrt{2\varepsilon + 1} \frac{\sin 2\gamma}{2} K_S - \varepsilon \sin \gamma \kappa K_1 - \sqrt{2\varepsilon + 1} \frac{\sin 2\gamma}{2} \kappa^2 K_2 - \frac{\sin \gamma}{2} \kappa^3 K_3, \quad (5)$$

$$M = \varepsilon \sqrt{2\varepsilon + 1} \cos \gamma K_1 + (\varepsilon + (2\varepsilon + 1) \cos^2 \gamma) \kappa K_2 + \frac{3}{2} \sqrt{2\varepsilon + 1} \cos \gamma \kappa^2 K_3 + \frac{1}{2} \kappa^3 K_4. \quad (6)$$

In Eqs. (1-6), the mass, damping and stiffness coefficients are given by

$$m_i = \int_{S_0} \rho y^i dA, \quad c_i = \int_{S_0} c y^i dA, \quad K_i = \int_{S_0} \mathcal{E} y^i dA, \quad K_S = \int_{S_0} \mathcal{G} dA, \quad (7)$$

where ρ , c , \mathcal{E} and \mathcal{G} are mechanical parameters and S_0 is the rigid cross section.

Since their introduction, Eqs. (1-3) have been analyzed in some depth [2, 3, 4], mainly through numerical investigations. On the contrary, the present paper, following [5, 6], is focused on analytical developments, based on the method of multiple scales [7]. In particular, to draw the frequency-response curves, the exact partial differential Eqs. (1-3) are analyzed around frequencies corresponding to certain natural bending modes.

Some preliminaries on multiple time scale equations of motion

We introduce three time scales and develop the time and time derivative operator respectively as $t = \tau_0 + \epsilon\tau_1 + \epsilon^2\tau_2$ and $(\cdot)_{,t} = (\cdot)_{,\tau_0} + \epsilon(\cdot)_{,\tau_1} + \epsilon^2(\cdot)_{,\tau_2}$, being $\epsilon \ll 1$ a book-keeping parameter, and assume that the unknowns u , v , and θ in Eqs. (1-3) are small of order ϵ at most and can be expanded, up to the 3rd order, as

$$w_i(x, t) = \epsilon W_{i1}(x; \tau_0, \tau_1, \tau_2) + \epsilon^2 W_{i2}(x; \tau_0, \tau_1, \tau_2) + \epsilon^3 W_{i3}(x; \tau_0, \tau_1, \tau_2), \quad i = 1, 2, 3 \quad (8)$$

where w_i are dummy functions such that $u = w_1$, $v = w_2$, $\theta = w_3$, and W_{ij} are unknown functions to be determined. Based on appropriate choices of the geometric or mechanical properties of the beam, the loads, or even the reference frame, we can accept that some mechanical parameters are zero or negligible for some power of ϵ . In what follows, we assume that c_0 and K_3 are at most of order ϵ^2 ; m_1 , c_1 , c_2 , K_1 and q_2 are at most ϵ^3 ; q_1 and q_3 are at most ϵ^4 . We also assume that the loads are periodic functions as

$$q_i(t) = P_i \cos(\Omega_i t) = P_i \cos(\omega_i \tau_0 + \sigma_i \tau_2), \quad i = 1, 2, 3 \quad (9)$$

i.e., the excitation frequencies are chosen to be close to the corresponding natural frequencies ω_i by means of detuning parameters σ_i , which are assumed to be of order ϵ^2 .

Substituting Eq. (8) and corresponding derivatives and Eq. (9) in Eqs. (1-3), taking into account the chosen orders of magnitude of all the coefficients, and collecting terms of like powers of ϵ , we obtain, after some algebra, a perturbation hierarchy as a set of linear differential equations

$$m_0 W_{1j, \tau_0 \tau_0} - K_0 W_{1j, xx} = \mathcal{P}_{1j}, \quad (10)$$

$$m_0 W_{ij, \tau_0 \tau_0} + K_S^{-1} (m_0 m_2 W_{ij, \tau_0 \tau_0} - (m_0 K_2 + m_2 K_S) W_{ij, xx})_{, \tau_0 \tau_0} + K_2 W_{ij, xxx} = \mathcal{P}_{ij}, \quad i = 2, 3 \quad (11)$$

with the index j , that is the power of ϵ , spanning from 1 to 3.

Notice that terms \mathcal{P}_{i1} vanish, \mathcal{P}_{i2} depend on W_{i1} , and \mathcal{P}_{i3} depend on W_{i1} and W_{i2} . Moreover, because of our assumptions on the orders of magnitude of $q_i(t)$, \mathcal{P}_{23} is the first term in which an external load, namely $q_2(t)$, appears.

Although we consider only three time scales and neglect terms beyond the third order of ϵ in the expansions of unknowns, in multiple-scale approaches any number of scales and any order of ϵ can be considered. Indeed, the corresponding perturbation hierarchy is, at least in principle, simple to manage: starting by solving the first order problem, the right-hand side of second order problem can be computed; then, once second order problem is solved, the third order right-hand side is got, and so on. At any step proper solvability conditions must be met in order to avoid that resonant secular terms appear in the solution. However, typically, algebraic complexity allows to calculate a few terms of the expansion and convergence properties of the expansion remain unknown [8]. We should also point out that the asymptotic expansion introduced in Eqs. (8) for the unknown functions $w_i(x, t)$ gives an accurate representation of them for ϵ approaching zero. After this brief introduction to the approach, the next step of this study will be to detail about frequency-response curves and time histories, with the aim to compare the behavior of the model we are dealing with to those of other nonlinear beam models available in the scientific literature [9, 10, 11].

Conclusions

The present contribution, which is part of an ongoing research focused on the analysis of a geometrically exact beam model with nonlinear constitutive relationships, reports on preliminaries of a multiple time scale expansion of the equations of motion. The next step, which is still in progress, will focus on approximate time histories, frequency-response curves, and comparison with other nonlinear beam models available in the scientific literature and with results obtained through numerical approaches as finite element or finite difference methods.

Non-linear dynamics of straight beams with (or without) shape imperfections and very shallow arcs: similarities and differences controlled by boundary conditions

Vitalii Pauls^{*}, Stefano Lenci^{*} and Sergey Sorokin^{**}

^{*}*Polytechnic University of Marche, Ancona, Italy*

^{**}*Aalborg University, Denmark*

Summary. The free and forced vibration problems for slightly curved axially restrained beams are solved in two alternative formulations. The first one is the classical nonlinear model, which accounts for the so-called ‘stretching-due-to-bending’ effect. In its framework, a slightly curved beam is considered as the straight one with an initial shape imperfection. The second formulation is the standard model of a planar curved beam. Each model describes the interaction between transverse and longitudinal motion of a beam, but in profoundly different manner. Comparison of predictions of these models for small shape imperfections and various boundary conditions is the goal of this paper.

Introduction

Nonlinear vibrations of ideally straight axially restrained hinged beams have been studied in numerous publications with [1-3] being the most recent ones. The canonical model of such a beam implies that an interaction between flexural and axial vibrations occurs due to the essentially non-linear ‘stretching-due-to-bending’ effect. This coupling mechanism is preserved when a beam acquires arbitrarily small initial shape imperfections. However, vibrations of a slightly curved axially restrained beam can conveniently be modelled within the standard linear theory of planar curved beams, which captures an interaction between flexural and axial vibrations regardless the type of boundary conditions. Furthermore, the nonlinear theory of dynamics of planar curved beams is also well established [4-5]. In this framework, an obvious research question arises:

- What are the validity ranges of the non-linear theory of ideally straight axially restrained beams, the linear theory of curved beams and the non-linear theory of curved beams with respect to the amplitude of initial shape imperfection (initial curvature), vibration amplitudes and boundary conditions?

An attempt to find answer to this question constitutes the subject of the work in progress. Its first preliminary results are presented in what follows.

The model of a curved beam

Our point of departure is the nonlinear model of a circular cylindrical shell [4] adjusted to the plane strain state of deformation. Then two components of displacement (u , w) are considered and the coordinate s along the curved axis of a shell’s segment (which is now reduced to a beam) is introduced, see Figure 1.

Figure 1: A curved beam with sliding support and force applied

The governing non-linear differential equations obtained by means of the Hamilton’s principle are ($\beta \equiv \frac{L}{R}$):

$$\begin{aligned}
& -\frac{\rho L^2(1-\nu^2)}{E}\ddot{u} + u'' + \beta w' + (w' - \beta u)(w'' - \beta u') + \frac{h^2}{12L^2}\beta(\beta u'' - w''') \\
& + \left[u' + \beta w + \frac{1}{2}(w' - \beta u)^2 \right] (w' - \beta u)\beta = 0 \\
& -\frac{\rho L^2(1-\nu^2)}{E}\ddot{w} - \left[u' + \beta w + \frac{1}{2}(w' - \beta u)^2 \right] \beta + \frac{h^2}{12L^2}(\beta u''' - w''') \\
& + [u'' + \beta w' + (w' - \beta u)(w'' - \beta u')](w' - \beta u) + \left[u' + \beta w + \frac{1}{2}(w' - \beta u)^2 \right] (w'' - \beta u') = 0
\end{aligned}$$

The boundary conditions at $s=0$ are $u = w = \beta u' - w'' = 0$, while the boundary conditions at $s=1$ for the case illustrated in Figure 1 are

$$\begin{aligned}
& u' + \beta w + \frac{1}{2}(w' - \beta u)^2 + \frac{h^2}{12L^2}(\beta u' - w'')\beta + \frac{p(1-\nu^2)}{Eh}\cos\left(\frac{L}{2R}\right) = 0 \\
& \left[u' + \beta w + \frac{1}{2}(w' - \beta u)^2 \right] (w' - \beta u) + \frac{h^2}{12L^2}(\beta u'' - w''') + \frac{p(1-\nu^2)}{Eh}\sin\left(\frac{L}{2R}\right) = 0 \\
& \beta u' - w'' = 0
\end{aligned}$$

Alternative formulations of boundary conditions at $s=1$ (e.g., sliding support in an absence of the force or full constrain of displacements) are obvious. Likewise, the limit cases of a linear curved beam [4-5] and a nonlinear ideally straight beam [1-3] are readily available from the proposed formulation.

The solution methods and the eigenfrequency analysis

The exact solution of the linear problem of free/forced vibrations of a curved beam is easily obtained regardless the type of boundary conditions. To solve a non-linear problem of vibrations of a curved beam, the canonical method of multiple scales adjusted for the system of partial differential equations is used. The reference solutions of a nonlinear problem of vibrations of an axially restrained beam by the same method are presented in the references [1-3].

Figure 2: The first and the second eigenfrequency of a curved beam versus curvature parameter

The results of eigenfrequency analysis of an axially restrained hinged beam are presented in Figure 2. The appreciable (exceeding 5%) differences correspond to the amplitude of shape imperfection around $0.06L$.

Conclusions

The results obtained so far suggest that the simple linear theory of curved axially restrained beams agrees with the nonlinear theory of straight beams with shape imperfections in a broad range of curvature parameter. Nonlinear vibrations of a curved beam still require careful asymptotic analysis, especially in the case of a vanishingly small curvature.

Low Voltage Operation of Vilnius Chaotic Oscillator

Dmitrijs Pikulins^{*}, Sergejs Tjukovs^{*}, Iheanacho Chukwuma Victor^{*}, Aleksandrs Ipatovs^{*}, Juris Grizans^{*}

^{*}*Institute of Radioelectronics, Riga Technical University, Riga, Latvia*

Summary. The paper is dedicated to the numerical study of nonlinear oscillations exhibited by the Vilnius chaotic generator. The need for practical applicability of the mentioned generator in chaotic communications defined the necessity to study the low-power operation of the circuit, designed initially to be powered from high voltage sources. The bifurcation map and corresponding one-parameter diagrams reveal complex nonlinear dynamics and regions of robust chaotic oscillations.

1. Introduction

The use of chaotic signals generated by various electronic systems has been growing for the last several decades, and it is considered a major candidate for future technologies. Chaotic oscillators have found applications in communications [1]-[3], random number generators [4], chaotic computing [5] and other fields. The main requirements for the practical application of a chaotic oscillator are the circuit's simplicity, the variety of different chaotic modes, and robustness.

The rapid expansion of the Internet of Things (IoT) creates new challenges to electronic circuit design. Numerous applications like environmental sensing and healthcare monitoring impose the need for long-term autonomous operation of electronic modules. In [6], the authors conclude that batteries are the most promising energy source for IoT applications, particularly wireless sensor networks. Energy harvesting techniques suffer from insufficient power levels and often are unpredictable and thus insecure. This, in turn, implies DC voltage levels available to power electronic circuits being in the range of several volts.

Furthermore, industry trends and the natural need for miniaturization of sensor nodes create new challenges in power circuit design. The battery life may determine the useful lifespan of the device in cases where the batteries are not replaceable for any number of reasons. The requirement of long autonomous operation of IoT devices dictates additional restrictions on chaotic generators, including energy efficiency and low power operation.

The current study is dedicated to a comprehensive analysis of the low-voltage operation of the Vilnius chaos oscillator. First presented in 2004 [7], this circuit has been intended to operate from a 20 V source. However, several attempts have been made to adapt this oscillator to IoT applications [3], [8]. Thus, there is a need to study the nonlinear dynamics of the system operated at much lower voltages than it originally was supposed to.

This paper is organized as follows. The second section is devoted to the description of the schematic and analytical model of the Vilnius oscillator. The third section presents the nonlinear analysis of the system dynamics under study at low voltage operation. The last section is devoted to the overall conclusions and suggestions on the applicability of this type of chaotic oscillator.

2. Vilnius Oscillator Schematic and Model

The schematic of the Vilnius chaotic oscillator is depicted in Fig.1. The circuit is easy to implement and modify, as it includes no unique components, just the off-the-shelf operation amplifier, diode, capacitors, inductors and resistors.

Figure 1: The schematic diagram of the Vilnius oscillator

This oscillator exhibits complex behaviour under specific component parameters despite being relatively simple. The frequency of the waveforms observed in the circuit is determined by reactive components $C1$, $L1$, and $C2$. Thus, it is possible to adapt the scheme for the frequency range of interest. Diode $D1$ is the mandatory nonlinear element needed for the chaotic oscillator. It can be a general purpose silicon diode like 1N4148 or Schottky diode. Also, no special

requirements apply for the operational amplifier. A reader can use, for example, an LTspice computer simulation program to get quick insight into the operation of the circuit and to observe typical waveforms. However, even such a brief study reveals that the number of parameters that affect the system's dynamics is too large to adopt a trial and error approach when the robust chaos is of interest. That is why the comprehensive study of nonlinear dynamics using bifurcation diagrams must be performed to identify the regions of chaotic behaviour for further practical implementation of the Vilnius oscillator.

In this study, a system of equations initially developed in [1] is used to describe the dynamics of the system:

$$\frac{dx}{dt} = y \quad (1)$$

$$\frac{dy}{dt} = ay - x - z \quad (2)$$

$$\varepsilon \frac{dz}{dt} = b + y - c(e^z - 1), \quad (3)$$

where $x = \frac{V_{C1} \cdot q}{k_B \cdot T}$; $y = \frac{I_{L1} \cdot q \cdot \sqrt{\frac{L}{C_1}}}{k_B \cdot T}$; $z = \frac{V_{C2} \cdot q}{k_B \cdot T}$; $a = \frac{(k-1) \cdot R_1}{\sqrt{\frac{L}{C_1}}}$; $b = \frac{I_{R4} \cdot q \cdot \sqrt{\frac{L}{C_1}}}{k_B \cdot T}$; $c = \frac{I_S \cdot q \cdot \sqrt{\frac{L}{C_1}}}{k_B \cdot T}$; $\varepsilon = \frac{C_2}{C_1}$;

$k = 1 + \frac{R_2}{R_1}$; $I_{R4} = \frac{V_b}{R_4}$; k_B is Boltzmann's constant; T is the temperature in Kelvins.

The system's parameters of interest are a , b and ε , which could be adjusted by input voltage, variable capacitor C_2 and variable resistors R_1 , R_2 , R_3 , and R_4 .

The study of the nonlinear dynamics of the Vilnius oscillator will be provided based on one and two-parameter bifurcation diagrams that allow estimation of the system's mode of operation for various combinations of component values. However, this approach requires obtaining the discrete-time model of the original oscillator. The models could be constructed by application of the Poincare map. In the case of the Vilnius oscillator, $y=0$ is selected as the Poincare plane. Thus, the trajectories crossing this plane from one side will define the sampled model and provide the required information on the periodicity of the regimes under study (see Fig.2.).

Figure 2. The introduced Poincare plane for obtaining a sampled model of the Vilnius oscillator

All the calculations are made utilizing specially prepared MATLAB scripts, including the solution of the equations with the Runge-Kutta (4,5) method, implemented in the *ode45* function. As the construction of bifurcation diagrams in the wide range of system parameters could be a time-consuming task, the Parallel Computing Toolbox functionality has been intensively utilized to efficiently distribute the computation tasks between all available physical cores of the computer. The results of calculations and the analysis of the obtained diagrams are provided in the next section.

2. Nonlinear Dynamics at Low Voltage Operation

The main goal of the current research is to study the dynamics of the Vilnius oscillator, operating in the voltage range viable for practical applications in wireless sensor networks. Thus, one of the parameters under study is b , which is directly connected to the current I_{R4} and voltage V_b . The task is to identify the lowest border of supply voltage at which the system could exhibit robust chaotic oscillations and study the qualitative changes in the dynamics as b is varied.

 Figure 3: Two parameter bifurcation diagram for $a=0.3$; $b=5-89$; $\varepsilon=0.05-0.4$.

The subsequent study of the nonlinear dynamics of the oscillator is based on the construction of a two-parameter bifurcation diagram of the system (bifurcation map) and analysis of the corresponding one-parameter bifurcation diagrams as the cross-sections of the map.

The second parameter, chosen to be varied for the bifurcation map, is ε , physically dependent on the capacitor C_1 and C_2 values. The obtained map for $\varepsilon=0.05-0.4$ and $b=5-80$ is shown in Fig. 3. Periodic operation modes are depicted up to period-7, and other high-periodic regimes and chaos are shown as white regions.

The bifurcation map demonstrates that for low values of b (defined by input voltage), the system's dynamics are mainly periodic- exhibiting period-1 to period-4 oscillations for all values of ε . From a practical point of view, the system could not be used as the generator of chaotic oscillations for extremely low voltages (defined by $b < 12$). This is also illustrated in Fig.4. The brute-force bifurcation diagram shows the clear transition from P1 to P4 and back to P1 through subsequent period doublings without any signs of chaotic oscillations in the main branches. No coexisting chaotic attractors could be detected either.

 Figure 4: Brute-force bifurcation diagram for $b=10$; $a=0.3$; $\varepsilon=0.05-0.4$.

However, there is a definite border ($b > 12$), where the system becomes chaotic for a relatively wide range of ε values. There could be intermittent chaotic dynamics (with various periodic windows) or robust chaos without interrupting periodic modes. Fig. 4 shows classical period-doubling routes to chaos enclosing several intervals of robust chaotic oscillations (RCh1-RCh4). It can be inferred that setting system parameters within the ranges indicated - $\varepsilon=0.1-0.23$ - should guarantee stable chaotic oscillations without the issue of transitioning to some periodic mode due to external noise or fluctuations in the component's values.

 Figure 5: Brute-force bifurcation diagram for $b=15$; $a=0.3$; $\varepsilon=0.05-0.4$.

The system's behaviour remains similar for higher values of b , as shown in Fig. 6. However, the amplitude of V_{CI} (variable x) increases. Compared to the previous diagram, the system exhibits a non-smooth transition to chaos from the left side. This phenomenon could be explained by the presence of a diode in the circuit, defining the non-smooth switchings as the voltage rises and a certain threshold is reached. It has been noticed that the systems with non-smooth bifurcations could exhibit robust chaotic oscillations. However, in this case, we still observe some periodic windows in the chaotic regions and the transition to stable periodic regimes as ε reaches 0.24.

 Figure 6: Brute-force bifurcation diagram for $b=50$; $a=0.3$; $\varepsilon=0.05-0.4$.

The second part of the investigation is dedicated to constructing the diagrams for fixed values of ε and varying the parameter b . For $\varepsilon < 0.12$, a wide diversity of dynamical patterns could be observed, as b is varied. Fig. 7. shows period doublings, intermittent chaos and wide periodic windows. These regimes could not be relevant for practical applications, as any slight supply voltage variations could cause unpredicted transitions between different modes, compromising the whole system's security. Chaotic attractors observed in the corresponding regions (see Fig.7- Ch) are not dense enough, indicating the insufficient level of diversity required by practical communication systems.

However, the further increase in parameter ε leads to the formation of several robust chaotic regions (see RCh1 and RCh2 in Fig.8.) with acceptable characteristics and durability to parameter changes. But some periodic windows are still present in the defined parameter range (see, e.g. P3 window in Fig.8.). As we are interested in the low-voltage operation of the system, the region of $b=12-28$ is the most appropriate for the proposed applications.

Setting the $\varepsilon=0.15$ in the middle of the predicted chaotic region in the bifurcation map (see Fig.3), it is possible to obtain the diagram where all periodic windows shrink, and the continuous robust chaotic area is formed. This is demonstrated in Fig.9.

As it could be deduced from Fig.3, the further increase of ε leads to the deterioration of chaotic dynamics and diagrams, similar to those shown in Fig.7 and Fig.8 could be obtained.

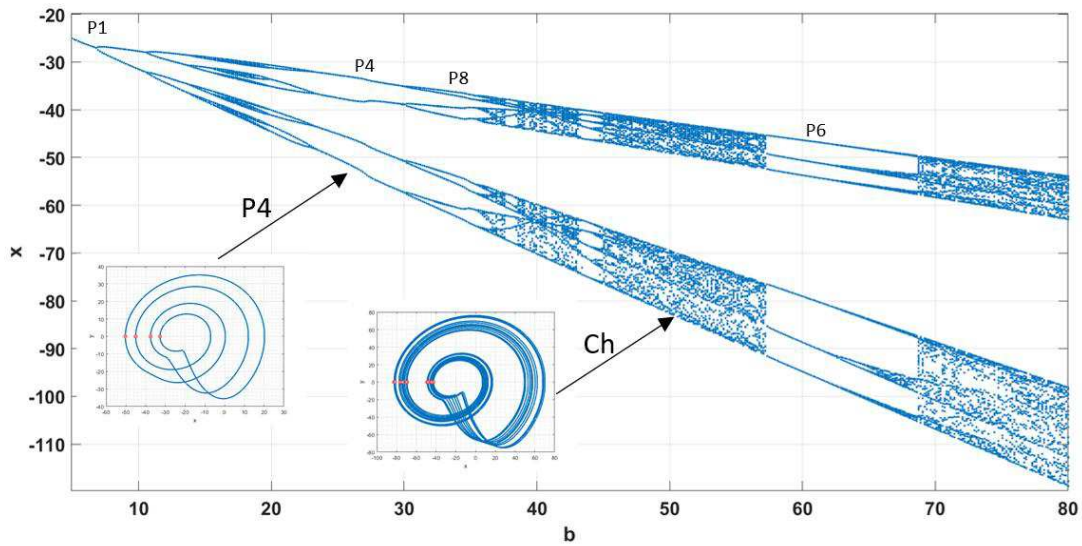

Figure 7: Brute-force bifurcation diagram for $a=0.3$; $\varepsilon=0.1$; $b=5-80$

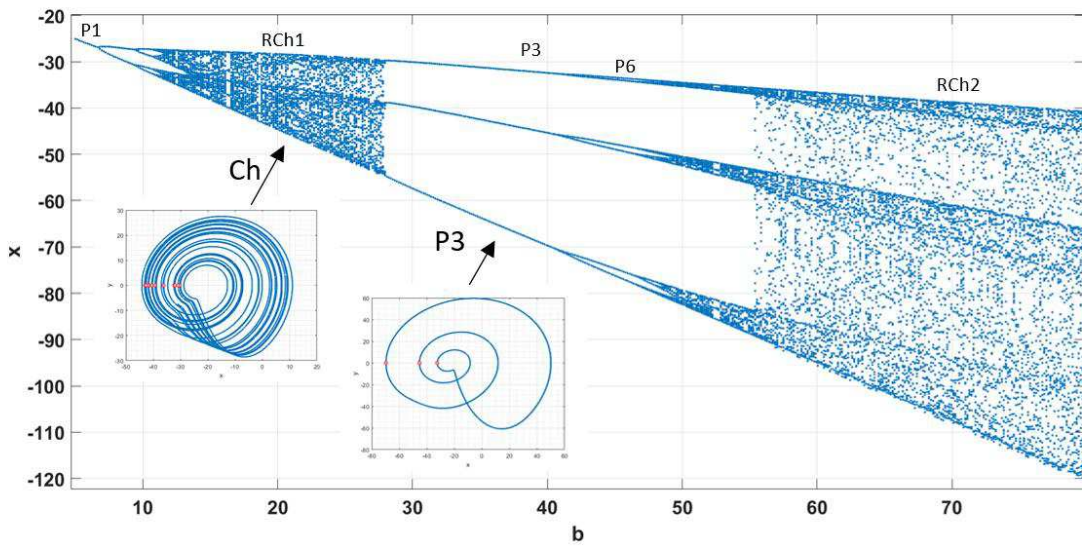

Figure 8: Brute-force bifurcation diagram for $a=0.3$; $\varepsilon=0.12$; $b=5-80$

Figure 9: Brute-force bifurcation diagram for $a=0.3$; $\varepsilon=0.15$; $b=5-80$

3. Conclusions

One of the key parameters defining the applicability of the chaotic oscillators to secure communication systems is energy efficiency (possibility to operate in low-power modes) and robustness (insusceptibility to slight parameter variations and noise). Thus, investigating the dependence of nonlinear dynamics of these kinds of generators on the operation voltage is crucial for practical solutions.

The paper demonstrated the numerical study of possible chaotization scenarios and various nonlinear phenomena observed in the Vilnius chaotic oscillator as system parameters vary. It has been shown that the construction of the bifurcation map allows for the convenient identification of the most appropriate parameter ranges to be used for obtaining robust chaotic modes of operation. The main conclusion is that the Vilnius oscillator could robustly generate chaotic signals required in secure communications, even in low-voltage modes of operation. However, the other systems parameters (e.g. ϵ) should be fine-tuned to exclude transitions to any periodic regime.

Further study could contain the laboratory experiments allowing the verification of numerical simulations and practical estimation of energy efficiency of the proposed robust chaotic regimes.

Nonlinearity in estimating bolt tension from vibrations

Marie Brøns* and Jon Juel Thomsen*
*Technical University of Denmark

Summary. Many technical installations are held together by critical bolted joints. A critical bolted joint can have many appearances, from bolted flanges with many bolts to smaller lap-joints with only a few bolts. Critical imply that failure is not accepted, as it would lead to dangerous situations and most likely very costly repairs. Such joints are found in wind turbines, pressurized pipelines, large machinery etc. To ensure safe operation, regular checking and documentation of bolt tension is required, which is both costly and time consuming, and traditional tightening techniques are not very accurate. Recent work has shown potential in estimating bolt tension by using vibrations actively, e.g. by analyzing the vibrational response in a bolt after a hammer impact. Tests of this have been carried out with good results for setups with a single bolt. However, most often a bolted joint consists of multiple bolts holding at least two parts together. The more parts and bolts, the more sources to nonlinear effects from frictional contacts and potential vibrational coupling. In this work, we present the current status of the method with new results from a multi-bolt setup, and raise the question of which potential nonlinear effects need to be considered to apply the method more generally for multi-bolt joints.

Introduction

Traditional tightening methods include torque wrenches and hydraulic tensioners [1]. These cannot estimate the tension, so checking is done by retightening. This can lead to overtightening, which can in turn introduce failure. Furthermore, it is time consuming to retighten all bolts, especially if the retightening revealed that only a few bolts were in fact loose. Newer technologies include bolts with incorporated strain gauge sensors, which is more expensive than traditional bolts and potentially fragile, and ultrasonic transducers [2], which measure bolt elongation. These new advances show that it is definitely of interest to improve both speed, cost and accuracy in estimation of bolt tension. Vibrations could be advantageous to use, as control can then be done without employing heavy equipment and there are direct correlations between tension and bending vibrations. The challenge is to ensure that other mechanism that influence the vibrational response have been investigated, so that a vibrational response of any bolt, in any structure, can be analyzed correctly, thus permitting a robust estimation of tension. To get to that point possible nonlinear effects must be understood.

Bolt tightness indicators based on bending vibrations

A bolt can be considered a beam with rotational and translational linear boundary stiffness springs [3], whose stiffness may increase nonlinearly with tension [3]. As a bolt is tightened the boundary stiffness increases, as well as the tension. In [4] demonstrated that a large number of nonlinear boundary micro springs can effectively behave as a linear spring. Firstly, a bolt can indeed bend as a beam. This is experimentally investigated in [5] by analyzing measurements from a scanning laser Doppler vibrometer and obtaining actual mode shapes. Furthermore, experimental results for a single bolt show that it is possible to get reproducible results of the first and second transverse natural frequency, increasing first strongly with tension and then linearly, as shows in Figure 1(a) from the small color markers [3,6]. A nonlinear stiffness model adapted from [3] can be fitted to the measurements (dashed lines in Figure 1(a)). The corresponding damping ratio decreases with tension, strongly for low tension, and weakly for high tension [3,6]. Combining the information coming from the bolt tightness indicators can provide an estimate of bolt tension [6,7].

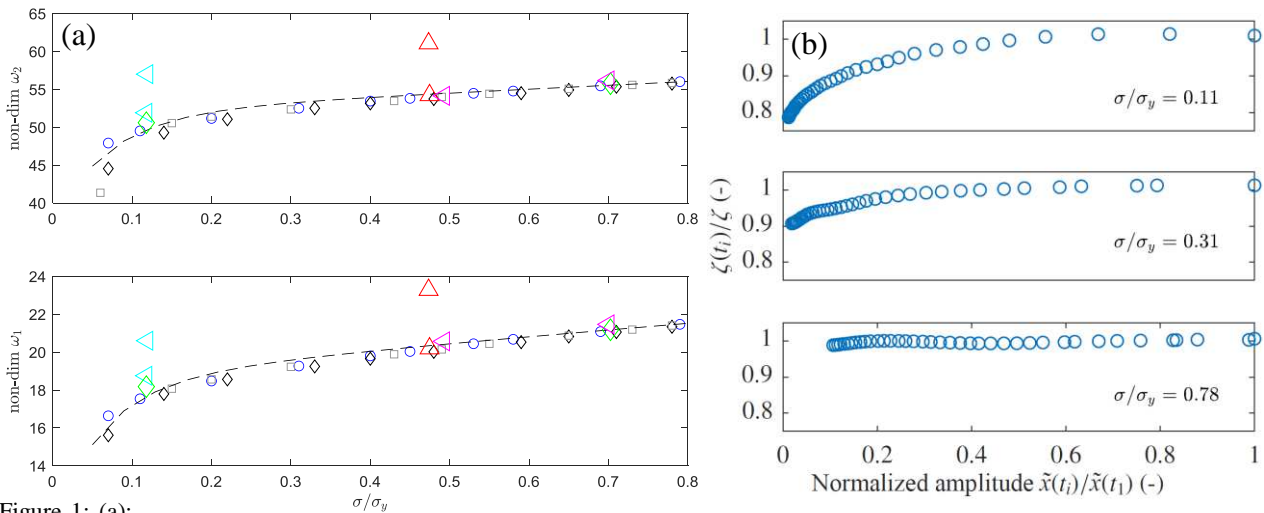

Figure 1: (a): Transverse natural frequency as function of bolt tension: small markers: single bolt experimental data; everything has been taken apart between each color. Large markers: data from a two-bolt setup. Dashed line: theoretical tension-stiffness model adapted from [2]. (b) Time-dependent damping ratio as function of normalized acceleration amplitude.

Nonlinear effects and modal coupling between bolts

Investigations of vibration amplitude dependencies (thus nonlinearity) of the above mentioned bolt tightness indicators, damping ratios and frequency, have revealed to be of significance only under certain circumstances [6]. For practically relevant ranges of excitation level, the transverse natural frequency of a single bolt in a solid cylinder is effectively independent of vibration amplitude [6]. However, the linear damping ratio is not. Figure 1(b) shows the amplitude dependency of the damping ratio (of the first natural frequency) for three levels of tension. It drops for lower tension and smaller amplitude.

Another issue is coupling of vibrations between different planes. A bolt has a symmetric cross section, so there is a possible coupling between the two transverse directions, which appears to be driven by linearly acting imperfection [8]. Another coupling is the nonlinear coupling between transverse and longitudinal vibrations, which can occur in tensioned beams [9]. This nonlinear effect, in combination with imperfections, can allow for exciting transverse vibrations from a longitudinal impact [10].

New experimental results reveal that coupling between two bolts with almost identical tension and boundary stiffness appear to behave as a single coupled system, with co-and anti-phase modes [11]. However, this is only seen for cases where the tension is almost identical, for two bolts with different tension, it appears that interpreting the two bolts as separate entities with separate vibrational response is adequate. This may be the case due to an unknown nonlinear effect: A 1D-beam model of two beams coupled with springs will predict that the anti-phase mode has a higher frequency than the co-phase mode, as pulling in opposite directions will activate the coupling spring and increase boundary stiffness. Experiments show very similar behaviour. Figure 1(a) show also large color markers in pairs; these are measurements from a setup with two bolts and the frequencies are extracted from accelerometer measurements of one of the bolts. For cases with equal tension, there is a jump in frequency, both for first and second mode. However, for two bolts with even slightly different tension, the results are as for two single uncoupled bolts. To be able to fit a 1D-beam model to the measurements of all the cases, it is necessary to change the value of the coupling spring, leading to the question if this can be better explained as a nonlinear vibrational coupling between tension and bending. To investigate this we will introduce a nonlinear coupling spring and compare the results to the linear model.

Conclusions

The first steps in estimation of tension by vibrations have been taken. It is possible to measure natural frequencies and damping ratios in a single bolt and use these as bolt tension indicators. Nonlinearity has been investigated, and shows to be influential only under certain conditions. Tests with multiple bolts show many similarities with results of a single bolt, though under certain conditions coupling can occur, and that coupling can potentially best be modeled as nonlinear. This will be investigated further and updated results will be presented at the conference.

Summary. The Vibro-Impact Nonlinear Energy Sinks (VI NES) is a highly nonlinear device employed for dissipating energy of a primary vibrating system. The simplest setup consists of a rigid container enclosing a spherical particle, which slips along the container and impacts against its walls under vibrations. This study assesses the sensibility of the VI NES dynamics to the impact velocity and the contact force estimation.

Introduction

Over the past few years, the use of vibro-impact dampers as vibration absorbers aroused the interest of the research community. Potentially, vibrational energy may be dissipated by the impacts that occur between a particle and one or more rigid barriers linked to a primary structure. Several configurations of vibro-impact systems were proposed, including single-sided VI NES [1, 2], symmetric single-sided VI NES [3] and double-sided VI NES [4, 5].

Refs. [6, 7] verified the efficiency of the VI NES for a primary system subjected to a seismic excitation. The greater part of the vibrational energy is dissipated at the beginning of the ground motion, when the primary structure is highly stressed. Notably, analytical and experimental studies revealed the existence of various dynamical regimes of the VI NES and their effect on the energy dissipation capability [8, 9].

This study focuses on the dynamics of a double-side Vibro-Impact Nonlinear Energy Sink (VI NES) shown in Fig. 1. Since the VI NES performs well in the vicinity of the 1:1 resonance, numerical simulations should be able to calculate as accurately as possible the rebound velocity and instant. We will show the effect of slight delays in the kinetic energy estimation and we will suggest some solutions to improve accuracy of the contact computation.

Instantaneous contact

In the framework of contact mechanics, instantaneous collisions between two rigid bodies lead to a change of direction and velocity depending on the value of the coefficient of restitution (COR) ϵ , which is defined as:

$$\epsilon = \frac{v_1(t_c) - v_2(t_c)}{v_2(0) - v_1(0)}, \quad (1)$$

with $0 \leq \epsilon \leq 1$. $\epsilon = 0$ for perfectly inelastic collisions and $\epsilon = 1$ for perfectly elastic collisions. The COR can be estimated by measuring experimentally the contact duration and the flight time of a bouncing ball [10]. $v_{1,2}(0)$ and $v_{1,2}(t_c)$ are the velocities of the particles before and after the collision, respectively, and t_c the contact duration. When the VI NES is coupled to a primary system for the passive vibration control, the contact duration t_c is generally very small with respect to the dominant time scale and the contact may be approximated as an instantaneous phenomenon. To solve numerically this problem, an event driven scheme may be used. At first, the simulation solves separately the free flight of the particle and the dynamics of the primary system. Then, when the particle collides with a barrier, the particle and primary system initial conditions (IC) are updated with new positions and velocities obtained from the law of conservation of momentum. The numerical integration scheme goes on until the end of the simulation.

Previous studies shown the close link between the VI NES damping capability and its dynamical regime, which ranges from periodic collisions to chaos. Hence, numerical resolution of this non-smooth numerical problem requires very high accuracy in the estimation of the impact velocities. Indeed, a small variation may lead to a huge change in the system

Figure 1: Schematic representation of a VI NES.

Figure 2: Simulated motion of the VI NES shown in Fig. 1. VI NES is shaken kinematically at $f = 1/T = \omega/2\pi = 100$ Hz with an amplitude $A = 10$ cm (see the red curves). The initial velocity of the particle is $v_0 = -62.8$ m/s. For the sake of clarity, the particle is considered as a point mass interacting with the inner walls of the container. (a) Position and (b) kinetic energy of the particle for $\epsilon = 0.7$ and by varying its initial velocity.

dynamics. As an example, we show in Fig. 2(a-b) the trajectory and the kinetic energy, respectively, of a steel spherical particle impacting against two rigid walls kinematically shaken at $\gamma_G(t) = -A\omega^2 \sin(\omega t)$. Here, we implement the instantaneous contact model defined in Eq. 1, such that the contact duration $t_c = 0$ is infinitely small compared to the period of oscillation T and the VI NES dynamics is solved for one period for different initial velocities. As it can be seen, a variation of the order of the 1% of initial velocity leads to a difference of the about the 4% in the kinetic energy after only one period. This bias leads to different energy transfers and thus of energy dissipation. Moreover, this delay can cause an error in the simulation of the system dynamics by falling into one dynamical regime in preference to another.

Conclusions

The capability of a VI NES to damp vibrations of a primary system depends on its dynamical regime. For this reason, much attention must be paid on the numerical computation of the impacts in terms of relative velocity and time. One solution that prevents to increase computational costs, is to enrich the contact model by computing the contact force and using a finite duration continuous interaction potential. Notably, it is possible to demonstrate that the contact duration has a considerable effect on the estimation of the dissipated energy, even for very fast collisions. Another benefit of finite contact modeling is that it allows to evaluate the accelerations and the repulsive forces, which are not provided by the instantaneous contact model.

Summary. A new algorithm for estimating the robustness of a dynamical system's equilibrium is presented. Unlike standard approaches, the algorithm does not aim to identify the entire basin of attraction of the solution. Instead, it iteratively estimates the so-called local integrity measure, i.e., the radius of the largest hypersphere entirely included in the basin of attraction of a solution and centred in the solution. The procedure completely overlooks intermingled and fractal regions of the basin of attraction, enabling it to provide a meaningful engineering quantity quickly. The algorithm is tested on various mechanical systems. Despite some limitations, it proved to be a viable alternative to more complex and computationally demanding methods, making it a potentially appealing tool for industrial applications.

Introduction

Local stability is one of the most critical properties of a dynamical state. Engineers heavily exploit this concept. Nevertheless, scientists dealing with dynamical systems are aware that, despite its local stability, a system might diverge from its state if subject to a perturbation sufficiently large to make it cross the boundary of its basin of attraction (BOA). However, the definition of a system's BOAs is computationally very demanding. A few methods for the identification of BOAs of dynamical systems exist [1]. Analytical methods are generally based on Lyapunov functions. However, they are not a feasible option for the majority of real applications. The cell mapping method is probably the most efficient numerical technique for BOA estimation [2]. Experimental methods are almost inexistent, except for a few exceptions [3, 4]. The objective of this study is to develop an algorithm for the robustness assessment of equilibrium points. The procedure reduces the computational cost for global stability analysis by identifying the local integrity measure (LIM) [5] only, overlooking fractal and intermingled portions of the BOA, which are hard to identify and practically less relevant.

Methodology

The algorithm is based on a simple framework. Considering a predefined region of the phase space, initially, the maximal value of the LIM is calculated, being equal to the minimal distance between the equilibrium point of interest and the boundary of the region of the phase space considered. Then, a trajectory of the system in the phase space is computed. If the trajectory does not converge to the desired solution, the LIM is estimated as the minimal distance between the equilibrium point of interest and any point of the non-convergent trajectory. The new estimated value of the LIM (an overestimate of the real LIM value) defines a hypersphere in the phase space denominated hypersphere of convergence, limiting the region of interest. If a simulation converges to the desired solution, then the LIM is not reduced in that iteration. Initial conditions of each simulation are chosen as the farthest point from any other already tracked point within the hypersphere of convergence.

In order to automatically classify the computed trajectories, the phase space is divided into cells. A trajectory is classified as converging or non-converging to the desired solution by analyzing the cells in which points of the trajectory lie. To reduce computational time, if a trajectory reaches a cell already tracked by a previous trajectory, the simulation is interrupted; all cells containing points of the trajectory are classified according to the reached and already tracked cell. A graphical explanation of the classification procedure adopted is illustrated in Fig. 1.

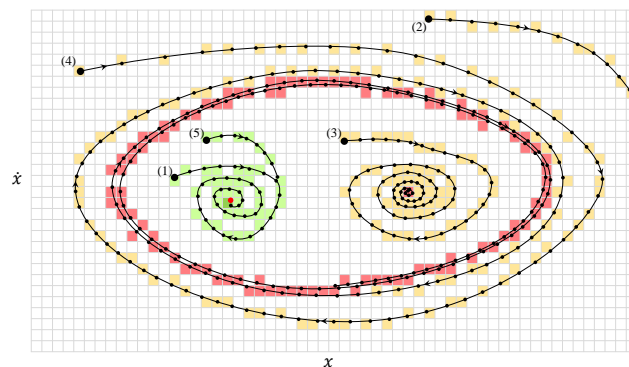

Figure 1: Illustrative examples of trajectory classification. (1) Converging to a known equilibrium; (2) leaving the considered phase space region; (3) converging to an unknown equilibrium; (4) converging to an unknown periodic solution; (5) converging to an already tracked cell.

Results

We implemented the algorithm on systems of various dimensions (up to dimension 8); the analysis illustrated that the algorithm could rapidly and efficiently estimate the LIM value in all cases studied. In particular, the first few iterations already provided a relatively accurate estimate of the real LIM value. The majority of the subsequent simulations converged to the equilibrium of interest, except few ones, which further improved the initial estimate of the LIM. Figure 2a represents the trend of the LIM estimate for the case of a Duffing-van der Pol oscillator with an attached tuned mass damper (4-dimensional system) [6]. The black line in Fig. 2a follows the described path. Light blue lines represent the LIM trend for other repetitions of the algorithm. All curves have a similar tendency. The system under study presents a stable equilibrium point (red cross in Fig. 2b) coexisting with a stable periodic solution (black line in Fig. 2b) for the considered parameter values. We remark that, in Fig. 2b, tracked points are projected on a section of the phase space, which makes it appear that red dots are within the hypersphere of convergence (green dashed line) while they are not.

Figure 2: (a) LIM estimated value; (b) projection of the points tracked during the computation; blue and red points: converging and non-converging points, respectively, dashed green line: section of the hypersphere of convergence.

Conclusions

In this study, a new algorithm for estimating the robustness – dynamical integrity – of a stable equilibrium was developed. The algorithm utilizes an approach different from existing numerical methods for global analysis. It does not aim at studying the whole basin of attraction of a solution; instead, it directly tries to estimate the local integrity measure (LIM). From an engineering perspective, this quantity has obvious relevance for the safety of a dynamical system. The obtained results suggest that the proposed algorithm is a viable option for the robustness assessment of an equilibrium point. In particular, thanks to its quickness, it has the potentiality to be utilized in industrial environments, where rapid solutions are generally pursued. Future research developments should aim to make the algorithm utilizable for the robustness estimation of other kinds of solutions, such as periodic motions.

Summary. We provide a general framework for optimization along periodic orbits or quasiperiodic invariant tori in dynamical systems with delay. Our recent study [1] developed a methodology for such problems based on the calculus of variations. The formulation presented in [1] did not exploit the typical structure of Jacobians in problems with delay, resulting in high computational costs and difficult-to-generalize algorithms. Here, we reformulate general boundary-value problems for delay equations by decomposing them into ordinary differential equation and algebraic interval coupling conditions. We consider such coupling conditions for various multi-segment boundary-value problems and describe how the necessary optimality conditions along with the corresponding Jacobians may be implemented in the continuation package COCO [2]. Several examples demonstrate the implications to computational efficiency, as well as the ease of problem construction.

Motivating example

Consider the retarded delay-differential equation with periodic forcing

$$\dot{x} = f(t, x, g(x, p)(t), p) := \begin{pmatrix} -\omega x_2 + x_1(t - \alpha)(1 + r(\cos(2\pi t/T - 1))) \\ -\omega x_1 + x_2(t - \alpha)(1 + r(\cos(2\pi t/T - 1))) \end{pmatrix}, \quad (1)$$

where $r = \sqrt{x_1^2 + x_2^2}$ and $p = (\alpha, \omega, T)$. Figure 1 shows a family of two-dimensional quasiperiodic invariant tori for this system obtained for fixed delay α and rotation number ρ (ratio of fundamental frequencies). In Fig. 1, the fold point at $\omega \approx 0.44$ separates stable (solid) from unstable (dashed) tori. We may locate the fold and further seek to locate extrema in ω under additional variations in α by considering the set of necessary conditions for stationary values of ω given corresponding dynamic constraints. Specifically, by suitable transformations [1, 2], an equivalent representation for a quasiperiodic invariant torus of (1) on the cylindrical domain $(\varphi, \tau) \in \mathbb{S} \times [0, 1]$ (here, \mathbb{S} denotes the unit circle) is in terms of a solution to the differential constraint

$$V_{,\tau}(\varphi, \tau) = Tf(T\tau, V(\varphi, \tau), [W_{\frac{\alpha}{T}}V](\varphi, \tau), p) \quad (2)$$

along with the boundary condition

$$V(\varphi, 1) - V(\varphi + 2\pi\rho, 0) = 0. \quad (3)$$

Here, the wrapping operator W_a is given by

$$[W_a\chi](\varphi, \tau) := \chi(\varphi - 2\pi j\rho, \tau - a + j), \quad (4)$$

where $j \in \mathbb{Z}$ is defined depending on a, φ, τ such that $\tau - a + j \in [0, 1]$. This operator captures the dependence of the vector field on a shifted V , consistent with the presence of delay. Let $f_{,2}(\varphi, \tau)$ and $f_{,\omega}(\varphi, \tau)$ denote the partial derivatives of f with respect to its second argument and ω , respectively, evaluated at $(T\tau, V(\varphi, \tau), [W_{\frac{\alpha}{T}}V](\varphi, \tau), p)$, let df/dT denote the total derivative of $f(T\tau, V(\varphi, \tau), [W_{\frac{\alpha}{T}}V](\varphi, \tau), p)$ with respect to T , and let $h_j(\varphi, \tau)$ denote the partial derivative of f with respect to its third argument evaluated at $(T\tau, V, V(\varphi - 2\pi j\rho, \tau - \frac{\alpha}{T} + j), p)$ for $j = 0, 1$. A set of suitably constructed necessary adjoint conditions for stationary values of ω are then given by

$$-\lambda_{f,\tau}^T - T\lambda_{f,2}^T - T(W_{-\frac{\alpha}{T}}\lambda_f)^T W_{-\frac{\alpha}{T}}h_0 = 0, \quad (\varphi, \tau) \in \mathbb{S} \times (0, 1 - \alpha/T), \quad (5)$$

$$-\lambda_{f,\tau}^T - T\lambda_{f,2}^T - T(W_{-\frac{\alpha}{T}}\lambda_f)^T W_{-\frac{\alpha}{T}}h_1 = 0 \quad (\varphi, \tau) \in \mathbb{S} \times (1 - \alpha/T, 1), \quad (6)$$

and

$$\lambda_f^T(\varphi, 0) + \lambda_{\text{rot}}^T(\varphi - 2\pi\rho) + \lambda_{\text{ph}}V_{,\varphi}^{\star T}(\varphi) = 0, \quad \lambda_f^T(\varphi, 1) + \lambda_{\text{rot}}^T(\varphi) = 0, \quad (7)$$

$$-\int_0^{2\pi} \int_0^1 \lambda_f^T T f_{,\omega} d\tau d\varphi + \eta_\omega = 0, \quad -\int_0^{2\pi} \int_0^1 \lambda_f^T (f + Tdf/dT) d\tau d\varphi + \eta_T = 0 \quad (8)$$

in terms of the original variables V , ω , and T , a reference function V^* , and a set of Lagrange multipliers λ_f , λ_{rot} , λ_{ph} , η_ω , and η_T , where $\eta_\omega = 1$ and $\eta_T = 0$ at a stationary point. The analysis in [1] demonstrates the successful location of such stationary points (and of the fold in Fig. 1) using a method of successive continuation, first pioneered by Kernévez and Doedel [3].

Figure 1: One-dimensional family of quasiperiodic tori [1] obtained with rotation number $\rho \approx 0.6618$ and $\alpha = 1$.

Software implementation

In the present work, we describe an effort to improve the computational efficiency of the implementation of the continuation problem in the previous section. Specifically, in contrast to the implementation in [1], which involved numerically computed Jacobians and no vectorization of the corresponding discretized problem, we describe an ongoing effort to encode explicit Jacobians in a vectorized form that supports an entire class of continuation problems with delay. These include initial-value problems, multisegment periodic orbits, and quasiperiodic invariant tori, even in the presence of multiple delays. The development platform is COCO, a MATLAB-based software package with an object-oriented construction paradigm that supports building composite problems by coupling instances of simpler problems. As an example, continuation of quasiperiodic invariant tori for a problem without delay was considered in [2] in terms of a multisegment boundary-value problem with all-to-all coupling of segment end points in terms of a suitably formulated Fourier interpolant. This past work motivates the implementation sought in the presence of delay.

Problem decomposition

To illustrate our approach, consider replacing the equation

$$x' = f(\tau, x, g(x, p)(\tau), p) \quad (9)$$

with the decomposition

$$x' = f(\tau, x, y, p), \quad y(\tau) = g(x, p)(\tau) \quad (10)$$

for $\tau \in (0, 1)$ in terms of a differential equation and an interval condition. A special case is obtained for $g(x, p)(\tau) := x(\tau - p_1|_{\text{mod } [0, 1)})$ corresponding to a periodic-orbit problem (omitting the discrete condition of periodicity at $\tau = 0$) with a single discrete delay p_1 . In this case, vanishing variations of the Lagrangian

$$L = \int_0^{p_1} \lambda_{\text{int}}^\top(\tau) (y(\tau) - x(1 + \tau - p_1)) \, d\tau + \int_{p_1}^1 \lambda_{\text{int}}^\top(\tau) (y(\tau) - x(\tau - p_1)) \, d\tau \quad (11)$$

with respect to λ_{int} yield the original interval condition, while variations with respect to x yield the contributions $-\lambda_{\text{int}}^\top(\tau + p_1 - 1)$ and $-\lambda_{\text{int}}^\top(\tau + p_1)$ on $\tau \in (1 - p_1, 1)$ and $\tau \in (0, 1 - p_1)$, respectively, to the adjoint differential equations. In general, the proposed decomposition allows us to develop a fully vectorized encoding with explicit Jacobians of a discretization of the differential equation constraint in (10) in terms of a corresponding discretization of x and y , without simultaneously imposing (a discretization of) the interval coupling constraint in (10). It is clear that we may similarly derive a general form of the discretized contributions to the adjoint conditions associated with the differential equation constraint, as well as their Jacobians, without also considering the contributions from the interval coupling constraint. Once these have been encoded in all generality, they may be invoked any number of times in the construction of a multisegment trajectory problem, such as that associated with continuation of quasiperiodic invariant tori. Of course, in a multisegment trajectory problem, the interval coupling conditions typically take a more general form in which y 's associated with different segments are expressed in terms of x 's associated with multiple other segments. A challenge is the derivation of a general form of the corresponding adjoint conditions, their discretization, and corresponding Jacobians.

Conclusions

A decomposition of the implementation of the necessary conditions for stationary values of an objective function along a constraint manifold defined by a boundary-value problem with delay is proposed in order to support optimization along families of periodic orbits or quasiperiodic invariant tori. The decomposition separates differential constraints from a set of interval conditions by the introduction of additional auxiliary unknowns. The advantage of the proposed decomposition is in the convenience of the implementation, including the vectorization of the discretized constraints and their Jacobians, and its generalization to a number of other problem types, including differential-algebraic problems. We argue that the expense of increasing the number of unknowns is outweighed by the shortened development time for different classes of user-specific optimization problems, per the underlying philosophy of the COCO software development.

Summary. In this contribution, a method for the numerical computation of nonlinear modes for damped systems is presented. The main idea is to introduce a conservative force term to compensate the non-conservative effects, in such a way that the condition of energy resonance is verified. We describe a systematic approach for the construction of the associated backbone curves and discuss related subjects such as their stability and practical applications.

Introduction

Nonlinear Normal Modes (NNM), which extend the familiar modal analysis to the case of nonlinear mechanical systems, have been a central research topic in dynamics over the past decades. Besides being an interesting theoretical concept, they have been shown to lead to numerous practical applications thanks to their relation to forced resonances, localization, energy transfers and model reduction (see [1] for a review, as well as references therein). Simply stated, the idea behind all methods for the computation of NNMs is to construct an invariant manifold of the conservative equations of motion, either directly or through the continuation of periodic solutions on the manifold [2]. However, modes computed in this fashion do not take into account the presence of non-conservative effects. As a consequence, deviations from the actual backbone curves of the system are to be expected: while they remain small in the case of small proportional damping, they can be considerable when damping is large or when the nonlinear forces involved are fundamentally non-conservative. Hence, just as for the conservative case, efforts have been made to extend the concept of non-conservative modes to nonlinear systems, yielding Non-Conservative Nonlinear Modes (NCNM). Different methodologies for the computation of NCNMs exist, relying on generalizations of the manifold-construction, complex-mode and periodic-motion-continuation techniques. The latter of these, introduced by Krack [3], consists in adding an artificial damping term to compensate for all non-conservative effects and thus achieve periodic motions. This method was applied by Jahn and co-workers [4] to study self-excited vibrations, and in particular to detect limit cycle oscillations. Nevertheless, one of the assumptions of this method is that the non-conservative terms are frequency-independent, which is not the case of, e.g., systems with memory terms. The present contribution introduces a novel, general method for the computation of NCNMs, based on extending the concept of energy resonance from linear modal analysis to the nonlinear case. Upon application of the Harmonic Balance Method (HBM), this leads to the formulation of a conservative equation where the effect of non-conservative terms of any form can be accurately taken into account, and whose solutions correspond to NCNMs.

Energy Resonance

Consider the equations of motion for a system of damped, unforced, nonlinear oscillators. By applying the HBM, they are expressed in the frequency domain with the Fourier coefficients of displacements \mathbf{X} and the fundamental frequency ω as unknowns, giving:

$$\mathbf{R}(\mathbf{X}, \omega) = \mathbf{Z}(\omega)\mathbf{X} + \mathbf{F}_{\text{NL}}(\mathbf{X}, \omega) = \mathbf{0} \quad (1)$$

where $\mathbf{Z}(\omega) = \omega^2 \nabla^2 \otimes \mathbf{M} + \omega \nabla \otimes \mathbf{C} + \mathbf{I} \otimes \mathbf{K}$ is the dynamical stiffness matrix containing inertial, damping and stiffness terms, and $\mathbf{F}_{\text{NL}}(\mathbf{X}, \omega)$ represents the Fourier coefficients of all nonlinear forces. Excluding the case of limit cycle oscillations, this equation has no non-trivial solution since it contains non-conservative terms and thus no periodic solutions. If these terms are ignored, a conservative system is obtained, whose solution yields the traditional, undamped nonlinear modes as per Rosenberg's definition:

$$\mathbf{R}_p(\mathbf{X}, \omega) = [\omega^2 \nabla^2 \otimes \mathbf{M} + \mathbf{I} \otimes \mathbf{K}] \mathbf{X} + \mathbf{F}_{\text{NL},c}(\mathbf{X}, \omega) = \mathbf{0} \quad (2)$$

Drawing a parallel with linear modal analysis, these solutions describe phase resonance. Another possibility, as proposed by Grenat et al. [5], is to compensate the non-conservative terms through the addition of a fictitious conservative force in such a way that the underlying invariant manifold is kept unchanged. This is achieved by considering the condition for energy -rather than phase- resonance, which can be expressed by the scalar equation:

$$\frac{\partial (\mathbf{X}^T \mathbf{X})}{\partial \omega} = 0 \quad (3)$$

In this work, we show that Eq. (3) leads to the following conservative system:

$$\mathbf{R}_E(\mathbf{X}, \omega) = (\omega^2 \nabla^2 \otimes \mathbf{M} + \mathbf{I} \otimes \mathbf{K}) \mathbf{X} + \mathbf{F}_{\text{NL},c}(\mathbf{X}, \omega) - \mathbf{G}_D(\mathbf{X}, \omega) = \mathbf{0} \quad (4)$$

where the non-linear terms have been split into a conservative ($\mathbf{F}_{\text{NL},c}$) and a non-conservative part ($\mathbf{F}_{\text{NL},nc}$). The term \mathbf{G}_D , for which we have derived an explicit analytical expression, is a function of all non-conservative terms, both linear and

nonlinear. Eq. (4) can be used to compute normal mode solutions regardless of the specific form of the non-conservative terms, under the condition that they are continuous functions of \mathbf{X} and that, as for any autonomous system, a phase equation be appended for closure. Illustrative examples are presented below:

1. Viscous damping

Assuming linear damping of the form: $\mathbf{f}_{nc}(t) = \mathbf{C}\dot{\mathbf{x}}(t)$:

$$\mathbf{G}_D = \frac{1}{2} \mathbf{I} \otimes (\mathbf{M}^{-1} \mathbf{C} \mathbf{C}) \mathbf{X} \quad (5)$$

Fig. 1 a) superimposes the frequency response of a Duffing oscillator with high damping to its corresponding NNM and NCNM backbones, for varying excitation levels.

2. Flow-induced added damping

Following [7], forces induced by transverse flow on a flexible cylinder within a rigid array can be modelled by a memory function of the form: $\mathbf{f}_{fe}(\mathbf{x}, t) = \sum_{k=0}^N \mathbf{A}_k \int_0^t e^{-b_k \tau} \mathbf{x}(t - \tau) d\tau$. This leads to added damping terms which are linear in \mathbf{X} but frequency-dependent through the matrices $\mathbf{D}_k(\omega, b_k)$:

$$\mathbf{G}_D = \frac{1}{2} \left\{ \sum_{k=0}^N [\mathbf{I} \otimes \mathbf{M} + b_k \mathbf{D}_k \otimes \mathbf{A}_k]^{-1} [\mathbf{I} \otimes \mathbf{C} - (\mathbf{D}_k + \omega \nabla^2 \mathbf{D}_k^2) \otimes \mathbf{A}_k] [\mathbf{I} \otimes \mathbf{C} - \mathbf{D}_k \otimes \mathbf{A}_k] \right\} \mathbf{X} \quad (6)$$

3. Doubly-clamped viscoelastic beam

Considering a Kelvin-Voigt model [6] to describe the stress-strain relation within the beam, the equations of motion for modal coordinates q_j include non-conservative terms of the form: $\eta q_i q_j \dot{q}_k$ as a result of mid-plane stretching. Fig.1 b) shows the NCNM curves near a 1:5 internal resonance between the first and third bending modes, where considerable deviation from the undamped case is observed for high values of η .

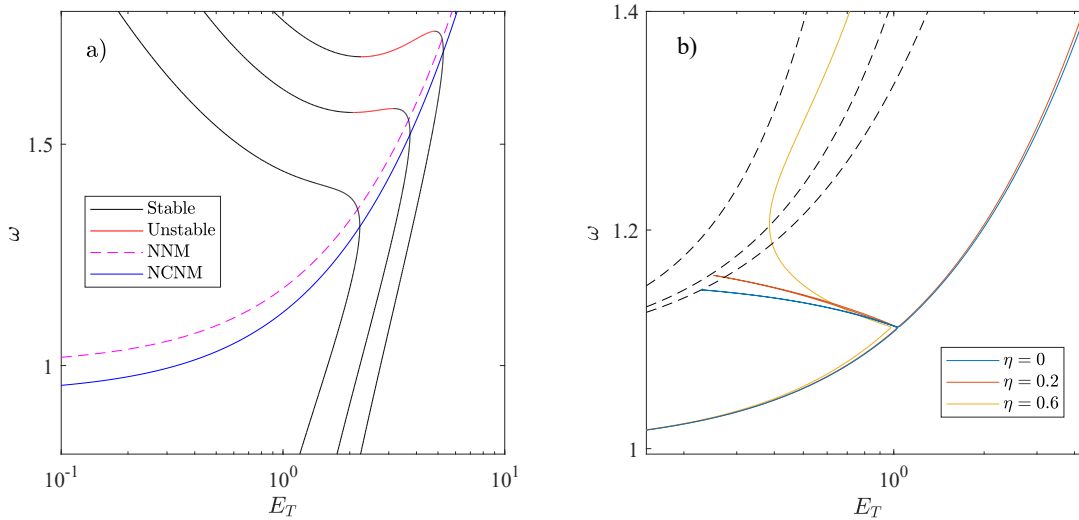

Figure 1: Examples of backbone curves with NCNM formalism. (a) Internal resonance of viscoelastic beam: first (solid) and third (dashed) nonlinear modes for different values of η . (b) Duffing equation with high viscous damping, contrasting NNM and NCNM backbone curves.

Conclusions

In this contribution, we introduced a systematic method for NCNM construction based on the concept of energy resonance. Likewise, its application to diverse mechanical vibration problems was showcased. Further work on this subject includes: bifurcation analysis, a detailed comparison with alternative methods and the experimental targeting of particular nonlinear modes by exploiting the function \mathbf{G}_D .

† Institut für Mathematik, Universität Oldenburg, D26111 Oldenburg, hannes.uecker@uni-oldenburg.de

Summary. Shape equations, such as the constant mean curvature (CMC) equation or the Helfrich equation, are geometric partial differential equations that arise for example in modeling liquid bridges or red blood cells. Analytical solution of these equations are known only in few situations, and we use numerical continuation to compute solutions and study their parameter dependence. The problems require adaptations of typical PDE numerics because of the quasilinear nature of the equations and the geometrical background. We discuss how some of these issues are treated in the numerical continuation and bifurcation package `pde2path`. To illustrate the implementation, we present some examples of CMC and Helfrich surfaces.

Introduction

Shape equations are differential geometric partial differential equations that typically describe critical points of some energy functional under some constraints. For example, let M be a two dimensional surface (possibly with boundary) immersed in \mathbb{R}^3 and parametrized by $\varphi : \Omega \rightarrow M$. Then the area functional is

$$\text{area}(M) = \int_M dS. \quad (1)$$

Now adding a volume constraint one finds that constant mean curvature (CMC) surfaces are critical points, leading to the following boundary value problem: given $V_0 \in \mathbb{R}_+$, find $\varphi : \Omega \rightarrow \mathbb{R}^3$ and $H_0 \in \mathbb{R}$ such that

$$H(\varphi) - H_0 = 0, \quad \text{Vol}(\varphi) - V_0 = 0, \quad \varphi|_{\partial\Omega} = \partial M, \quad (2)$$

where H is the mean curvature, $V(\varphi)$ the enclosed volume, and the constant H_0 can for instance be interpreted as a pressure difference when the CMC surfaces model interfaces between fluids.

In general, only a few solutions of (2) and of related (often more complicated) problems are known explicitly, and we have to resort to numerical approximation of solutions. There are various methods for this, see, e.g., [BGN20] for a review of sophisticated methods. Here we follow an approach from [Bru18] and aim to numerically continue solutions of (2) and related problems in parameters, within the framework of the `Matlab` continuation and bifurcation package `pde2path` [Uec21a, Uec21b]. The basic idea is as follows: Let M_0 be a known surface with parametrization $\varphi_0 : \Omega \rightarrow \mathbb{R}^3$ satisfying (2) for some V_0 and with mean curvature H_0 , and define a new surface via the parametrization $\varphi = \varphi_0 + u\nu$, $u : \Omega \rightarrow \mathbb{R}$ with suitable boundary conditions, where $\nu : M_0 \rightarrow \mathbb{S}^2$ is the unit normal vector of M_0 . Then (2) reads

$$F(u, H, V) = \begin{pmatrix} H(\varphi) - H \\ V(\varphi) - V \end{pmatrix} = 0, \quad \text{with boundary conditions for } u, \quad (3)$$

which is a quasilinear elliptic equation for u , and after solving (3) we can update $M_0 = M_0 + u\nu$ and repeat. This point of view is also useful analytically, see, e.g., [ES98], and numerically it allows to apply standard predictor–corrector continuation and bifurcation methods to the quasilinear elliptic system (3). In `pde2path`, the (default) discretization of (3) works by the finite element method (FEM), and the associated mesh adaption capabilities turn out to be very useful to deal with possibly strong deformations of the manifolds M under the continuation.

The method can also be applied to other types of geometric PDEs, also of higher order, for instance fourth order models from mathematical biology, e.g., Willmore and Helfrich functionals for vesicle shapes. In this case, (3) can be rewritten as a system of (2nd order) PDEs for a vector valued (u_1, u_2) , and the same ideas apply.

Examples

Simple examples of CMC surfaces with boundaries are spherical caps, for instance the one–parameter CMC family of spherical caps S immersed in \mathbb{R}^3 with the boundary $\partial M = \{(x, y, z) \in \mathbb{R}^3 : x^2 + y^2 \leq 1, z = 0\}$. These are useful testing problems since a spherical cap with prescribed boundary is uniquely characterized by its volume, and we have an analytical relation between volume and mean curvature, which yields an explicit error analysis. Figure 1 shows a simple continuation of the caps in volume, starting from $H = 0$ (flat disk), and applying some mesh adaptation when under continuation the stretching of the triangles becomes large.

For the spherical caps it is known and intuitively clear that no bifurcations occur along the branch in Fig. 1, cf. [KPP15]. This is different for another classical example, namely liquid bridges [SAR97]. In Fig. 2 we consider CMC surfaces between two unit circles located at $z = \pm 1/2$. For $V = \pi$ we have a straight cylinder with $H_0 = 1/2$, and continuing to larger V we find bifurcations to non–axisymmetric surfaces with 1, 2, ... bulges, with the first bifurcation occurring at $V \approx 5.81$ where the surface meets the planes $z = \pm 1/2$ at the circles tangentially. Here, for efficiency we compute only half the bridges with Neumann boundary conditions in angle, and the algorithm works fast and robustly (including mesh adaptation).

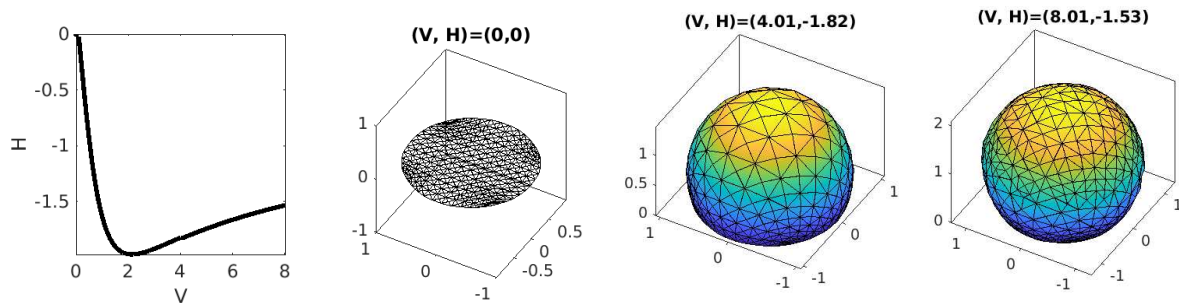

Figure 1: $2H$ over V for the spherical cap example, and sample solutions. At $V = 4.01$ and $V = 8.01$, the colors indicate u in the last step; at $V = 4.01$ we adaptively refine the mesh, see $V = 8.01$.

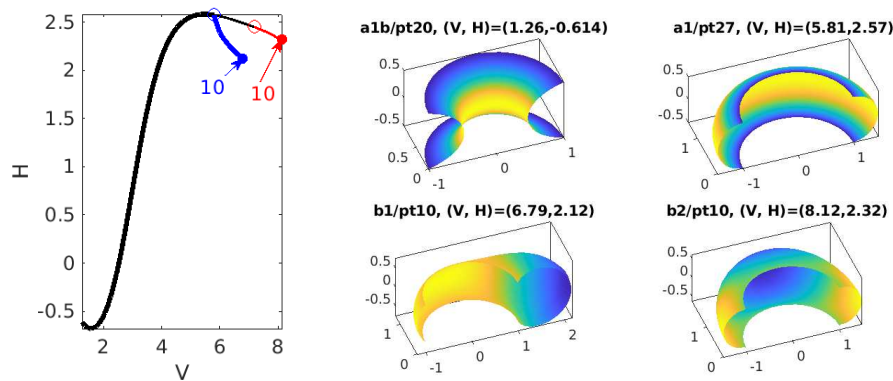

Figure 2: Bifurcation diagram of liquid bridges, and sample solutions. Top row: axisymmetric (black branch), with pt27 near the 1st BP. Bottom: pt10 on blue (left) and red (right) branches. The colors again indicate the last u .

After the above standard examples (also considered in [Bru18]), we consider more complicated problems, including: liquid bridges in different geometries, under gravity and with further terms, bifurcating nodoids [MP02, KPP15] and triply periodic surfaces [KPS18], and time permitting give an outlook on bifurcation results for 4th order equations such as Canham–Helfrich equations for vesicles modeling for instance red blood cells [Sei97].

Combinatorial models of global dynamics: learning cycling motion from data

Ulrich Bauer*, David Hien*, Oliver Junge*, Konstantin Mischaikow[†] and Max Snijders[‡]

**Department of Mathematics, Technical University of Munich, Germany*

[†]*Department of Mathematics, Rutgers University, Piscataway, NJ, USA*

[‡]*Boston Consulting Group*

Summary. We describe a computational method for constructing a coarse combinatorial model of a dynamical system in which the macroscopic states are given by elementary cycling motions of the system. Our method is based on tools from topological data analysis and can be applied to time series data. We illustrate the construction by a perturbed double well Hamiltonian as well as the Lorenz system.

Introduction

Conley’s fundamental theorem [4] characterizes the global structure of the dynamics of a continuous map on a compact metric space. It states that the space can be decomposed into a (chain) recurrent set and its complement, on which the map behaves gradient-like, i.e. trajectories transit from one recurrent component to another. Around the turn of the century, a computational approach to this theory has been developed [12, 7, 9, 10, 1, 11].

Relatedly, ideas have been put forward in order to characterize the dynamics *within* a transitive component of the chain recurrent set. For example, in [6], certain eigenfunctions of the transfer (or push forward) operator have been used in order to decompose a transitive component into, e.g., *almost invariant* (or metastable) subsets.

The purpose of this note is to outline a computational procedure by which certain *cycling behaviour* of the system can be detected and agglomerated into a coarse model. More precisely, we describe how to detect whether the system exhibits motions along a topological circle in some geometric complex that represents a transitive recurrent component of the system. A key ingredient in this procedure is a construction of circle-valued coordinates on simplicial complexes [5]; its usefulness for analyzing recurrent dynamics was already suggested in [14].

In particular, our technique is applicable if no model is available, but the dynamics is only given in form of a time series of data points $x_k = x(t_k) \in \mathbb{R}^d$, $k = 0, \dots, m$, that are, e.g., sampled from solution curves $x : [0, 1] \rightarrow \mathbb{R}^d$ of some differential equation or constructed by a time-delay embedding of scalar measurement data.

The construction

Given a time series x_0, \dots, x_m in \mathbb{R}^d , we construct a combinatorial model which captures different types of cycling motion. Our pipeline consists of three main steps: constructing a topological space, finding dynamically relevant coordinates and constructing a combinatorial model.

Discretization of phase space

A first attempt at obtaining a topological space from a time series x_0, \dots, x_m is to construct a Vietoris–Rips complex with base set $X = \{x_0, \dots, x_m\}$. In our setting, this is impractical since the resulting complexes are usually too large to be computationally tractable. In order to circumvent this problem we first quantize our data. For this, choose a radius $r \in \mathbb{R}_{>0}$ and consider the *cubical grid*

$$\mathcal{B} = \mathcal{B}(r) = \left\{ \prod_{\ell=1}^d r \left[z_\ell - \frac{1}{2}, z_\ell + \frac{1}{2} \right) \mid z \in \mathbb{Z}^d \right\}.$$

Since the elements of \mathcal{B} (which we call *cubes* or *boxes*) form a partition of \mathbb{R}^d , we can define $Q : \mathbb{R}^d \rightarrow \mathcal{B}$ by mapping each point to the unique cube containing the point. Then

$$\mathcal{X} := \{Q(x) \mid x \in X\}$$

is a *cubical* or *box covering* of the point cloud X . For a cube $\xi = \prod_{\ell=1}^d r \left[z_\ell - \frac{1}{2}, z_\ell + \frac{1}{2} \right)$ let $z(\xi) = (rz_1, \dots, rz_d)$ be its *center*. We can identify \mathcal{X} with the subset

$$Z := \{z(\xi) \mid \xi \in \mathcal{X}\}$$

of the integer lattice $r\mathbb{Z}^d$. The set Z of box centers is called the *quantization of the point cloud* X . Fig. 1a shows a time series with its cubical cover and the corresponding set of box centers Z .

We then resample the time series such that consecutive points lie in different cubes. For this, set $\tau(0) = 0$ and recursively define

$$\tau(i) = \min\{j > \tau(i-1) \mid Q(x_j) \neq Q(x_{\tau(i-1)})\}$$

The time series $\hat{x}_i = z \circ Q(x_{\tau(i)})$, $i \in [0, T]$ is called the *quantization of the time series* x_0, \dots, x_m at radius r . Here we let T denote the largest finite value of τ and $[k, \ell] := \{k, \dots, \ell\} \subset \mathbb{N}_0$.

Figure 1: Time series, its quantization and the resulting Vietoris–Rips complex.

Given a set of box centers Z , we construct the Vietoris–Rips complex $\mathcal{K} = \text{VR}(Z, d, \delta)$, where $d(x, y) = \|x - y\|_\infty$ and $\delta = r$ (see the appendix for a definition of the Vietoris–Rips complex). Note that the choice of d and δ allows a point in Z to be connected to all its diagonal neighbors. An example is shown in Fig. 1b.

Coordinates for dynamics

Circular coordinates are the key tool which we use to detect cycling. In the following paragraphs, we review their construction from cohomology, explain how they can be lifted with respect to a time series, and outline how to find elements of $H^1(\mathcal{K}; \mathbb{Z})$ that induce dynamically relevant coordinates. In particular, we will also define what it means to be cycling with respect to a coordinate.

1. Cohomology and circular coordinates. A circular coordinate, as introduced in [5], is a function $\mathcal{K} \rightarrow S^1$ with minimal variation along edges in its homotopy class (in particular, there is no relation to coordinates in the sense of differential geometry). Abstractly, the construction of circular coordinates is motivated by the bijection $H^1(\mathcal{K}; \mathbb{Z}) \cong [\mathcal{K}, S^1]$ where $[\mathcal{K}, S^1]$ denotes the homotopy classes of maps $\mathcal{K} \rightarrow S^1$. Explicitly, given a cocycle $\alpha \in Z^1(\mathcal{K}; \mathbb{Z})$, the coordinate $\theta_\alpha : \mathcal{K} \rightarrow S^1$ can be constructed by first computing the *harmonic representative* which is given by

$$\text{argmin}\{\|\bar{\alpha}\|^2 \mid \bar{\alpha} = \alpha + d_0\theta, \theta \in C^0(\mathcal{K}; \mathbb{R})\}, \quad \text{where } \|\alpha\|^2 = \sum_{e \in \mathcal{K}^1} \alpha(e)^2,$$

and then using the construction from [5] to obtain a function $\mathcal{K} \rightarrow S^1$ which "varies by $\bar{\alpha}(e)$ on each edge e ". In this work, the precise construction is not important since we only use the values of this function on the vertices of \mathcal{K} which is given by composing the minimizing θ with the canonical projection $\pi_{S^1} : \mathbb{R} \rightarrow S^1 = \mathbb{R}/\mathbb{Z}$. We denote this function by $\theta_\alpha : \mathcal{K} \rightarrow S^1$. We remark that θ_α only depends on the cohomology class of α and is unique up to an additive constant on each connected component of \mathcal{K} . Examples can be found in Figs. 2 and 3.

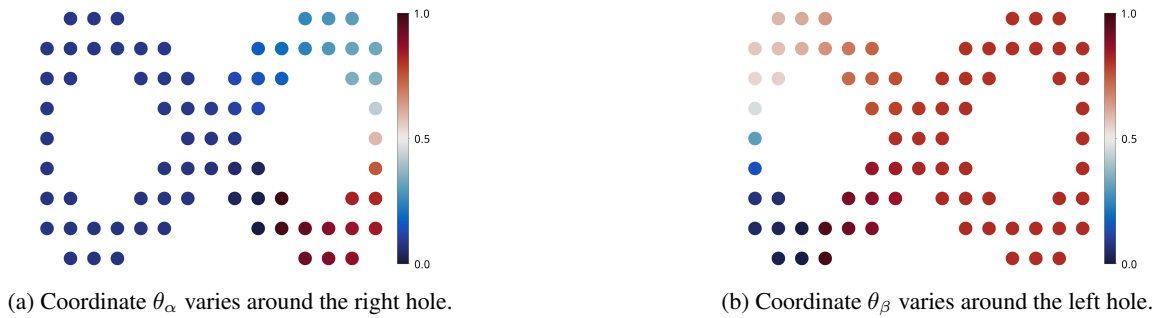

Figure 2: Circular coordinates which capture holes in the complex.

2. Lifted coordinates. Given a quantized time series $\hat{x} : [0, T] \rightarrow Z$ and a circular coordinate $\theta : Z \rightarrow S^1$ we can form the composite $\theta \circ \hat{x} : [0, T] \rightarrow S^1$ which captures the change of the coordinate θ over time. Analogous to continuous maps, we lift this function to a function $\hat{\theta} : [0, T] \rightarrow \mathbb{R}$ such that $\pi_{S^1} \circ \hat{\theta} = \theta \circ \hat{x}$. We define the *lifted coordinate* of θ and \hat{x} via $\hat{\theta}(0) = 0$ and

$$\hat{\theta}(t) = \hat{\theta}(t-1) + d_{S^1}(\theta(\hat{x}_t), \theta(\hat{x}_{t-1})), \quad t = 1, \dots, T,$$

where $d_{S^1}(x, y)$ denotes the signed geodesic distance from y to x on S^1 .

For an example, let \hat{x} denote the quantized time series from Fig. 1a. Fig. 4a shows the first 80 time steps of $\theta_\alpha \circ \hat{x}$, Fig. 4b shows the lift $\hat{\theta}$ over the same period of time. One can see from Fig. 4a that the time series does approximately 3.5 turns with respect to the coordinate. The lifted coordinate Fig. 4b captures this directly, as it increases by 3.5.

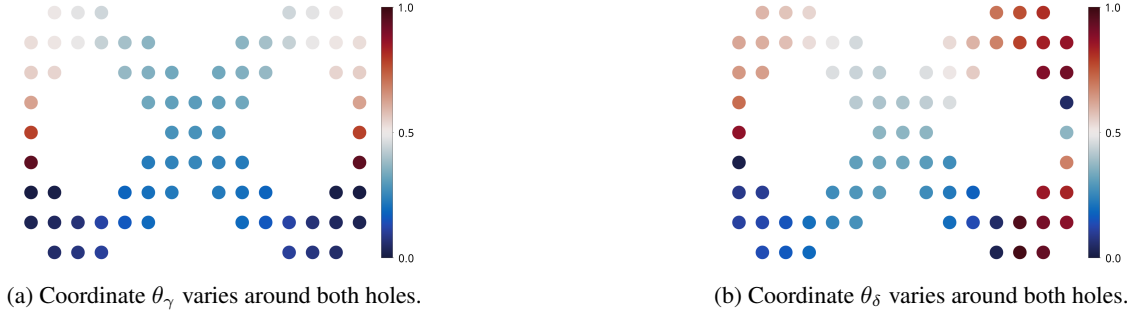

Figure 3: A pair of bad coordinates.

Figure 4: Circular coordinate and its lift along a time series.

3. Dynamically relevant generators. As described before, every cohomology class in $H^1(\mathcal{K}; \mathbb{Z})$ induces a circular coordinate. Some of these coordinates can be used to detect cycling dynamics. For example, the coordinate in Fig. 2a is almost constant on the left side of the complex while it maps the right half of the complex surjectively onto the circle. Therefore, a lift of this coordinate changes significantly if and only if the time series "cycles" around the right hole in the complex. In particular, the coordinate can be used to detect cycling around the right hole. Similarly, the coordinate in Fig. 2b can be used to detect cycling around the left hole. However, not all cohomology classes induce coordinates suitable for detecting cycling dynamics. For example, the coordinates in Figs. 3a and 3b are not suited for detecting cycling dynamics since they vary around both holes.

We now explain how dynamically relevant coordinates can be obtained. Intuitively, we want different coordinates to describe different features of the dynamics. Therefore, large changes in different lifted coordinates should occur at disjoint periods of time. To capture this, we define the *correlation* of two lifted coordinates $\hat{\theta}$ and $\hat{\eta}$ as

$$c(\hat{\theta}, \hat{\eta}) = \langle |\Delta \hat{\theta}|, |\Delta \hat{\eta}| \rangle \quad (1)$$

where the i -th entry of the vector $\Delta \hat{\theta}$ is the forward finite difference $\hat{\theta}_{i+1} - \hat{\theta}_i$ and $\langle \cdot, \cdot \rangle$ denotes the standard Euclidean inner product. Since we are interested in describing all possible cycling dynamics in the system, we want to find a correlation minimizing basis. For a basis B of $H^1(\mathcal{K}; \mathbb{Z})$ we define its *correlation* as

$$I(B) = \sum_{\substack{\alpha, \alpha' \in B \\ \alpha \neq \alpha'}} c(\hat{\theta}_\alpha, \hat{\theta}_{\alpha'}). \quad (2)$$

As an example, we again consider the time series 1a. From Fig. 4b we know that for the first 80 time steps, the series does 3.5 turns around the right hole. Now consider Fig. 5 where the lifted coordinates for the bases $\{\alpha, \beta\}$ and $\{\gamma, \delta\}$ are plotted for the first 80 time steps. The plots indicate that the lifted coordinates in Fig. 5a have a lower correlation than the ones in Fig. 5b. An explicit computation (for all 1000 time steps) yields the values 0.158 and 12.8, respectively, confirming that the preferred basis has lower correlation.

We now search for a basis with minimal correlation. Assuming $\alpha_1, \dots, \alpha_n$ is any basis for the free group $H^1(\mathcal{K}; \mathbb{Z})$, every basis can be written as $A\alpha_1, \dots, A\alpha_n$ where $A \in \text{GL}_n(\mathbb{Z})$. In order to find a correlation minimizing basis, we search $\text{GL}_n(\mathbb{Z})$, starting with the identity $A := I$ and recursively applying basis change operations (sums of rows/columns, multiplication of rows/columns with a unit) to A up to a given depth. Of all these bases we return the one with minimal correlation.

This approach works sufficiently well for simple examples. However, since we are only searching a finite subset of $\text{GL}_n(\mathbb{Z})$ we have no guarantee of actually finding a minimizer. A better algorithm for finding a correlation minimal basis is a topic for future work.

Given a quantized time series and a circular coordinate, cycling dynamics can be inferred from changes in a lift of the coordinate. More precisely, we define a quantized time series \hat{x} to be *cycling along* α if there is an interval $[k, \ell]$ where $\hat{\theta}_\alpha$

(a) Lift of the coordinates in Fig. 2.

(b) Lift of the coordinates in Fig. 3.

Figure 5: Lifted coordinates for two different bases.

satisfies a *monotonicity criterion* and $|\hat{\theta}_\alpha(\ell) - \hat{\theta}_\alpha(k)| > 1$. The second condition ensures that the time series completes at least one full turn during the segment $[k, \ell]$. The monotonicity criterion we use is the following: Given $\varepsilon > 0$, $\bar{t} \in \mathbb{N}_{>0}$, the lifted coordinate $\hat{\theta} : [0, T] \rightarrow \mathbb{R}$ is called (ε, \bar{t}) -increasing along $[k, \ell]$ if

- $|\theta_\alpha(t + \bar{t}) - \theta_\alpha(t)| > \varepsilon$ for all $t = k, \dots, \ell - \bar{t}$, and
- the sign of $\theta_\alpha(t + \bar{t}) - \theta_\alpha(t)$ is the same for all $t = k, \dots, \ell - \bar{t}$.

For $\bar{t} = 1$, this definition requires $\hat{\theta}_\alpha$ to be monotonic. In practice, it is usually necessary to use $\bar{t} > 1$ due to small back-and-forth movement which decreases the lifted coordinate, or movement orthogonal to the cycling direction which keeps the lifted coordinate constant. Note that the parameters ε and \bar{t} have to be specified by the user; we typically do this by inspecting the lifted coordinates.

We define the subset $E \subset B$ of all *dynamically relevant generators* of a basis B as all $\alpha \in B$ for which the time series is cycling along θ_α . The elements in $B \setminus E$ will be called *spurious generators*.

Macro model for cycling dynamics

We transfer the information on cycling motion back to the cubical covering: A cube ξ in the covering \mathcal{X} is α -cycling if the time series is cycling along α on some interval $[k, \ell]$ and there is $j \in [k, \ell]$ such that $\hat{x}_j \in \xi$. For $\xi \in \mathcal{X}$, let $E(\xi) \subset E$ be the set of all dynamically relevant generators α for which ξ is α -cycling.

The cubical covering \mathcal{X} can now be decomposed into equivalence classes: Two cubes are equivalent if they are cycling with respect to the same set of non-spurious generators of $H^1(\mathcal{K}; \mathbb{Z})$:

$$\xi \sim_1 \xi' \iff E(\xi) = E(\xi').$$

We can furthermore distinguish cubes in which the trajectory ceases to be cycling. For this, assume the time series is α -cycling along an interval $[k, \ell]$ which is maximal in the sense that the time series is not α -cycling on any interval which contains $[k, \ell]$. Now let $t \in [k, \ell]$ be the first time step such that $|\hat{\theta}_\alpha(\ell) - \hat{\theta}_\alpha(t)| < 1$. Then the cubes $Q^{-1}(\hat{x}_t), \dots, Q^{-1}(\hat{x}_\ell)$ are precisely those cubes which are hit during the "last full turn" with respect to α in $[k, \ell]$. We call such cubes α -transient. For a given cube ξ , we let $E_t(\xi)$ denote the set of all generators which ξ is transient for. As a finer classification of cubes we define

$$\xi \sim_2 \xi' \iff E(\xi) = E(\xi') \text{ and } E_t(\xi) = E_t(\xi').$$

We now classify the cubes in \mathcal{X} according to either of these two equivalence relations and count transitions between the classes. That is, we build the quotient

$$[\mathcal{X}] := \mathcal{X} / \sim = \{[\xi_1]_\sim, \dots, [\xi_T]_\sim\}$$

as well as the transition matrix

$$P(\sim) = (p_{ij}), \quad p_{ij} = \#\{t \in [1, T] \mid \hat{x}_{t-1} \in [\xi_j]_\sim, \hat{x}_t \in [\xi_i]_\sim\}.$$

We now call $(\mathcal{X} / \sim_1, P(\sim_1))$ a macro model, and $(\mathcal{X} / \sim_2, P(\sim_2))$ an extended macro model for the given time series. Figs. 6 and 7 show both macro models for the time series in Fig. 1a.

Experiments

The following results are obtained using our implementation of the pipeline in Section in the programming language Julia [2]. In particular, we use the algorithm in [8] for computing H^1 with integer coefficients.

Figure 6: Macro model for the double well system.

Figure 7: Extended macro model for the double well system.

Perturbed double well

The time series in Fig. 1, which was used to illustrate the constructions in the previous section, was obtained by integrating a stochastically perturbed version of the double well Hamiltonian system

$$dx = f(x)dt + \sigma dB, \quad (3)$$

with $x = (q, p)$, $f(x) = (p, q - q^3)$, $\sigma = (0, 0.025)$ and B denoting Brownian motion. We integrate (3) from the initial value $x = (1, 0.7)$ by the SRIW1 scheme [13] with step size 0.01.

The macro models in Fig. 6 and Fig. 7 were generated using the coordinates in Fig. 2 and the monotonicity criterion " θ is (0.02, 2)-increasing". These models are as we would expect for such simple dynamics. The yellow boxes capture the location in phase space where direct transition between loops is possible and the green and blue boxes capture the location where the trajectory cycles around the natural holes.

The Lorenz system

For this example we generated a time series by integrating the Lorenz system with the classical parameters $\sigma = 10$, $\beta = \frac{8}{3}$ and $\rho = 28$ with time step size 0.1 for 1 million time steps using the classical fourth order Runge Kutta method. As starting value, we choose $(0, 10, 0)$, but we discard the first 6000 time steps since they 'close up' the left holes of the complex. This highlights one shortcoming of our current technique which will be addressed in future work.

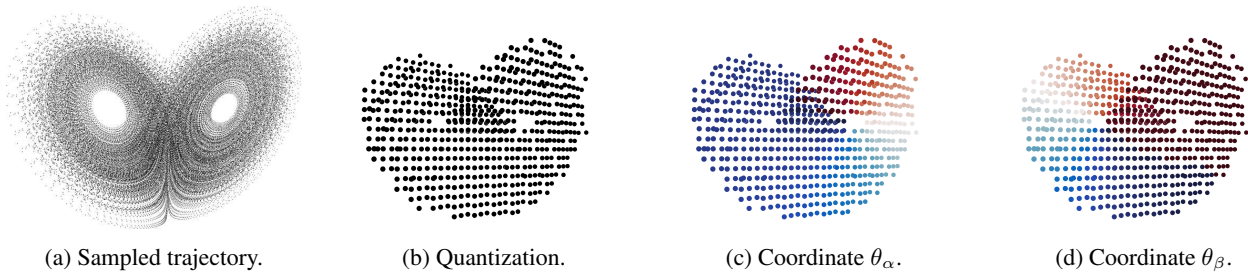

Figure 8: Illustration of the pipeline for a trajectory on the Lorenz attractor.

We choose the quantization radius $r = 2.5$ and obtain a Vietoris-Rips complex with two-dimensional first cohomology. We use the monotonicity criterion " θ is (0.02, 6)-increasing" for both coordinates. Plots of the time series, the quantized point cloud as well as the coordinates of the correlation minimizing basis are shown in Fig. 8.

The macro model shown in Fig. 9 nicely captures many important aspects of the dynamics on the Lorenz attractor. We learn that there are (at least) two different types of cycling motion, that each of these occurs in a distinct region in phase space (the blue and green regions), and that these regions intersect (yellow region). We furthermore see that cycling dynamics are present everywhere in the box decomposition since there are no non-cycling boxes.

In the extended macro model (Fig. 10), we see that the cycling regions are subdivided into a cycling set near the center of the wings and a transient set near the outside of the wings. This indicates that all cycling dynamics in the inside of

Figure 9: Macro model for the Lorenz system.

Figure 10: Extended macro model for the Lorenz system.

the wings eventually moves to the outer regions. The extended model furthermore identifies the regions where direct transitions between cycling dynamics can occur. The purple and yellow regions in Fig. 10a are the only regions where a direct transition from α - to β -cycling dynamics is possible and the orange and yellow regions are the only places that can contain the reverse transition.

Discussion

The techniques described in this paper appear to be a promising novel approach to identifying from time series data regions of phase space in which oscillations occur and locations at which transitions between these oscillations occur. However, a number of distinct questions need to be answered to obtain confidence in applying this technique to complicated higher-dimensional systems, where the results cannot be inspected and modified by visualization. We briefly address those in the following paragraphs.

Construction of the complex. The computation of circle-valued coordinates from data requires the construction of a geometric complex. The approach chosen in this article accomplishes this by constructing a Vietoris–Rips complex from a suitably quantized version of the given time series. In particular, we rely on finding a quantization radius r which is small enough to contain those holes which give rise to dynamically relevant coordinates and large enough to connect the data in a meaningful way. In general, such a radius need not exist. This even happens in the Lorenz system with a trajectory that starts very close to the center of one of the wings.

Finding optimal coordinates. When searching for dynamically relevant coordinates, we encounter the problem of finding a correlation minimizing basis. This poses the natural question of existence and uniqueness of such a basis. In addition, an algorithm is needed to compute this basis or a suitable approximation. Furthermore, even the computation of an arbitrary basis for $H^1(\cdot; \mathbb{Z})$ is currently not as efficient as we would like. We hope to address this using techniques inspired by those for the computation of (persistent) cohomology with coefficients in a finite field [3].

Identifying cycling motion. In this contribution, cycling motion is identified by analyzing the monotonicity behavior of circular coordinates. While this leads to satisfactory results in the presented examples, we have no general reliable procedure of identifying recurrence. For example, a cycling time series with a bit of back-and-forth movement in every full turn would be difficult to identify using the presented methods.

Appendix: Background

Simplicial complexes. Let V be a finite set. An (abstract) simplicial complex with base set V is a subset \mathcal{K} of the power set of V which is closed under the subset relation, i.e. $\sigma \in \mathcal{K}$ implies $\tau \in \mathcal{K}$ for every subset τ of σ . A $\sigma \in \mathcal{K}$ is called a *simplex*, or more precisely a k -*simplex*, where $k = |\sigma| - 1$; the set of k -simplices is denoted by $\mathcal{K}^{(k)}$. In the special cases $k = 0, 1$ or 2 we call σ a vertex, an edge or a triangle, respectively.

Given a finite set $V \subset \mathbb{R}^n$, a metric d on \mathbb{R}^n and a simplex $\sigma \subset V$, the diameter of a simplex is defined as $\text{diam } \sigma = \max_{v,w \in \sigma} d(v,w)$. The simplicial complex $\text{VR}(V, d, r) = \{\sigma \subset V \mid \text{diam } \sigma \leq r\}$ is called the *Vietoris–Rips complex* of V at scale r .

Cochain groups. A *basis* for an abelian group G is a set $(g_i)_{i \in I}$ of elements such that every $g \in G$ can be written uniquely as a finite sum $g = \sum n_j g_j$ with $n_j \in \mathbb{Z}$. An abelian group with a basis is called *free*.

The cochain groups of a simplicial complex are the free abelian groups

$$C^k(\mathcal{K}; \mathbb{Z}) = \{\text{functions } \mathcal{K}^{(k)} \rightarrow \mathbb{Z}\}$$

where a basis for each group is given by the functions which are 1 on one simplex and 0 on all others.

First Cohomology. Fix a total order on V . We write $[v_0, v_1, \dots, v_k]$ for a subset $\{v_0, v_1, \dots, v_k\}$ of V if $v_0 < v_1 < \dots < v_k$. Clearly, for every $\sigma \in \mathcal{K}$ there are unique $v_0, \dots, v_k \in V$ such that $\sigma = [v_0, v_1, \dots, v_k]$.

We define coboundary maps $d_0 : C^0(\mathcal{K}; \mathbb{Z}) \rightarrow C^1(\mathcal{K}; \mathbb{Z})$ and $d_1 : C^1(\mathcal{K}; \mathbb{Z}) \rightarrow C^2(\mathcal{K}; \mathbb{Z})$

$$\begin{aligned} (d_0 f)([v_0, v_1]) &= f(v_1) - f(v_0) \\ (d_1 \alpha)([v_0, v_1, v_2]) &= \alpha([v_1, v_2]) - \alpha([v_0, v_2]) + \alpha([v_0, v_1]) \end{aligned}$$

Elements in $\ker d_1$ are called *cocycles*, elements in $\text{im } d_0$ *coboundaries*. A calculation shows that $d_1 d_0 = 0$ and therefore $\text{im } d_0 \subset \ker d_1$. We can therefore define the *first cohomology group* as the quotient

$$H^1(\mathcal{K}; \mathbb{Z}) = \ker d_1 / \text{im } d_0.$$

It follows from the universal coefficient theorem for cohomology (see section 3.1 of [15]) that $H^1(\mathcal{K}; \mathbb{Z})$ is again a free abelian group.

Summary. The stability of a vehicle's driving state depends on the mechanical properties of the vehicle and the road conditions, but to a large amount also on the characteristics of the human driver. The aim of this talk is to study the influence of the driver's reaction on the stability of the steady cornering motion, which for constant control input is asymptotically stable.

Introduction

The stability of a vehicle's driving state depends on the mechanical properties of the vehicle and the road conditions, but to a large amount also on the characteristics of the human driver. The human driver might be replaced by a robot in the case of an automated vehicle. The aim of this talk is to study the influence of the driver's reaction on the stability of the steady motion, which for constant control input is asymptotically stable.

We investigate the loss of stability of a controlled understeering vehicle along a steady-state cornering motion, according to the model described in [1]. To control the trajectory of the vehicle, the human driver is assumed to either adjust the front steering angle δ_F or the driving torque M_R of the rear wheels, according to the deviation of a point P from a reference circle (Fig. 1). If we denote the deviation of the point P from the reference circle by Δr_P and the deviation of the control input $u \in \{\delta_F, M_R\}$ from the stationary value by Δu , the "simplified precision model" [2] takes the form

$$T_M \frac{d\Delta u(t)}{dt} + \Delta u(t) = c_P \Delta r_P(t - \tau) + c_D \frac{d\Delta r_P}{dt}(t - \tau), \quad (1)$$

with human reaction time τ . Delay time T_M , the control gains c_P and c_D depend on the driver's skills and on the handling behaviour of the vehicle. A similar control loop with delay for a vehicle dynamics was investigated in [3].

While frequently used driver models, based on the above modelling approach, are applied for a linear driving regime, a nonlinear design is focussed here. In particular, the brush tyre model, [4] is used for the nonlinear tyre forces at higher lateral accelerations. The driver model is able not only to control the given trajectory with the steering angle, but also with the longitudinal tyre force resulting from the rear wheel drive. This is a skill of a human (expert) driver, but rarely addressed in human driver modelling, but will become in particular important also at automated driving, when individual drive torques may be used to stabilise critical driving manoeuvres in the nonlinear driving regime.

Figure 1: Geometric relations for the driver's preview model: To follow a circle with radius r_0 , the driver spots a point P at a distance L_P straight ahead, which should move along a circle with radius r_{P0} .

Figure 2: Handling diagram for the considered vehicle for a steady cornering motion along a circle with radius 80 m. For the considered steady velocity $v = 20$ m/s the equilibrium point is asymptotically stable.

Preliminary results

In order to investigate the linear stability of the cornering motion, we choose parameters and control inputs, for which the steady state cornering motion is asymptotically stable. As an example for such a stable motion we select the point indicated in Fig. 2, corresponding to a constant speed $v = 20$ m/s. Neglecting the reaction time τ we select control gains, for which the vehicle-driver model is still asymptotically stable. Fixing these parameters, we vary the reaction time τ and determine the critical parameter values, for which a loss of stability due to a Hopf bifurcation occurs.

As can be seen from Figs. 3 and 4, the steering control depends very sensitively on the reaction time for the considered parameter values, whereas the critical reaction time τ_c for pure throttle control is far beyond the usual values.

Figure 3: Critical reaction time τ_c for the occurrence of a Hopf bifurcation for varying preview length L_P and control gain c_P , varying from 0.1rad/m (blue) to 0.5rad/m (magenta) with fixed value $c_D = 0.02\text{rad s/m}$ for pure steering control.

Figure 4: Critical reaction time τ_c for the occurrence of a Hopf bifurcation for varying preview length L_P and control gain c_P varying from varying from 2N (blue) to 10N (magenta) with fixed value $c_D = -30\text{Ns}$ for pure Throttle control.

Further research

We plan to outline realistic estimates for the drivers' control behaviour and explore the resulting driving conditions. Further we will investigate the nonlinear system after loss of stability. In the uncontrolled system considered in [1] we already observed Canard explosions and relaxation oscillations; the feedback control (1) for the drivers' behaviour introduces further time scales into the system dynamics, so we are expecting interesting slow-fast dynamic behaviour of the model.

[‡]*Department of Applied Mathematics and Computer Science, Technical University of Denmark, Kongens Lyngby, Denmark*

Summary. We investigate nonlinear and dissipative acoustic waves in a tube driven by a sinusoidal driver at one end and imposing a fixed wall boundary condition at the opposite end. For driving amplitudes close to resonances in the tube, we have found multiple oscillating shock waves in a weakly nonlinear thermoviscous acoustic model. For slow off resonance driving, we observed a nearly linear oscillating ground state superimposed by bursts of oscillating shock waves. The small amplitude nearly harmonic oscillations are slow, whereas the oscillating shock waves exhibit fast propagation back and forth in the tube.

Higher order nonlinear acoustic wave equation

In nonlinear acoustics the wave fields for the flow velocity or pressure will not be simple harmonic waves. Localized shock waves may be generated or acoustic streaming may appear. The resulting flow patterns results from balancing dissipation and nonlinear effects. In the literature oscillating solitons or solitary waves have been studied in a wide range of systems as long Josephson junctions and optical fiber systems. Motivated by these investigations we shall here study oscillating solitary shock waves in a tube driven by a harmonic driver at one end while imposing a fixed wall at the opposite end. We shall assume plane waves in a cylindrical tube of length ℓ .

Mathematical model

A number of model equations for weakly nonlinear acoustic wave propagation have been derived in the literature [1]. Here we use a model for acoustic waves in a Newtonian, viscous and heat conducting gas. Our model is based on the dynamical equations for the fluid motion, continuity, the heat transfer and entropy together with an equation of state. Introducing the velocity potential $\psi = \psi(x, t)$ as function of position x along the tube center axis and at time t , our one dimensional plane wave model in dimensionless variables and coordinates reads [2]

$$\psi_{tt} - \psi_{xx} = \psi_t \psi_{xx} + (\gamma - 2)\psi_{tt}\psi_t + 2\psi_{xt}\psi_x + b\psi_{xxt}, \quad (1)$$

where subscripts x and t denote partial derivatives with respect to the space and time variables. The fluid flow velocity $u(x, t)$ is given by the potential through $u = -\psi_x$ and the fluid pressure p is given by $p = \psi_t$. The term $b\psi_{xxt}$ models dissipation and γ equals C_p/C_v with C_p being the specific heat at constant pressure and C_v is the specific heat at constant volume.

Boundary conditions

At the left end ($x = 0$) of the tube a sound generator is mounted and at the right end ($x = \ell$) we have a fixed wall. The boundary conditions become

$$u(0, t) = -\psi_x(0, t) = D \sin(\omega t) \quad \text{and} \quad u(\ell, t) = -\psi_x(\ell, t) = 0. \quad (2)$$

The parameter D is the driver amplitude and the driving frequency is denoted by ω . Initially we take a fluid at rest corresponding to $\psi(x, 0) = 0$ and $\psi_t(x, 0) = 0$. We solve Eq. (1), together with the initial conditions (2), by a semi difference method discretizing to second order in space and integrating in time using a 4-5 order Runge Kutta method. Integration is conducted until steady state has emerged. The following parameters are kept fixed $\ell = 1$, $b = 5 \cdot 10^{-4}$ and $\gamma = 1.4$.

Numerical results

For the driver parameters $D = 0.01$ and $\omega = 2\pi$ the left panel of Fig. 1 shows a three dimensional plot of the fluid velocity field $u(x, t)$ as function of x and t . The driver frequency corresponds to the eigenfrequency of the second harmonic of the linearized model (1). This means we drive the nonlinear equation at a resonance frequency. However, due to damping and the nonlinear terms the emerging steady state solution consists of two oscillating shock waves, travelling forth and back in opposite directions.

The right panel of Fig. 1 shows a plot of the fluid velocity $u(x, t)$ driven at the nonresonant frequency $\omega = 0.1$ and with driver amplitude $D = -0.125$. The simulations reveal the surprising result that the slowly varying ground state oscillation is superimposed a fast back and forth oscillating shock wave. We observe that during one driver cycle the shock wave oscillations appear for decreasing $u(0, t)$ corresponding to compression of the fluid and disappears for increasing $u(0, t)$ corresponding to decompression.

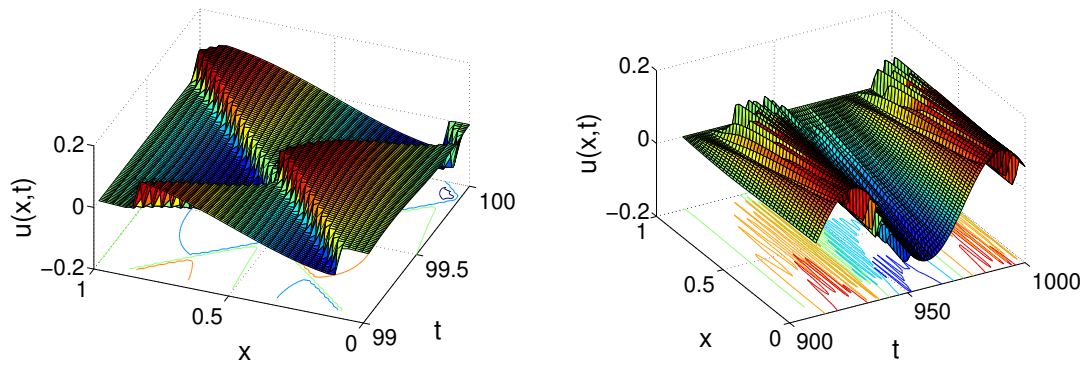

Figure 1: Left: Resonant oscillations of two counter propagating shock waves. Right: Non resonant oscillations superimposed fast travelling shock waves.

Conclusion

Driving nonlinear acoustic plane waves at resonance in a cylindrical tube leads to oscillating shock waves. A driving frequency corresponding to the n 'th linear excitation mode in the linearized model of Eq. (1) leads to n oscillating fully nonlinear shocks. However, an upper limit for the number of oscillating shocks is expected given by the width of the shocks and the space available in the tube. For the nonresonant driving case full numerical simulations revealed excitation of a nearly linear ground state superimposed oscillating shock waves in bursts. The shock waves oscillates fast back and forth in comparison to the slow ground state wave oscillation.

Controlling canard cycles

Hildeberto Jardon-Kojakhmetov*, and Christian Kuehn *

*Zentrum Mathematik, Technische Universität München, Boltzmannstr. 3, 85748 Garching bei München, Germany

Summary. Canard cycles are periodic orbits that appear as special solutions of fast-slow systems (or singularly perturbed Ordinary Differential Equations). It is well known that canard cycles are difficult to detect, hard to reproduce numerically, and that they are sensible to exponentially small changes in parameters. By combining Geometric Singular Perturbation Theory and state feedback control techniques, we design controllers that stabilize canard cycles of planar fast-slow systems with a folded critical manifold. As an application, we propose a controller that produces stable mixed-mode oscillations in the van der Pol oscillator.

Introduction

Fast-slow systems (also known as singularly perturbed ordinary differential equations) are often used to model phenomena occurring in two or more time scales. Examples of these are vast and range from oscillatory patterns in biochemistry and neuroscience all the way to stability analysis and control of power networks, among many others. The overall idea behind the analysis of fast-slow systems is to separate the behavior that occurs at each time scale, understand such behavior, and then try to elucidate the corresponding dynamics of the full system. Many approaches have been developed, such as asymptotic methods, numeric and computational tools and geometric techniques, see e.g. [4, 10].

Although the time scale separation approach has been very fruitful, there are some cases in which it does not suffice to completely describe the dynamics of a fast-slow system. The reason is that, for some systems, the fast and the slow dynamics are interrelated in such a way that some complex behavior is only discovered when they are not fully separated. An example of the aforementioned situation are the so-called *canards* [1]. Canards are orbits that, counter-intuitively, stay close for a considerable amount of time to a repelling set of equilibrium points of the fast dynamics. Canards are extremely important in the theory of fast-slow systems, and through them one can explain, for example, the very fast onset of large amplitude oscillations due to small changes of a parameter in neuronal models [3, 9], and the delayed loss of stability due to a slow passage through a singularity [11, 12]. However, due to their very nature, canard orbits are not robust, meaning that small perturbations may drastically change the shape of the orbit.

On the other hand the application of singular perturbation techniques in control theory is far-reaching. Perhaps, as already introduced above, one of the biggest appeals of the theory of fast-slow systems is the time scale separation, which allows the reduction of large systems into lower dimensional ones for which the control design is simpler. Applications range from the control of robots, all the way to industrial biochemical processes, and large power networks [7]. However, as already mentioned, not all fast-slow systems can be analyzed by the convenient time scale separation strategy, and although some efforts from very diverse perspectives have been made, a general theory that includes not only the regulation problem but also the path following and trajectory planning problems is, to date, lacking.

Here we merge techniques of fast-slow dynamical systems with control theory methods to develop controllers that stabilize canard orbits. The idea of controlling canards has already been explored in [2], where an integral feedback controller is designed for the FitzHugh-Nagumo model to steer it towards the so-called “canard regime”. In contrast, here we take a more general and geometric approach by considering the canard normal form.

Main results

The formal statements of these results and the corresponding proofs are available in [5].

Consider the fast-slow control problem

$$\begin{aligned} x' &= -y + x^2 + u(x, y, \varepsilon, \alpha) \\ y' &= \varepsilon(x - \alpha), \end{aligned} \tag{1}$$

where $(x, y) \in \mathbb{R}^2$ are the fast and slow variables respectively, $\alpha \in \mathbb{R}$ is a parameter, $0 < \varepsilon \ll 1$ is the perturbation parameter responsible for the time scale separation, and $u \in \mathbb{R}$ denotes a state-feedback controller.

Our main result is a controller u that renders canard cycles of (1) asymptotically stable as shown in Figure 1.

As an application we consider controlled the van der Pol equation

$$\begin{aligned} x' &= -y + x^2 - \frac{1}{3}x^3 + u \\ y' &= \varepsilon x. \end{aligned} \tag{2}$$

and design a controller that is able to produce in a robust way any type of Mixed-Mode Oscillation (MMO) allowed by the geometry of the critical manifold. An example of such MMO is shown in Figure 2.

Our main techniques of analysis are the blow-up method [6], canard theory [1, 8] and state feedback control design based on Lyapunov stability [13].

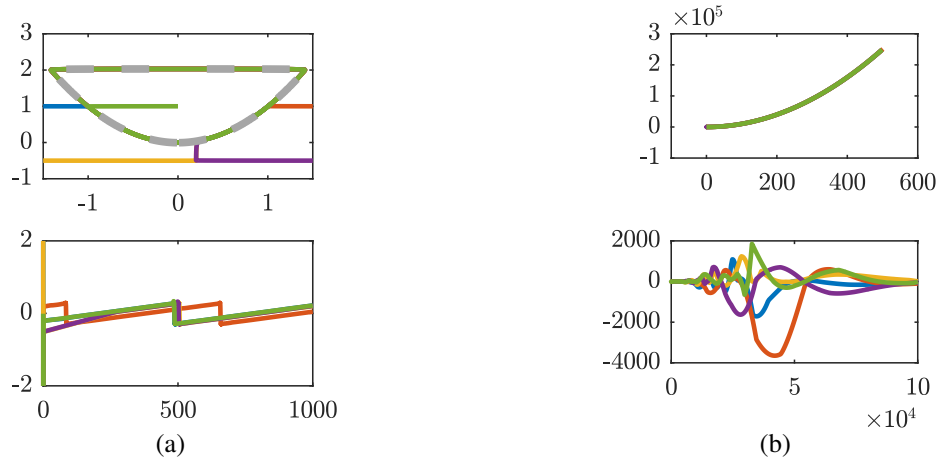

Figure 1: In both columns we show, in the first row the (x, y) phase portrait of the closed-loop system (1) and in the second row the time-series of the corresponding controller. In all these simulations $\varepsilon = 0.01$. (a) The case of bounded canard cycles, where the desired canard cycle to be followed is shown in dashed-grey. (b) The maximal canard case, which is unbounded, and yet can be followed with a bounded controller.

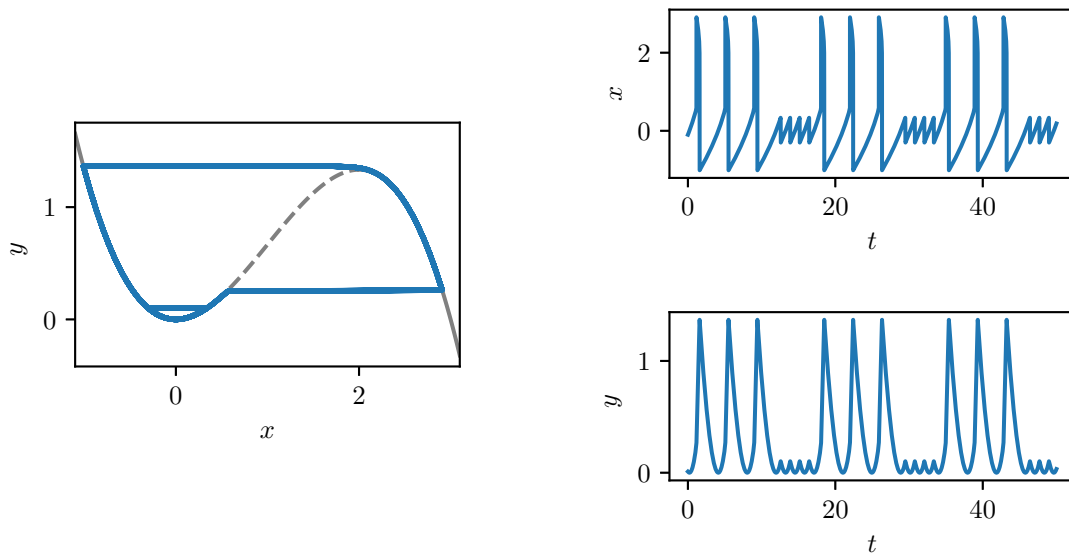

Figure 2: A sample of a Mixed-Mode Oscillation (MMO) with 3 Large Amplitude Oscillations (LAOs) and 4 Small Amplitude Oscillations (SAOs) produced by our controller. Such a controller has as parameters the number of LAOs, the number of SAOs, and the height of the canards.

Non-smooth Two Variable Expansions for Separation of Motions In Impact and Impulsively Loaded Oscillators

Valery Pilipchuk

Wayne State University, Detroit, USA

Summary. Non-smooth two variable expansions for impact and impulsively loaded oscillators are introduced. In particular, the role of fast temporal scale is assigned to the triangle sine wave, whereas amplitude and/or frequency modulations are described in a smooth slow temporal scale. The developed tool allows for derivations of closed form solutions describing non-stationary oscillatory dynamics of systems with cyclical impacts or external impulses. Different illustrating examples of oscillators with amplitude limiters are considered assuming the coefficient of restitution is closed to unity.

Introduction

Nonstationary dynamics of oscillating systems under non-holonomic constraint conditions became of significant interest due to different ideas of using impact oscillators as elements of energy absorbers or harvesters. In contrast to the harmonic oscillator, the basic impact oscillator has no specific natural frequency and therefore can interact with different subsystems in a wide range of spectrum, which is important property for the design of such devices. It is shown in this work that the ‘hyperbolic complexification’ of the state variables provides the adequate way to describing the effect of energy loss through specific boundary conditions generated by the triangle wave temporal argument. Then analytical algorithms for solving the corresponding boundary value problems are applied. In addition to the possibility of calculations without conditioning the variables at collision times, the suggested type of solutions can be effectively used in different analytical manipulations dictated by the purpose of study due to the closed form of solutions.

Technical details

The present analytical procedure essentially involves a couple of piecewise linear functions admitting also representation in a closed form through elementary functions (Fig. 1a)

Figure 1: a) Non-smooth basis, and b) harmonic oscillator with amplitude limiters.

Functions (1) are used in different variations and contents in the literature, see for instance references [1, 2] as relevant to the area. However, normalizations for the amplitudes and periods shown in Fig.1 are essential for the present methodology, in which the rectangular wave $e(t)$ plays the role of a *unipotent* of the so-called *hyperbolic number* due to the property $e^2 = 1$. Namely any periodic process $x(t)$ of the period $T = 4$ admits representation in the form [3] $x(t) = X(\tau) + Y(\tau)e$. In case of modulated oscillatory motions a slow time η is added as

$$x(t) = X(\tau, \eta) + Y(\tau, \eta)e, \quad e^2 = 1 \quad (2)$$

where $\tau = \tau(\varphi)$, $e = e(\varphi)$, $\dot{\varphi} = \omega(\eta)$, $\eta = \varepsilon t$ ($0 < \varepsilon \ll 1$).

Then the triangle wave τ is considered as a fast temporal scale of the following two variable expansions

$$\begin{aligned} X(\tau, \eta) &= X_0(\tau, \eta) + X_1(\tau, \eta)\varepsilon + X_2(\tau, \eta)\varepsilon^2 + O(\varepsilon^3) \\ Y(\tau, \eta) &= Y_0(\tau, \eta) + Y_1(\tau, \eta)\varepsilon + Y_2(\tau, \eta)\varepsilon^2 + O(\varepsilon^3) \\ \dot{\varphi} = \omega(\eta) &= \omega_0(\eta) + \omega_1(\eta)\varepsilon + \omega_2(\eta)\varepsilon^2 + O(\varepsilon^3) \end{aligned} \quad (3)$$

Substituting (2-3) into differential equation of motion and using the corresponding condition on velocity at impact times leads to the sequence of boundary value problems for X and Y on the interval of the oscillating time argument $-1 \leq \tau \leq 1$ [4]. Some of the boundary conditions occur as a result of elimination of singularities produced by differentiation of the

basic functions (1), whereas specific boundary condition is imposed by the dissipative interaction with amplitude limiters. *Note that the conventional two variable procedure, which is typically applied to quasi linear vibrating systems, produces the differential equations for slow motions as a result of elimination of secular terms from the expansions [5]. Instead the present analytical algorithm derives the slow time equations from the boundary conditions at $\tau = \pm 1$.* Due to technical complexity of analytical manipulations with series (3) in general form, different adaptations for particular cases at the preliminary stage of derivations can be applied. For instance, free impact vibrations of the model shown in Fig. 1b do not have amplitude modulations as long as the energy remains sufficient for reaching the amplitude limiters. In this case, the explicit dependence on η in X and Y terms of expansions (3) can be ignored as it is done in the example below. The effect of energy loss is completely captured by the slow varying frequency terms.

Example

Free vibrations of the illustrating model, which is shown in Fig. 1b, is described with equations

$$\ddot{x} + \Omega^2 x = 0, \quad |x| \leq \Delta, \quad \dot{x}(t_i + 0) = -k\dot{x}(t_i - 0), \quad k = 1 - \varepsilon, \quad 0 < \varepsilon \ll 1 \quad (4)$$

This oscillator experiences impulsive reaction forces from the amplitude limiters at collision times. Therefore, assuming that the condition $|x| \leq \Delta$ holds, equation (4) is replaced with

$$\ddot{x} + \Omega^2 x = p\delta'(\varphi), \quad p = p(\eta) = p_0(\eta) + p_1(\eta)\varepsilon + p_2(\eta)\varepsilon^2 + O(\varepsilon^3) \quad (5)$$

where the slowly varying intensity of impulses $p(\eta)$ is sequentially determined from the boundary conditions obtained by substituting (2) in (5) as

$$\tau = \pm 1: \quad Y = 0, \quad X = \pm \Delta, \quad X'\omega^2 = p \quad (6)$$

The condition on velocity in (4) gives

$$\tau = \pm 1: \quad Y' \mp X' = -(1 - \varepsilon)(Y' \pm X') \quad (7)$$

As mentioned, conditions (6) eliminate singularities produced by substitution of (2) in (5), whereas conditions (7) require somewhat detailed consideration [4]. Then conducting two steps of the asymptotic procedure gives finally the closed form solution (Fig. 2)

$$x(t) = \Delta \left[\frac{\sin \lambda \tau}{\sin \lambda} - \frac{\varepsilon}{2\Omega} \frac{d\lambda}{d\eta} \left(\frac{\cos \lambda \tau}{\cos \lambda} - \tau \frac{\sin \lambda \tau}{\sin \lambda} \right) e \right] + O(\varepsilon^2) \quad (8)$$

$$\tau = \tau(\varphi), \quad \frac{d\varphi}{dt} = \frac{\Omega}{\lambda}, \quad \frac{d\lambda}{d\eta} = \frac{\Omega}{2} (1 + \cos 2\lambda) \left(1 + \frac{\sin 2\lambda}{2\lambda} \right)^{-1}$$

(a)
(b)

Figure 2: Time history of the state variables of impact oscillator with energy loss at its boundaries: a) coordinate, and b) velocity showing transition to the so-called ‘grazing’ regime with near zero impact pulses.

Conclusion

A class of vibrating systems with perfectly stiff amplitude limiters is considered by means of non-smooth time substitutions. The motion is represented as a combination of the oscillating component, which is due to cyclic collisions with the limiters, and a slow decay caused by the energy loss at collision times. A specific modification of the two variable expansions is used, where the non-smooth (triangle wave) temporal argument is viewed as a fast time while the energy decay is described in a slow time scale. As a result, closed-form analytical solutions are obtained that automatically satisfy collision conditions with the energy loss. Three qualitatively different basic types of vibrations are considered to cover periodic, frequency modulated, and amplitude-frequency modulated motions.

²*thyssenkrupp Transrapid GmbH, Munich, Germany*

Summary. Magnetic levitation (maglev) is a promising technology for high-speed transportation systems, as shown by the Transrapid line in Shanghai operating successfully for nearly 20 years. Currently, a new high-speed train based on this technology is being developed, driven by China's Ministry of Science and Technology. Magnets are one of the key components of a maglev vehicle's suspension system. Attractive magnet forces ensure the contactless coupling of the vehicle to the guideway. Electromagnets are usually described using finite element (FE) models, electromagnetic circuit models, or simple analytical models for simulation purposes. However, FE magnet models are computationally often overwhelming, especially for transient studies, and thus too slow to use them in large vehicle models for vehicle dynamics simulations. Moreover, the parameterization of FE models often is non-trivial. Therefore, less detailed but fast-computable models are used in such simulations, often providing only a coarse discrete distribution of magnet forces along the vehicle. In this contribution, the coupled vehicle-guideway dynamics is investigated regarding different discretizations of levitation magnet forces. A two-dimensional model of the maglev vehicle Transrapid moving along an infinite elastic guideway is used, considering the heave-pitch motion of the vehicle and the vertical guideway bending. Simulations are performed using either a coarse distribution with two magnet forces per magnet or a fine distribution with twelve magnet forces per magnet, i.e., one magnet force at each magnet pole. It is shown that the simplification of two magnet forces per levitation magnet is valid for vehicle dynamics simulations. The model is parameterized with data from the Transrapid TR08 and uses a self-developed model predictive control (MPC) scheme to control the magnets.

Introduction

In Shanghai, the only commercial high-speed magnetic levitation (maglev) train based on electromagnetic suspension (EMS) technology is in operation at the Shanghai Maglev Transportation (SMT) line between Pudong International Airport and Longyang Road Station. It is operating with a maximum speed of 430 km/h. A new high-speed maglev train with a designed top speed of more than 600 km/h is developed at the Chinese rolling stock manufacturer CRRC Qingdao Sifang Co., Ltd. A prototype of the vehicle has already been presented to the public [1]. In Japan, at the same time the SCMaglev, a high-speed maglev train based on the electrodynamic suspension (EDS) technology using superconducting magnets, is developed [2]. High-speed maglev trains can close the gap between current high-speed railway technology with top speeds of 300 to 350 km/h and aircraft traveling at around 900 km/h. To investigate the dynamic behavior of the coupled system of guideway, vehicle, magnet, and controller, simulations and analyses with suitable models are essential tools in the development process regarding, e.g., the general design or safety and ride comfort aspects.

Magnets are key components of a maglev vehicle's suspension system. Hence, mathematical magnet models sufficiently describing the magnet statics and dynamics are essential for reliably predicting the behavior of a single magnet and eventually of the complete coupled system of vehicle and guideway by means of computer simulations. Depending on the issue to be investigated, the complex electromagnetic field needs to be modeled in different levels of detail. On the one hand, simple magnet models usually neglect effects like magnetic saturation and eddy currents, which become relevant for high loads, failure scenarios, and high velocities. Detailed magnet models taking these effects into account, on the other hand, are often computationally intensive and therefore unsuitable for application in large vehicle models for dynamics simulations. Basically, three ways to simplify physically detailed but computationally intensive magnet models exist. Firstly, simplification by neglecting highly nonlinear physical effects like saturation, see [3], secondly, model reduction procedures still considering these physical effects and at the same time reducing the computational effort, as elaborated in [4], and, thirdly, simplifications concerning the distribution of magnet forces along the vehicle. In literature, various maglev vehicle models are described with different levels of detail regarding the distribution of levitation magnet forces along the vehicle. In [5], a very coarse distribution is applied with four levitation magnet forces per vehicle section in the most complex model variant. The models from [6, 7] use one or two magnet forces per magnet, respectively. In [8], a model of the controlled magnets is presented, providing two magnet forces per magnet, combining both the magnet model and the control law in a PID-T1 system. Another approach is used in [9], where two torques are applied in addition to two forces per magnet. Both are multiplied with position-dependent factors mapping the discrete force application points (FAPs) to the continuous magnet force distribution of the real magnet. A fine distribution with one force per pole is implemented in [3], but the corresponding magnet model is simple with limited valid operational range. In [10], a magnet model with two forces per magnet from [4] is used to analyze the coupled dynamics of a vehicle consisting of three sections with 48 levitation magnet forces in total, moving along an infinite series of elastic guideway elements. While the influence of nonlinear physical effects like saturation and eddy currents has been investigated in detail in [4], the influence of magnet force distribution has not yet been investigated systematically. Therefore, the question arises whether it is a valid simplification in simulations of coupled vehicle-guideway dynamics to summarize the magnet force, which is actually distributed continuously along the magnet, in a single concentrated substitute magnet force per magnet or half magnet, respectively, or if a finer distribution is required with forces acting, e.g., at each pole.

Figure 1: Coupled system of a rigid multibody maglev vehicle and an elastic guideway modeled and visualized with Neweul-M².

Simulation Model

In this contribution, the influence of levitation magnet force distribution on the dynamic behavior of the coupled vehicle-guideway system is investigated. A two-dimensional model of a maglev vehicle moving along an infinite elastic guideway based on [10] is used, mapping the heave-pitch motion of the vehicle and the vertical guideway bending. The infinite track is represented by a small number of identical single-span Euler-Bernoulli beams, which are used repeatedly, following the concept of moving system boundaries. The vehicle is modeled as a rigid multibody system with three sections, each one consisting of a car body, levitation chassis, and levitation magnets coupled by air springs and elastomer elements. The mechanical model has 76 degrees of freedom. Figure 1 shows the coupled system modeled and visualized with the in-house multibody simulation toolbox Neweul-M² [11]. The vehicle mechanics is parameterized with values from the Transrapid model called TR08, the predecessor of the SMT vehicle running in Shanghai. Parameters representing the first generation of concrete girders at the test facility in northern Germany (TVE) are taken for the guideway elements. The simulation model is basically the one described in [10], therefore, the interested reader is referred to this publication for a complete model description. Nevertheless, to provide a good understanding of the model, its most important aspects are summarized below, as well as the extensions and changes made for the work at hand.

Mechanical Vehicle Model

The vehicle model represents a detailed two-dimensional rigid multibody model of the maglev vehicle Transrapid mapping the heave-pitch motion in the x - z -plane. It represents a longitudinal section of the system. The left and right side of the system, that is the y -direction, are summed up. An overview of the mechanical vehicle components is given in Fig. 2.

The model comprises a rear end section, a mid section, and a front end section. Each section consists of rigid bodies for a car body, four levitation chassis, and seven or eight levitation magnets, respectively. Each section has the length of eight standard levitation magnets, but the magnets are arranged in such a way that a magnet connects the neighboring levitation chassis of two sections. At the front and rear end of the vehicle, bow levitation magnets are installed that are longer and have 14 poles, while standard levitation magnets have twelve poles. Thus, bow levitation magnets have a shifted center of gravity and higher mass and inertia compared to a standard levitation magnet. Each rigid body has two degrees of freedom (DOF): a translational one in z -direction and a rotational one about the y -axis, making up 76 DOF for the complete vehicle.

Stiff elastomer elements connect the car bodies. The support of the car bodies on the levitation chassis is realized by rather soft air springs, also called secondary suspension. The primary suspension, i.e., the connection of levitation magnets and levitation chassis, is realized by stiff elastomer elements again. All elastomer elements and air springs are implemented as linear spring-damper combinations in the model.

Furthermore, the magnets are attracted to the guideway by magnet forces computed by the magnet models described below. For the coupling with the magnet computation, the distances to the guideway reference plane are outputs of the mechanical system for calculating the air gaps, and the magnet forces are inputs to the mechanical system. As shown in Fig. 3, there are two or twelve such inputs and outputs for each standard magnet. For the longer bow magnets, there are

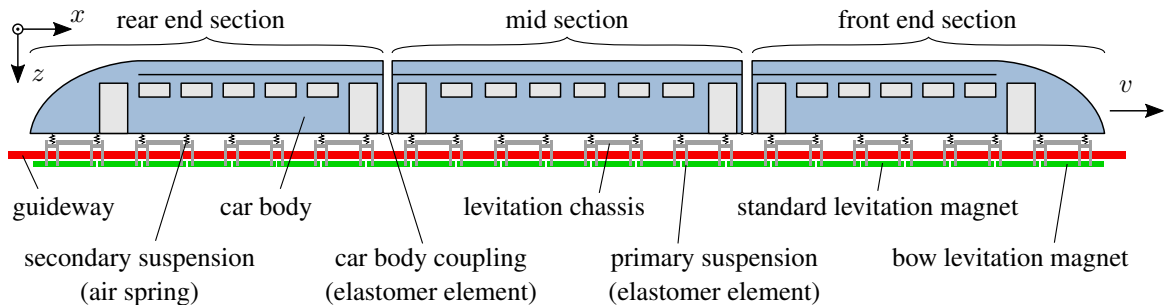

Figure 2: Components of the complete vehicle model on the guideway.

Figure 3: Variants of magnet force distributions along a levitation magnet.

either three or fourteen inputs and outputs. Furthermore, the velocities of the poles or FAPs of concentrated substitute forces, respectively, are defined as outputs of the mechanical model. They are necessary to compute the time derivatives of the air gaps at each of the poles or FAPs of concentrated substitute forces, respectively, required by the magnet model to compute the magnet forces.

Mechanical Guideway Model

The track is implemented as a regularly pillared elastic guideway of infinite length. Applying the concept of moving system boundaries as proposed in [12], a small number of identical Euler-Bernoulli beams is used repeatedly, as shown in Fig. 4. In [10], the implementation of this concept to obtain an infinitely long track is described. In short, a guideway element is taken from behind the vehicle as soon as it is no longer required there, its states are reset, and it is placed in front of the vehicle again.

A detailed description of a single guideway element, a simply supported single-span elastic Euler-Bernoulli beam discretized by 24 finite beam elements and reduced to its first three eigenmodes, can be found in [13]. The application of moving magnet forces to the beam by means of equivalent nodal forces and torques at its nodes and the interpolation of nodal coordinates to get the deflections at arbitrary positions between the nodes using Hermite interpolation polynomials is explained there as well.

Compared to the guideway described in [10], additional static guideway disturbances are added to the model for the work at hand. According to the design principles for high-speed maglev systems from the German Federal Railway Authority,

Figure 4: Concept of moving system boundaries: A small number of guideway elements is used repeatedly to realize an infinitely long elastic guideway in an efficient manner.

see [14], different types of guideway irregularities are to be considered. First, there is the bending of the girders when loaded with the vehicle. This effect is taken into account by modeling the guideway elements as elastic Euler-Bernoulli beams. Second, the pillars supporting the girders may have different heights resulting in not perfectly flat positions of the supported girders. And third, for the vertical position of the stator packs mounted to the girders, there are tolerances as well. The last two disturbances are applied to the guideway model in a statistical manner as presented in [15].

Magnet Model

Vehicle and guideway are coupled by the magnet forces of the levitation magnets. With the work at hand, the influence of magnet force distribution on vehicle and guideway dynamics is investigated. Actually, the magnetic field between the poles and the stator is distributed continuously along the magnet. To represent such a continuous distribution with a high degree of detail, a finite element model would be desirable, but this is unsuitable for vehicle dynamics simulations because of the tremendous computation time, enormous parameterization effort, or meshing difficulties. Therefore, the continuous force field must be discretized for computer simulations, and the question arises of how detailed this discretization must be. Therefore, two different discretization approaches are analyzed and compared here: a fine one with one magnet force per pole, and a coarse one with one magnet force per half magnet, i.e., two forces per standard levitation magnet. Both approaches are depicted in Fig. 3.

In [4], a detailed magnet model is presented, considering the physical effects of magnetic reluctances, fringing and leakage flux, magnetic saturation, and eddy currents. It is validated for a standard levitation magnet of the maglev vehicle Transrapid and computes the magnet forces at each of the twelve poles. Additionally, a simplified magnet model is derived from the detailed one based on a reduction technique, providing just one concentrated substitute magnet force per half magnet. Concerning the magnetic and electric properties, it was shown in [4] that the difference with respect to the detailed model is negligible if the air gap is identical at all poles of one magnet. Its computation time is two orders of magnitude faster, making it usable for dynamics simulations of large vehicle models. In the contribution at hand, the influence of magnet force distribution is investigated by applying both magnet models from [4], the detailed magnet model providing one magnet force per pole and the simplified one providing one force per half magnet, to the model of the coupled vehicle-guideway system described above and comparing the results.

Controller

The reciprocal relation of the air gap and the attractive magnet forces – that pull the vehicle to the stator of the guideway from below – leads to an unstable system, which must be actively controlled to allow stable levitation. The air gap must be kept in a safe range to avoid physical contact between the vehicle and the guideway and simultaneously the acceleration has to be reduced to improve ride comfort. Each half magnet has its own gap measurement unit (GMU) and is controlled individually by its own magnet control unit, which provides the voltage for the magnet based on the gap, acceleration, and current measurements. As shown in [10], a self-developed offset-free model predictive control (MPC) scheme from [16] shows a promising performance even for higher speeds than the TR08 was designed for. Therefore, for both levels of detail of magnet force discretization, the magnets are controlled by this MPC controller instead of the actual control algorithm implemented for the TR08.

Coupled System

All subsystems, i.e., vehicle mechanics, guideway mechanics, magnets, and controllers are combined in a Simulink model representing the complete coupled system. The schematic setup of the Simulink model is shown in Fig. 5. For more details

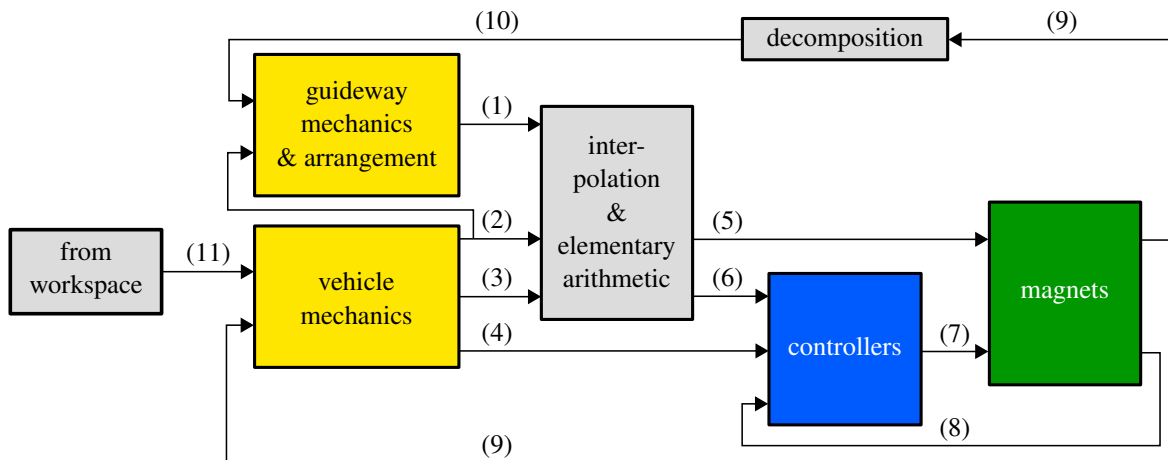

Figure 5: Schematic setup of the coupled model in Simulink. (1) nodal coordinates and velocities of beams, (2) x -positions of magnet forces, (3) magnet z -positions and velocities at magnet FAPs, x -positions of GMUs, magnet z -positions at GMUs, (4) magnet z -accelerations at GMUs, (5) air gaps and air gap velocities at magnet FAPs, (6) air gaps at GMUs, (7) magnet voltages, (8) magnet currents, (9) magnet forces, (10) nodal forces and torques, (11) x -position of front end car body. For more details see [10].

regarding the Simulink model and its signal flow, please refer to [10]. Due to the modular structure of the Simulink model, the individual components can be replaced with little effort. Thus, the simplified magnet model can be replaced easily with the detailed magnet model for the simulations described in the following.

Simulation Results

In the simulated scenario, the vehicle consisting of three sections is traveling on the infinite elastic guideway with a constant speed of 300 km/h. By comparing the two configurations with different force discretization, the necessary degree of detail is determined for vehicle and guideway dynamics analyses.

The simulation results plotted in Figs. 6-10 compare different dynamical quantities for both the detailed and the simplified magnet model. Figure 6 shows various quantities related to the magnet and the controller in the time domain, that is, the air gap s_{GMU} measured at the GMU normalized with the desired air gap s_{des} , the vertical magnet acceleration a_{GMU} measured at the GMU normalized with its maximum a_{max} , the voltage U_{mag} applied to the magnet normalized with the nominal voltage U_{nom} , the current I_{mag} flowing through the magnet normalized with the nominal current I_{nom} , and the magnet force F_{mag} provided by the respective half magnet normalized with the nominal force F_{nom} . Each of them is shown for three positions along the vehicle: at the very rear end, at the center of the mid section, and at the transition from the mid to the front section. An exemplary time range of one second is shown. For the plot of F_{mag} , the forces in the detailed model belonging to the six poles of the respective half magnet are summed up to be compared to the force calculated by the simplified model. In Fig. 7, for the same quantities as in Fig. 6 the relative frequency of occurrence is plotted as bar plot on the left vertical axis together with the corresponding cumulative frequency of occurrence as line plot on the right vertical axis. Figures 8 and 9 show the motion of the levitation chassis and the car body, respectively. That is the vertical translations z_{LC} and z_{CB} and the rotations β_{LC} and β_{CB} about the y -axis. Again, the results obtained with the detailed model are compared to those obtained with the simplified magnet model. For the car body motion, exemplary time ranges of four seconds are plotted. In Fig. 10, the deflection w_{mid} of a single guideway element at mid span is plotted versus the position $x_{\text{MF,front}}$ of the foremost magnet force of the simplified model for both the detailed and the simplified magnet model.

In general, all results are in very good accordance for the simulations with the detailed and the simplified model. For the internal magnet dynamics small differences occur between the detailed model and the simplified model, as revealed by the plots for voltage, current, and magnet force in Figs. 6 and 7. These small differences can be explained by the differences and simplifications made in the simplified model with respect to the detailed model. While it was shown in [4] that the difference is negligible if the air gaps are identical at all poles of one half magnet, the air gaps and their change with time are individually computed here for each magnet pole. By summarizing the magnet forces of a half magnet in a single concentrated substitute magnet force, spatial balancing effects caused by different pole gaps occurring while traveling along an uneven guideway are neglected. However, as can be seen from Figs. 6-10, quantities describing the mechanical vehicle and guideway dynamics like air gap, magnet acceleration, levitation chassis motion, car body motion, and guideway motion are nearly identical for both magnet model variants. For the translation of the levitation chassis z_{LC} , the maximum difference between both model variants is less than 0.43 mm at all three considered positions, corresponding to less than 2.1 % of the maximum absolute amplitude. The mean deviation is below 0.1 mm at each of the three positions. The deviation of the car body translation z_{CB} remains smaller than 0.24 mm for all three sections. This is less than 1.5 % of the maximum absolute amplitude. On average it is even smaller than 0.06 mm for each section. For the guideway deflection at midspan w_{mid} , the difference is less than 0.07 mm between the detailed and the simplified model. That is only 1.2 % of the static guideway deflection when loaded with the vehicle. This means that for the analysis and prediction of vehicle and guideway dynamics, the simplified magnet model is here a sufficiently accurate approximation of the detailed magnet model.

This is a satisfying result, because the simulation time is about a factor of 100 faster with the simplified model than with the detailed model. It takes about 100 hours of real time for 62 seconds of simulation time with the detailed model, while for the same simulation time it takes just about one hour of real time with the simplified model. Additionally, the preprocessing time for creating the mechanical vehicle model takes some extra time if the detailed magnet model is to be used compared to when the simplified model shall be used.

With the results at hand, it can be concluded that a coarse spatial discretization of magnet forces along the maglev vehicle with one magnet force per half magnet is sufficient for vehicle dynamics simulations. Thus, neither finer magnet force discretizations nor FE models for detailed mapping of the magnetic field are necessary for determining the vehicle dynamics. Due to enormous simulation times, such models are unsuitable for application in vehicle dynamics simulations with large vehicle models and multiple magnets. Even with a view to the next few years, simulations with such high computational effort will not be reasonable. Therefore, it is all the more gratifying to see that the simplified model represents the detailed model so well regarding the resulting vehicle and guideway dynamics in a large vehicle model. However, for other simulations such as the elastic deformation of a magnet more complicated and spatially distributed magnet forces are required. As frequently in simulations, the simulation purpose determines the required level of detail in the modeling.

Conclusions

This publication investigates the degree of detail of spatial magnet force discretization required for reliable analyses of maglev vehicle and guideway dynamics. Maglev vehicle dynamics simulation models often use fast-computable magnet models providing concentrated substitute magnet forces to approximate the actually continuously distributed magnetic field. However, to the best of the authors' knowledge, no analysis has been published yet showing that this simplification is a valid assumption. Therefore, the novelty of this contribution is the simulative investigation of the high-speed maglev train Transrapid TR08 regarding the influence of different magnet force distributions along the levitation magnets on the behavior of the coupled vehicle-guideway dynamics while the vehicle is traveling along the guideway.

For this purpose, two different magnet force discretizations are compared: a coarse one with one magnet force per half magnet, and a fine one with one magnet force per pole. It is shown that a coarse discretization with a single concentrated substitute magnet force per half magnet is a sufficient approximation when mechanical vehicle and guideway dynamics are in focus and if the magnet model computing this single force provides a sufficiently accurate representation of the magnet dynamics. The used magnet model from [4] proves to fulfill this requirement. There are minor differences in the internal magnet dynamics like voltage or current due to the simplifications of the simplified magnet model providing one force per half magnet with respect to the detailed model providing one force per pole. However, the mechanical vehicle and guideway dynamics turn out to be nearly identical for the simplified and the detailed model.

This is an important and relieving result, because the simplified magnet model providing forces with a coarse discretization has significantly shorter simulation times, about a factor of 100, than the detailed model with a fine discretization. Such detailed magnet models with fine magnet force distributions thus are unsuitable for application in large vehicle models for vehicle dynamics simulations. Instead, the fast-computable simplified magnet model with one force per pole can be used for this purpose, allowing much faster simulations with hardly any loss of quality in the relevant quantities. However, the simplified magnet model has to map the magnet physics sufficiently accurately, of course.

Joint Reactions Distribution and Uniqueness in Overactuated Multibody Systems

Marek Wojtyra* and Marcin Pękal*

**Institute of Aeronautics and Applied Mechanics, Warsaw University of Technology, Warsaw, Poland*

Summary. Overactuation is introduced in various mechanisms, especially in parallel kinematic machines. The evident result of overactuation is the non-uniqueness of driving forces required to execute the planned motion. However, in some cases, redundant driving constraints may also affect the uniqueness of joint reactions. In this contribution, the influence of overactuation on the uniqueness of calculated joint reactions is investigated. A procedure for testing the solvability of calculated reactions in the presence of redundant driving constraints is devised. The known numerical methods for constraint reactions uniqueness analysis are adapted to the overactuated case. An example illustrates the investigated problems and demonstrates the proposed analysis methods.

Introduction

Overactuation in multibody systems (MBS) is understood as employing more actuators than required by the number of controlled degrees of freedom of the system. It is introduced due to several reasons, e.g., to eliminate gear backlash or clearances [1], to improve the performance of the system [2], or to reduce torques in joints of the MBS [3]. In the case of parallel kinematics machines, frequently exploited in robotic applications, overactuation may contribute to singularity avoidance [4] or be utilized for obtaining desired torque distribution [5]. Overactuated multibody systems can be treated as a particular case of redundantly constrained systems, where redundancy applies to driving constraints.

Rigid body assumption is commonly utilized in multibody simulations. With this assumption, multibody modeling is less complicated, requires less data, and allows for faster computations. However, in the case of redundantly constrained MBS, this assumption leads to various problems, mainly related to the rank deficiency of the constraint matrix. One of the unwelcome effects is the non-uniqueness of calculated joint reaction forces (or at least some of them). Various methods to handle and analyze overconstrained MBS have been proposed—see, e.g., [6, 7, 8, 9]. Most often, these methods are focused on constraint redundancy introduced by the kinematic structure of the system, whereas overactuation is seldom considered.

In this work, rigid body models of redundantly actuated MBS are analyzed. The research concentrates on the uniqueness of calculated driving forces and joint reaction forces. Methods of uniqueness analysis are developed, and the influence of redundant actuation on joint reaction solvability is pointed out and investigated. An example is provided to exemplify the investigated issues and illustrate the proposed analysis methods.

Outline of the methods and results

Equations of motion of a MBS subjected to geometric and linear nonholonomic constraints can be written as (we assume that absolute coordinates \mathbf{q} are employed to describe the system [10]):

$$\mathbf{M}\ddot{\mathbf{q}} - \mathbf{J}^T \boldsymbol{\lambda} = \mathbf{Q}, \quad (1)$$

where \mathbf{M} is the matrix of inertia, $\boldsymbol{\lambda}$ is the vector of Lagrange multipliers, \mathbf{Q} is the vector of the other generalized forces and velocity-dependent inertial terms.

If no driving constraints are imposed, the constraint matrix is \mathbf{J} defined as:

$$\mathbf{J}^T = \mathbf{J}_K^T = [(\boldsymbol{\Phi}_q^K)^T \quad (\boldsymbol{\Psi}^K)^T], \quad (2)$$

where $\boldsymbol{\Phi}_q^K$ is the geometric constraints Jacobian and $\boldsymbol{\Psi}^K$ is the linear nonholonomic constraint matrix.

When driving constraints are appended, the constraint matrix becomes:

$$\mathbf{J}^T = \mathbf{J}_{KD}^T = [(\boldsymbol{\Phi}_q^K)^T \quad (\boldsymbol{\Psi}^K)^T \quad (\boldsymbol{\Phi}_q^D)^T \quad (\boldsymbol{\Psi}^D)^T], \quad (3)$$

where superscript D stands for driving constraints.

The presence of redundant constraints makes the constraint matrix \mathbf{J} rank deficient. The number of redundant constraints is indicated by the magnitude of the matrix \mathbf{J} rank deficiency. As a result of redundant constraints existence, at least some of the joint reaction forces are non-unique. There are some methods that make it possible to determine whether or not the reactions in a specified joint are solvable (e.g., [6, 8]). In the present work, these methods were adapted to analyze systems with driving constraints.

To check if the driving constraints influence the uniqueness of calculated joint reactions, one must first analyze the constraint matrix from Eq. (2) that represents the MBS structure independently from its actuation, and then the complete constraint matrix as of Eq. (3). In this paper, we have proven that **if the driving constraints are non-redundant** (i.e., when the magnitude of matrix \mathbf{J} rank deficiency does not change after introducing driving constraints), then **the solvability of joint reactions remains unchanged**; moreover, the driving forces are unique.

On the other hand, **if the system becomes overactuated** (i.e., the magnitude of rank deficiency increases after the introduction of driving constraints), then: (1) previously non-unique joint reactions remain non-unique, (2) **some of otherwise unique joint reactions may become non-unique**, (3) some (or all) driving forces are non-unique. Note that the methods developed in the present work enable us to determine the solvability of any individual joint reaction before and after the introduction of driving constraints. The crucial point is that the results of the uniqueness analysis obtained for joint reactions alone may differ from those obtained for joint reactions together with redundant driving forces.

Example

The developed analysis methods were used to investigate the uniqueness of joint reactions and driving forces in a redundantly constrained and overactuated mechanism with nonholonomic constraints presented in Fig. 1. Three different actuation variants were analyzed: without driving constraints, with non-redundant driving constraints, and with redundant driving constraints. The results of performed analyses corroborated the findings presented in this contribution.

Figure 1: Redundantly constrained and overactuated mechanism with nonholonomic constraints

Conclusions

Overactuation may, in some cases, affect the uniqueness of joint reactions. For the overactuated systems, it is useful to perform a two-stage uniqueness analysis—with and without considering the driving constraints. Such a proceeding enables us to determine the origin of the reaction non-uniqueness of the considered MBS—whether it comes from the system's structure or the redundancy of the driving constraints imposed on the MBS.

Flight Behaviour of a Two-Line, Four-Point Disk Kite

Luke Roeven, Stefanie Gutschmidt and Keith Alexander

Department of Mechanical Engineering, University of Canterbury, Christchurch, New Zealand

Summary. Existing work on kite behaviour mainly considers single-line kites and associated dynamics are limited to quasi-static analyses. Mathematical descriptions rely on generalised aerodynamic models which have not been validated experimentally and thus lack being suitable for design optimization purposes. Kites are utilized in both professional sporting activities and potential new energy generation applications. Understanding the dynamics of these kites allows for innovative improvements for such applications. Furthermore, derivations of existing models are typically based on energy methods which are not immediately helpful to inform design optimisation guidelines. In this work we derive the fully non-linear governing dynamic equations of motion for a two-line four-attachment point kite using a four degree of freedom Newton-Euler formulation. We implement an aerodynamic model which has been previously tested and validated (CFD/wind-tunnel) by our group. The analysis considers and focuses on stability regions of selected flight scenario and the maneuverability of the kite for relevant kite design parameters.

Background

A kite is an atypical aerodynamic object and knowledge about its flight dynamics is rare in literature. Over the last decade few articles have been published about two-line kites, even fewer include dynamic analysis [1, 2]. Quasi-static analysis was performed by Dawson [3] to investigate the turning maneuver of a kite. Other existing work has been done on the dynamics of two-line kites by Sánchez et al. [1]. Their work used the Lagrangian formalism to investigate the stability of the kite for different wind speeds and one control parameter, but did not investigate the reason for turning and restorative mechanisms of the kite flight. Research on the topic has recently increased with new applications of kites for energy generation and ship propulsion [4], but the underlying, inherently nonlinear, dynamics is still under-studied. The kite considered in this work consists of two lines, one for each hand (as depicted in new applications) which connect to each side of the kite. These lines, each split to connect to four attachment points on the kite surface, introduce the necessary moments to control the kite. The kite is modelled with circular disks to represent the aerodynamic surfaces as suggested by Stevenson [5] to be able to validate theoretical models with experimental investigation and observation. This is a first approach implementing a validated model; additional, more complex geometries can be introduced in future investigations. The kite system suggests two modes of behaviour: the first representing the stalling behaviour of the kite, the other representing the expected (typical) kite flight. The dynamics of the considered kite shows restorative behaviour along the elevation and pitch variables, but requires attention to control significant changes of the azimuthal angle. In this work we focus on the roll control of a user and its stability regions for a selected set of parameters and ranges.

Model

This kite system is described by five coordinate systems: **global**, **line**, **kite**, and two **disks** (Figure 1). Euler angles are used to define the kinematics of the kite with a 3-2-1 body-fixed rotation [6] resulting in four degrees of freedom, with θ_1 being the elevation of the kite, θ_2 the azimuthal deviation of the kite, θ_3 the pitching of the kite, and θ_4 the yaw of the kite. The nonlinear set of governing state-space equations is of the form

$$\mathbf{A}_{8 \times 8} \dot{\mathbf{q}}_{8 \times 1} = \mathbf{f}_{8 \times 1}(\mathbf{M}^L, \mathbf{M}^K, \mathbf{q}, t) \quad (1)$$

$\mathbf{A}_{8 \times 8}$ represents the inertia matrix, $\mathbf{f}_{8 \times 1}$ is the forcing vector containing the lift and drag moments as well as the kinematic constraint relations, and $\mathbf{q}_{8 \times 1}$ is defined in Eq. (2a). The moment equations are derived using the **line** and **kite** systems where i denotes the disk number.

$$\mathbf{q}_{8 \times 1} = [\theta_1, \dots, \theta_4, \dot{\theta}_1, \dots, \dot{\theta}_4]^T \quad (a) \quad \mathbf{M}_{\text{Lift \& Drag}} = (\mathbf{r}_{\text{CP}_i} + \mathbf{r}_{\text{OC}}) \times \mathbf{F}_i \quad (b) \quad (2)$$

$$\mathbf{M}^K = \left[\underbrace{\sum_{i=1}^2 \mathbf{r}_{\text{CP}_i} \times \mathbf{F}_i}_{\text{Lift and Drag}} \right]^K \quad (3) \quad \mathbf{M}^L = \left[\underbrace{\sum_{i=1}^2 \mathbf{r}_{\text{OC}} \times \mathbf{F}_i}_{\text{Lift and Drag}} + \underbrace{\mathbf{r}_{\text{OC}} \times m_k \mathbf{g}}_{\text{Weight Force}} \right]^L \quad (4)$$

Parameter values for the centre of pressure and aerodynamic forces are taken from Dawson's work [3]. The kinematic constraint originates from the lines being straight resulting in a limitation of the moment along the roll axis and the magnitude of the pitching angle with respect to the lines.

Analysis & Results

The analysis considers the full set of non-linear equations. The governing equation (1) is solved using a standard numerical integration scheme, Runge-Kutta $\mathcal{O}(4)$. For the stability analysis, the Jacobian of the forcing term was approximated with a central difference formula; its eigenvalues were computed for a selected parameter range of interest.

Figure 2 depicts stability regions of pitch θ_3 and yaw θ_4 angles for a selected azimuthal angle θ_2 of 0° and increasing elevation values θ_1 from $0^\circ - 90^\circ$. In the order from left to right, the top left figure being $\theta_1 = 0^\circ$ and the bottom right being $\theta_1 = 90^\circ$. Blue zones represent stable solutions, while orange crosses represent unstable solutions, and grey zones represent spurious solutions (e.g. referring to negative line tension or collision with the ground). At $\theta_1 = 0^\circ$ there are two columns of stable solutions, the spurious solution referring to the collision with the ground. As the elevation angle increases the spurious solution disappears and the stable blue region becomes a circle-like zone which migrates from negative to positive θ_3 values. This variation in θ_3 creates a restoring moment which brings the system back to it's elevation equilibrium. However, when the azimuthal angle is varied, the resultant twisting behavior acts to further exacerbate the azimuthal deviation — an unstable equilibrium.

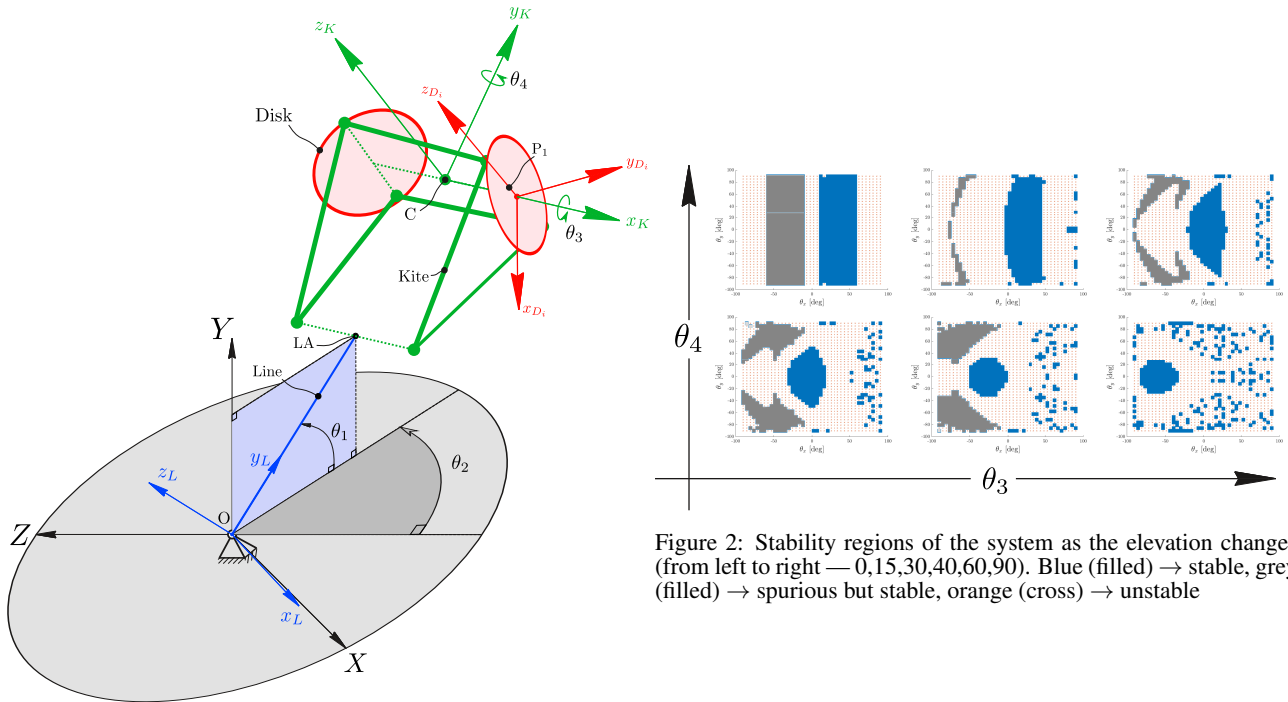

Figure 1: Coordinate systems for the two line kite

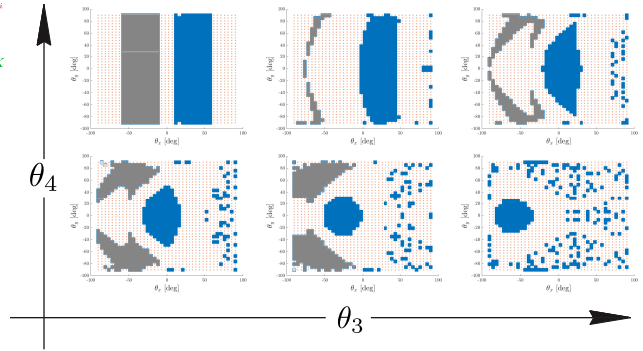

Figure 2: Stability regions of the system as the elevation changes (from left to right — 0,15,30,40,60,90). Blue (filled) → stable, grey (filled) → spurious but stable, orange (cross) → unstable

Conclusion

Kites are being utilised within new applications for energy generation, professional sporting activities, and ship propulsion [4]. Further development of accurate models for these fields will allow for vast and effective design improvements to enhance applications. In this work, a two-line four-attachment point disk kite is modelled using a Newton-Euler formulation. This model utilises validated wind-tunnel data for the aerodynamic forces. The stability of the system is analysed for a specific range of elevation angle values. Results demonstrate how the kite pitches to reach its equilibrium elevation. This technique can be used to optimise multiple design parameters for numerous applications. By observing the stability zones of the kite, the design parameters can be adjusted for specific flight behaviour and characteristics. Additionally, the user control mechanism for operating such kites can be further investigated for better performance.

Identification of Friction Models for MPC-based Control of a PowerCube Serial Robot

Jörg Fehr*, Arnim Kargl* and Hannes Eschmann*

**Institute of Engineering and Computational Mechanics, University of Stuttgart, Germany*

Summary. For model-based control, an accurate and in its complexity suitable representation of the real system is a decisive prerequisite for high and robust control quality. In a structured step-by-step procedure, a model predictive control (MPC) scheme for a Schunk PowerCube robot is derived. Neweul-M² provides the necessary nonlinear model in symbolical and numerical form. To handle the heavy online computational burden involved with the derived nonlinear model, a linear time-varying MPC scheme is developed based on linearizing the nonlinear system concerning the desired trajectory and the a priori known corresponding feed-forward controller. To improve the identification of the nonlinear friction models of the joints, a nonlinear regression method and the Sparse Identification of Nonlinear Dynamics (SINDy) are compared with each other concerning robustness, online adaptivity, and necessary preprocessing of the input data. Everything is implemented on a slim, low-cost control system with a standard laptop PC.

Introduction

The use of robots to increase work performance or human-machine interaction for rehabilitation are topics of high topicality. For the performance of robotic manipulators, modeling, control, and sensing play an essential role. Modeling plays an important role in the development process as well as for controlling the robot, e. g., for model-based control concepts like model predictive control (MPC). Model-based control schemes offer many advantages in comparison to individual joint control. The benefits are: (i) operation as a centralized control scheme – the highly nonlinear behavior of such a system is considered; (ii) intuitive parameter tuning – an elaborate and time-consuming parameter tuning necessary for PI or PID-based individual joint control is unnecessary; (iii) constraint considerations - actuator and state limitations are already considered in the control design.

In [1] a model predictive controller (MPC) was derived and implemented for a modular 6-axis Schunk PowerCube robot, see Fig. 4. The general MPC algorithm, see, e. g., [2, 3] is the following: (i) obtain a measurement/estimate of the state; (ii) obtain an optimal input sequence by solving online an open-loop optimal control problem (OCP) over a finite horizon subject to system dynamics and constraints; (iii) apply the first input of the optimal input sequence to the plant/robot; (iv) continue with the first step. Challenges for the application are the highly nonlinear system dynamics as well as the limited computation capacity. Everything should run on a slim low-cost setup, i. e., a standard laptop PC.

These challenges are met by a linear time-variant two-step approach, see Fig. 1. In a first step the nonlinear system dynamics are approximated with a linear time-varying model [4] around the desired trajectory –using an inverse dynamic approach / computed torque approach [5]. In the second step sophisticated techniques for linear MPC are exploited, i. e., the open-source quadratic programming solver qpOASES [6] is used.

The proposed LTV MPC control of the robotic system is able to perform complex trajectories, i. e., motion reversal and zero crossing [1]¹. Nevertheless, the noticeable difference between calculated feed forward and MPC output, see Fig. 2 along the trajectory implies model inaccuracies. These findings imply that the friction model of the robot's joints still has some weaknesses which limits the performance of the overall control system. Therefore, more effort is needed to identify the friction properties of the joints. Prior to this work, a classical system identification method, i. e., data pre-processing in combination with nonlinear regression, was used to identify the friction properties of a single disassembled module.

Therefore, aim of this work is to evaluate how the large amount of data from different sources, i. e., Artificial Intelligence will facilitate the complex and challenging modeling and system identification of an assembled system – e. g., can the large amount of data be used to identify the effects in the assembled state and/or difference between individual products due to production tolerances.

More specifically, we want to answer the question of whether the Sparse Identification of Nonlinear Dynamics (SINDy) method [7, 8] improve the friction identification. In contrast to black-box AI methods, like Neural Networks or Gaussian Processes – which try to approximate the data by adjusting some weights of a topological system, the SINDy method tries to identify the governing equations from data. It approximates an unknown function f with a library $\Theta(X)$ of r potential (nonlinear) terms. The SINDy approach is a parametric approach that, compared to NNs, works without massive amounts of data. The approach allows for on-the-fly model adaptation due to its low computational complexity.

Let us recap the overall goal: "Improve the model-based control performance of a robotic manipulator by improving friction identification using the SINDy approach to identify the governing equation from data." The main features are: (i) the robustness of the approach and (ii) only the friction characteristic is identified – other well-identified or known terms of the system are incorporated as prior knowledge.

In the next section, we describe the model and the methodology in more detail: (i) the robot which serves as an example; (ii) the process control framework; (iii) the derivation of the equation of motion of the rigid multibody system with Neweul-M² [9] (iv) the existing friction model, (v) the SINDy concept and (vi) the recording of measurement data. In Section Friction Identification the results of the approach are presented. Finally, in the Conclusion the overall control performance of the system with the improved friction model is discussed.

¹The complete motion of the manipulator can be seen in the deposited video <https://www.itm.uni-stuttgart.de/en/research/vision-based-control-of-a-powercube-robot/>.

Figure 2: Feed forward torque of the old robot model compared to the MPC output torque applied at joint β during a trajectory with motion reversal.

Model and Methodology

The performance of the SINDy approach is evaluated on a modular 6-axis *Schunk PowerCube Robot*, see Fig. 4. For the considered modular robot a *Process Control Framework* in Matlab Simulink and a *Simulation Model* in Neweul-M² is available. We focus on the friction identification of the first three joints of the robot, which are each a rotary unit PR 90 with a Harmonic Drive gear to see the influence of assembly and production differences of the same product. Therefore measurement data is gathered during experiments followed by offline identification of the friction characteristics with nonlinear regression and the proposed *SINDy Framework*, relying on *Sparse Linear Regression*. In the following, we explain the single building blocks for model, *Experimental Measurements* and mathematical methodology.

Schunk PowerCube Robot

The properties of the various links are described in Tab. 1. For the design of the robot a "divide et impera" approach is used. For the first three links the same rotary module (PR 90) is used. The fourth link, is the smaller version (PR 70) within the model series. The fifth and six links of the robot consist of a pan-tilt unit in combination with an anthropomorphic gripper with a spherical wrist, is constructed from the single modules. The robotic manipulator is designed in such a way that the arm has an analytically calculable inverse kinematics.

Each rotary module, consists of a brushless DC-motor which drives a Harmonic Drive gear, which provides torque at each degree of freedom (DOF) based on the defined motor current. The control and power electronics are integrated, and an incremental encoder is used for position and speed evaluation. Furthermore, a brake is incorporated in case of shutdown or power failure.

Process Control Framework

The process control framework is depicted in Fig. 3, consists of a Microsoft Windows laptop PC with Matlab R2014b and Simulink, including the additional toolboxes Real-Time Windows Target and Simulink Coder. The laptop PC is equipped with an Intel Core i5-3210M CPU (2x2.5 GHz, 8 GB DDR3). The communication between the Simulink model and the hardware is based on a USB-CAN bus interface, which is embedded into Simulink via S-Functions and a communication library from Schunk. A sampling rate of 50 Hz, corresponding to a sampling interval of 20 ms, is used. An external power supply with constant voltage of 24 V in combination with the integrated control and power electronics of modules ensures the necessary torques at the links.

Real-Time Windows Target [10] realizes a real-time engine for Simulink models on a Microsoft Windows PC and offers the capability to run hardware-in-the-loop simulations in real-time. It is a lean solution for rapid prototyping and provides an environment in which a single computer can be used as a host and target computer. Consequently, real-time simulations are executed in Simulink without an external target machine.

Simulation

The robotic manipulator is modeled as rigid multibody system with joint friction. In a first step Neweul-M² [9] aids calculating a rigid body model *without friction* with the advantage of generating equations of motion in symbolic and numerical form. A natural choice for generalized coordinates \mathbf{y} are the joint coordinates $\mathbf{y} = [\beta, \gamma]^T$. Therefore the resulting equation of motion (*without friction*) in minimal form can be denoted as

$$\mathbf{M}(\mathbf{y})\ddot{\mathbf{y}} + \mathbf{k}(\mathbf{y}, \dot{\mathbf{y}}) = \tilde{\mathbf{q}}(\mathbf{y}, \dot{\mathbf{y}}) + \mathbf{B}\mathbf{u} \quad (1)$$

with the positive definite mass matrix \mathbf{M} , the vector of generalized Coriolis, centrifugal and gyroscopic forces \mathbf{k} and the vector of generalized forces without friction $\tilde{\mathbf{q}}$. The system input is the vector $\mathbf{u} = [T_2, T_3]^T$ which consists of the applied

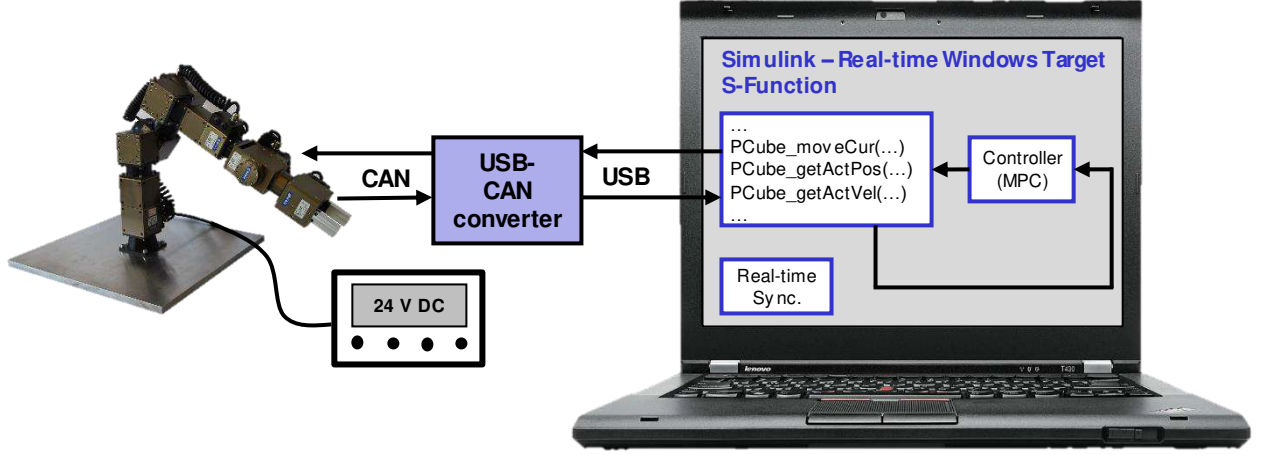

Figure 3: Slim process control framework of the robotic manipulator

motor torque at each joint. Those motor torques are scaled accordingly with gear ratios included in \mathbf{B} . A linear model $\mathbf{u} = K_M \mathbf{i}$ describing the relation between motor torque and motor current is assumed. The motor constant K_M has been identified manually at the hardware. System parameters, such as masses, inertias, link lengths and gear ratios are taken from CAD data and datasheets, supplied by the manufacturers.

In a second step friction torques $\tau(\dot{\mathbf{y}})$ are included into the model without friction, resulting in the vector of generalized forces

$$\mathbf{q}(\mathbf{y}, \dot{\mathbf{y}}) = \tilde{\mathbf{q}}(\mathbf{y}, \dot{\mathbf{y}}) - \tau(\dot{\mathbf{y}}). \quad (2)$$

For a more intuitive understanding τ is subtracted from $\tilde{\mathbf{q}}$, since positive friction works against the current movement. The equation of motion *with friction* can be gained by substitution of $\tilde{\mathbf{q}}$ with \mathbf{q} in eq. (1). Joint friction models of the form

$$\tau_i(\dot{y}_i) = a_1 \dot{y}_i + a_2 \tanh(a_3 \dot{y}_i) + a_4 \exp(-a_5 |\dot{y}_i|) \tanh(3a_3 \dot{y}_i), \quad (3)$$

derived in [11] are used in a first application which results in the stated mismatch between feed forward and MPC output. This form of friction model with parameter vector \mathbf{a} includes the share of viscous friction corresponding to $a_1 \dot{y}_i$, the share of Coulomb friction corresponding to $a_2 \tanh(a_3 \dot{y}_i)$ as well as the superelevation of the Stribeck curve which is characterized by $a_4 \exp(-a_5 |\dot{y}_i|) \tanh(3a_3 \dot{y}_i)$. The smooth *tanh*-function replaces the *sgn*-function to avoid discontinuities within the model.

Focus lies on identifying more accurate friction models for both joints with either the SINDy method or general nonlinear regression. Therefore data of \mathbf{y} , $\dot{\mathbf{y}}$, $\ddot{\mathbf{y}}$ and \mathbf{u} has to be collected during experiments or derived after running experiments respectively, such that

$$\tau(\dot{\mathbf{y}}) = \tilde{\mathbf{q}}(\mathbf{y}, \dot{\mathbf{y}}) + \mathbf{B}\mathbf{u} - \mathbf{M}(\mathbf{y})\ddot{\mathbf{y}} - \mathbf{k}(\mathbf{y}, \dot{\mathbf{y}}) \quad (4)$$

can be calculated. Stated methods can then be applied. The resulting values for τ obviously are dependent on all stated variables \mathbf{y} , $\dot{\mathbf{y}}$, $\ddot{\mathbf{y}}$ and \mathbf{u} . The notation $\tau(\dot{\mathbf{y}})$ is chosen due to the assumption that friction effects only depend on joint velocities.

SINDy Concept

The concept of **S**parse **I**dentification of **N**onlinear **D**ynamics (SINDy) founds in the field of applied mathematics. It represents a modern method to gain nonlinear models based on experiment data, a long known challenge in system theory. The main concept behind SINDy can be described as reducing the nonlinear fit to a collection of function candidates to a (sparse) linear regression, which can then be effectively solved with state of the art algorithms, providing robust and efficient solutions.

The SINDy setup consists of a standard representation of a nonlinear system

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}) \quad (5)$$

with state vector $\mathbf{x} \in \mathbb{R}^n$, possible input $\mathbf{u} \in \mathbb{R}^q$ and the unknown vector field \mathbf{f} . Starting out simple, assume the state \mathbf{x} , and its time derivative $\dot{\mathbf{x}}$ and the system input \mathbf{u} to be known for m unique time instances. The data can then be rearranged into three matrices \mathbf{X} , $\dot{\mathbf{X}}$ and \mathbf{U} as follows

$$\mathbf{X} = \begin{bmatrix} \mathbf{x}^T(t_1) \\ \mathbf{x}^T(t_2) \\ \vdots \\ \mathbf{x}^T(t_m) \end{bmatrix} \in \mathbb{R}^{m \times n}, \quad \dot{\mathbf{X}} = \begin{bmatrix} \dot{\mathbf{x}}^T(t_1) \\ \dot{\mathbf{x}}^T(t_2) \\ \vdots \\ \dot{\mathbf{x}}^T(t_m) \end{bmatrix} \in \mathbb{R}^{m \times n}, \quad \mathbf{U} = \begin{bmatrix} \mathbf{u}^T(t_1) \\ \mathbf{u}^T(t_2) \\ \vdots \\ \mathbf{u}^T(t_m) \end{bmatrix} \in \mathbb{R}^{m \times q}. \quad (6)$$

Goal is to approximate the vector field \mathbf{f} by a library of r candidate functions $\Theta(\mathbf{X}, \mathbf{U}) \in \mathbb{R}^{m \times r}$ which are weighed by coefficients $\Xi = [\xi_1, \xi_2, \dots, \xi_r] \in \mathbb{R}^{n \times r}$ as

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}) \approx \Theta(\mathbf{X}, \mathbf{U})\Xi, \quad (7)$$

where the columns of the library of candidate functions can contain all kinds of imaginable nonlinear terms. Those can be polynomials in \mathbf{x} , \mathbf{u} or combinations of both or other nonlinear terms like trigonometric functions. Filling this library with appropriate terms requires intuition on how the solution could look and is considered one critical point concerning the success of the SINDy method.

The solution to the linear regression problem introduced in eq. (7) may be calculated with aid of various solvers, e. g., a standard least squares solver

$$\xi_k = \arg \min_w \|\dot{\mathbf{X}}_k - \Theta(\mathbf{X}, \mathbf{U})\mathbf{w}\|_2^2. \quad (8)$$

Here ξ_k denotes the k -th column of Ξ while $\dot{\mathbf{X}}_k$ denotes the k -th column of $\dot{\mathbf{X}}$.

Doing so does result in a reasonable model but at the same time leads to very complex and detailed models with many active function terms. Key feature of the SINDy concept is solving the linear regression problem eq. (7) promoting sparsity within the solution vectors ξ_k , which corresponds to the fact that most systems of interest can be described by only a few active terms in \mathbf{f} . Therefore solution techniques for sparse linear regression are applied to eq. (7). A schematic overview and example for a system with two states is given with Fig. 5.

The overall concept appears to be very flexible regarding to all kinds of dynamical systems. There exists a wide range of extensions which, e. g., allow SINDy to perform in discrete time or even to identify PDEs [7, 12].

The SINDy concept, in general, brings some advantages and some disadvantages compared to other machine learning concepts, e. g., an artificial neural network (NN). Such a NN may be used to describe the unknown vector field \mathbf{f} , which also gives good results. One general disadvantage of a NN is the training process, which requires large amounts of measured data to obtain an suitable approximation for \mathbf{f} . SINDy on the other hand can work with one single short experimental trajectory as in Fig. 2. The SINDy method results in a set of nonlinear differential equations which may even be physically interpretable where a NN just results in some non-interpretable matrix layers. In addition to that, the SINDy results, being differential equations, can be evaluated in their whole domain and possibly even be extrapolated. This is a major advantage over neural networks, which often provide unsatisfying approximation results outside of the domain of the training data. Training data of course, has to cover all important system characteristics for both approaches. Otherwise, some system aspects and properties will be left out in the identified system model.

A crucial drawback of the SINDy concept lies in the function library Θ and in the fact that only linear combinations of these functions describe the resulting dynamics \mathbf{f} of the system. One critical disadvantage of the SINDy concept lies in its function library Θ and that only linear combinations of those functions can be described in the resulting \mathbf{f} . Looking at eq. (3), one cannot directly identify a nested term like $a_2 \tanh(a_3 \dot{y}_i)$ with SINDy. Having a look back at eq. (3) one cannot directly identify a term like $a_2 \tanh(a_3 \dot{y}_i)$ with SINDy. The problem is that the parameter a_3 is embedded inside a nonlinear term. We will later avoid this by including multiple terms $\tanh(a_3 \dot{y}_i)$ with different fix parameters a_3 into the library Θ .

The main advantages and problems of the SINDy concept have been briefly touched upon here. In [8], however, a much more detailed comparison of SINDy with artificial neural networks when used in model predictive control can be found.

Sparse Linear Regression

Two algorithms out of the wide variety of sparse linear regression methods were tested and could be applied to the setup. One of them is the so called Least Absolute Shrinkage and Selection Operator (LASSO), which is well known from the

Figure 4: Experimental setup and configuration of the six degrees of freedom Schunk modular manipulator. The control is based on Real-Time Windows Target and Simulink Coder.

Table 1: Technical properties of the Schunk modules.

module name	nom. torque/force	max. velocity
PR 90 (rotary)	44.8 Nm	$\omega_{\max} = 25$ rpm
joint α & β & γ		
PR 70 (rotary)	10.0 Nm	$\omega_{\max} = 25$ rpm
joint δ		
PW 70 (pan-tilt)	12.0 Nm & 2.0 Nm	$\omega_{\max} = 25$ rpm
joint ϵ & ζ		
PG 70 (gripper)	200 N	$v_{\max} = 82$ mm/s

field of statistics and often used in machine learning applications. The LASSO can be described as ℓ_1 regularized version of the standard least squares linear regression setup and can be written as

$$\xi_k = \arg \min_w \|\dot{X}_k - \Theta(X, U)w\|_2^2 + \lambda \|w\|_1. \quad (9)$$

The parameter $\lambda \geq 0$ adjusts the influence of the penalty term $\|w\|_1$ and therefore determines how sparse the solution vector ξ_k turns out. With $\lambda = 0$ the solution is equal to the standard least squares problem's solution stated in eq. (8).

Another sparsity promoting linear regression approach is given by the Sequential Thresholded Least Squares algorithm (STLS) introduced in [7]. The STLS algorithm is an iterative procedure based on standard least squares solutions and can be described as follows.

- An initial solution $\xi_k^{(0)}$ is calculated as least squares solution with the complete library matrix $\Theta^{(0)} = \Theta(X, U)$;
- In each iteration the regression setup reduces by
 - setting entries in $\xi_k^{(r)}$ with absolute value less than a threshold parameter λ to zero;
 - deleting the corresponding columns in $\Theta^{(r)}$, which would then be multiplied by zero, which leads to $\Theta^{(r+1)}$;

Solving the reduced least squares problem with $\Theta^{(r+1)}$ leads to a new solution vector $\xi_k^{(r+1)}$ which includes the remaining entries of $\xi_k^{(r)}$.

- Iteration ends if no more entries in $\xi_k^{(r)}$ fulfill the threshold condition.

Again, the parameter $\lambda > 0$ determines the sparsity of the solution. One iteration step of the STLS algorithm is illustrated in Fig. 6.

The critical point with both algorithms is choosing an appropriate value for the hyper parameter λ . In practice models for a broad range of parameters λ are calculated which allows finding a good compromise between sparsity of the resulting model and model error along a pareto front. The LASSO combined with k -fold cross validation is able to find this compromise by its own. With the STLS approach as it is described above one has to choose a model by hand. More sparse solutions on the one hand allow for some form of physical interpretation of the result but on the other hand may show a greater model error compared to other more flexible nonlinear regression techniques.

The whole SINDy setup was implemented in Matlab [13]. The STLS algorithm was implemented manually while a LASSO implementation already exists within the Statistics and Machine Learning Toolbox.

Figure 5: Application of the SINDy concept with sparse linear regression to a system with two states. Grey entries in ξ_k mark entries which are zero.

Figure 6: Illustration of the STLS algorithm. Grey entries in $\xi_k^{(r)}$ are set to zero. Corresponding columns in $\Theta^{(r)}$ are removed. $\xi_k^{(r+1)}$ is the new least squares solutions with slightly different entries.

Experimental Measurements

Before taking measurements, a suitable class of trajectories has to be defined used for friction identification. We chose sine-shaped trajectories with variable frequency within this study since they can be constructed relatively easily. Being at least two times continuous differentiable sine trajectories brings smooth acceleration and deceleration, which is crucial for not exceeding joint limitations. Furthermore, differentiation and integration can be done analytically. The sine part of the trajectory can be described as

$$y(t) = \hat{a} \sin(\omega(t)t) \quad (10)$$

with a constant amplitude \hat{a} . Polynomial acceleration and deceleration phases around the sine trajectory part are needed since the robot starts and ends in a static pose where velocities and accelerations must be zero. Part of such a trajectory can be seen in Fig. 7.

The figure also points out a difficulty with measurement data. The robot's joint positions are measured by absolute angle encoders within each joint, which results in a non-smooth velocity measurement with coarse resolution. Therefore a

suitable differentiation method is needed to calculate joint velocities and accelerations from joint position data. In [8] the use of Total Variation Regularization Differentiation (TVDiff) is recommended. The TVDiff algorithm is introduced in [14]. The paper and Matlab implementations of the algorithm for one- and two-dimensional data, can be found on the author's web page. The idea of TVDiff originates in the Tikhonov regularization where the energy of a signal is minimized according to an energy functional without influencing the signal in a way a low pass filter would do. Variational methods are quite popular in the field of imaging science for efficiently denoising images. TVDiff results for trajectory measurement data are presented in Fig. 7. Figure. 8 demonstrates the advantages of TVDiff over finite differences with a therefore synthesized signal with added white noise. With higher frequencies a slight low pass effect is visible but the results are sufficient for the application with SINDy.

Figure 7: Measured encoder velocity compared with the filtered velocity from position measurements via TVDiff and the desired velocity.

Figure 8: Synthesized example to demonstrate TVDiff advantages over finite differences with comparison to the analytically calculated reference signal.

Friction Identification

With previously described methods almost all infrastructure needed to identify friction models is present. Friction characteristics for robot joints B and C which correspond to the joint coordinates β and γ are displayed in Fig. 9 and Fig. 10. The resulting friction characteristics of both joints, if moved individually, will be dependent on the joint angle. These effects arise from model inaccuracies within the rigid multibody dynamics, e. g., incorrect inertia values or not modeling cables etc. The influence of gravity at non-zero joint angles makes the resulting friction characteristics dependent on the joint angle. This is against the assumption of friction only depending on joint velocity. Therefore for joint B the gained data is preprocessed by selecting data points with $|\beta| < 0.1$ where the influence of gravity is negligible. The filtered data is plotted in Fig. 12. Since many data points remain unused, a different strategy is chosen for joint C. Since it is the upper body of two joints, the influence of gravity can be easily compensated by moving both joints in opposite directions, keeping the upper part of the robot pointing straight upwards. Figure 11 illustrates half of a period of the particular periodic trajectory. Identification with the gravity compensated trajectory leads to the friction characteristics for joint C shown in Fig. 10. As stated earlier the SINDy results are compared to a model calculated by nonlinear regression. Eq. 3 therefore functions as template for the nonlinear regression with its parameters a_1 to a_5 . The nonlinear regression algorithm used is the `nlinfit` Matlab function which is included in the Statistics and Machine Learning Toolbox as well.

The application of the SINDy concept still requires us to specify a library of function terms. Over time and within many

Figure 9: Friction characteristic for joint B measured with a sine trajectory. Only joint B was moved for these measurements.

Figure 10: Friction characteristic for joint C measured with a sine trajectory. Joint B and joint C were moved equally in opposite directions to compensate gravity.

Figure 12: Fitted friction models for joint B after preprocessing measurement data.

Figure 13: Fitted friction models for joint C. No preprocessing is needed.

experiments the library

$$\Theta(\dot{\mathbf{y}}) = [\mathbf{1} \quad \dot{\mathbf{y}} \quad \text{sgn}(\dot{\mathbf{y}}) \quad \tanh(5\dot{\mathbf{y}}) \quad \tanh(10\dot{\mathbf{y}}) \quad \tanh(20\dot{\mathbf{y}}) \quad \tanh(100\dot{\mathbf{y}})] \quad (11)$$

lead to promising results. The library contains functional terms for describing friction characteristics and at the same time, leaves enough options for the sparse linear regression to cancel out function terms. Promoting sparsity without leaving enough options for the algorithm would not lead to the expected results. A finer sampling of the terms $\tanh(a\dot{\mathbf{y}})$ was tested but results in high correlations between these functions, ultimately leading to difficulties in sparse linear regression. The library does not contain terms describing the superelevation of the Stribeck curve. This will only be a minor disadvantage since such a superelevation is not noticeable within the measurement data.

Applying SINDy and nonlinear regression to the measurement data together with the earlier discussed preprocessing leads to the the friction models shown in Fig. 12 and Fig. 13. Both regression concepts deliver quite similar results. SINDy outperforms nonlinear regression in the case of joint C, having the ability to choose freely from its function library while the nonlinear regression always has to fit to its function template. While nonlinear regression for the data of joint B would not work properly without preprocessing, the SINDy method would still lead to reasonable results. Although the preprocessed data gives a better friction model and shows that SINDy can even work with a percentage of the available data, making it robust to the amount of available measurement data.

An additional friction identification was performed for link A (corresponding to α) for better comparison of the joint friction characteristics and models. Therefore a linear quadratic regulator was implemented, since there doesn't exist an MPC scheme for the rigid body model with $\mathbf{y} = \alpha$. The resulting friction models for link A are displayed in Fig. 14. Again, nonlinear regression as well as the SINDy method perform well, although the measurement data is spread quite heavily. Preprocessing the data is not necessary for either method.

Comparing the newly identified joint friction models to the previously used model from [11] points out two major aspects. At first, friction models differ from joint to joint, although being the same kind of link module (PR90). Secondly, whether the joint friction is identified for an isolated joint or at an assembled robot makes a big difference. Therefore the two newly identified joint friction models differ heavily from the model identified in [11]. While in [11] single isolated joint modules were researched, the additional weight of our robot above joints B and C amplifies friction at the joints' axes. Fig. 15 shows the comparison of the different models. Compared are the SINDy results identified above.

Conclusion

With the methods and results developed throughout this paper, we can finally find the following conclusion. Both, System Identification for Nonlinear Dynamics (SINDy) and nonlinear regression were applied to identify friction models for the relevant joints B and C of the PowerCube robot. Additionally, a friction model for joint A was identified for use with a linear quadratic regulator. The vast improvement of the feed-forward calculations together with the newly identified joint friction models imply a general improvement of the robot model. Although the feed-forward torque almost matches the controller output, slight differences still remain that result from model errors within the rigid body model without friction. However, better trajectory tracking performance, critical for practical usage of the robotic manipulator, could not be improved with the current setup. A first reason lies in using a linearizing MPC approach that does not adequately represent nonlinear system dynamics. Second, the setup underlies limitations in hardware and software. On the hardware side, communication between the robot and the centralized controller in Simulink is limited in speed since the Schunk PowerCube Robot is designed for decentralized joint control schemes such as PID. On the software side, the MPC online optimization cannot be evaluated arbitrarily fast. Both limitations contrast the need for trajectories and linearized dynamics with high resolution in time whenever using LTV MPC.

Further research out of the scope of this publication has shown improvements in trajectory tracking performance with the newly identified friction models when using a truly nonlinear MPC scheme.

When determining the friction, the research has been shown that the friction determination for isolated joint connection modules is not sufficient. Within the robot assembly, the axes of the joints have to bear an additional load, which leads to higher friction.

The SINDy method and its sparse regression algorithms make for a robust and fast method for identifying nonlinear system dynamics. Nonlinear regression in comparison leads to very similar results but needs more computation time due to its nonlinear optimization, making it less capable for real-time applications.

All in all, SINDy's potential to identify parts of unknown system dynamics was successfully presented.

Summary. More realistic simulation of complex cable structures shall need the introduction of unilateral constraints to predict the global behavior of a whole structure without neglecting the influence of a realistic boundary condition. Indeed systems like ropeways (or belt drives) may exhibit behaviors that are strongly affected by friction at contacting zones between the cable (or belt material) and support (or pulley). This consideration also opens the gate to the study of the interaction between successive spans. Moreover the numerical simulation of these systems remains delicate due to their geometrical non linearity.

Introduction

Cables are the main features of many light engineering devices among which electric transmission lines, ropeways installation, cable car or lifts. The equilibria of cable system found their root in the sixteenth century. One the first author about the subject might be Leibniz with the two following works on the catenary curve [1, 2]. Far from this historical anecdote, today's engineering design still relies on those works or the parabolic approximation of weighting rope, first introduced by Galileo and made popular by Irvine [3]. From this monograph to current day, the richness of cable behaviours never ceased to be explored. Major studies in modelling and dynamics have been gathered by Rega in his review and work [4]. However, sophisticated boundary condition or constraints never had been deeply investigated for the cable which almost always perfectly hanged between two points and freely hanging. This is the aim of this work.

Impacts, collisions and friction play a key role in the transient regime of vibrating media by producing a high frequency content responses. Beyond the scope of the current application is the case of string music instrument which vibration against an obstacle explain the signal richness [5]. Similar phenomena are expected in a larger problem such as a ropeway and could explain the apparition of large oscillations when a cabin passes along the top of an intermediary pylon. Although cable dynamics have been studied intensively for the three last decades [3, 4, 6] and numerical challenges never ceased to be attacked [7, 8, 9, 10], there are still unanswered questions about different techniques of the Finite Element Method (FEM) [11, 12] applied to a cable which is subjected to nonsmooth constraints despite the existing bibliography about nonsmooth dynamics [13, 14].

Current focus is drawn on the equations for a cable which is subjected to the presence of a circular-shape obstacle and on a FEM associated with this problem. One may refer to the research work done in succession by Bruno et al. [15], Such et al. [16], Impollonia et al. [17] and Crussels-Girona et al. [10] about the equilibrium of a cable subjected to an intermediary pulley as mean of comparison.

System of interest

We are interested in the mechanics of a cable belonging to the Cartesian space \mathbb{R}^3 equipped with an orthogonal basis $(\underline{e}_x, \underline{e}_y, \underline{e}_z)$. A cable can be described as a curvilinear domain [6] which cannot resist any torque and compression due to its slenderness and its micro-structure. Each particle of this domain is associated to a unique curvilinear abscissa $S \in [0, L]$ where L stands for the reference length of the cable and a triplet of the Cartesian space:

$$q(S, t) = \begin{bmatrix} x(S, t) \\ y(S, t) \\ z(S, t) \end{bmatrix}. \quad (1)$$

The cable is subjected to external loads collected by $f(S, t) \in \mathbb{R}^2 \rightarrow \mathbb{R}^3$. The cable equilibrium is satisfied when tensile forces balance external solicitations and inertial force, which reads:

$$\rho \dot{v}(S, t) = \left(EA(\|q'(S, t)\| - 1) \frac{q'(S, t)}{\|q'(S, t)\|} \right)' + f(S, t) \quad (2)$$

Where $\dot{\bullet}$ and \bullet' stand for derivatives of the variable \bullet with respect to the time and space, respectively. The parameters ρ and EA are respectively the linear density of the cable and the cable rigidity. The velocity of the particle located at S is denoted by $v(S, t)$.

The equations of motion are supplemented by equality and inequality constraints to account for more detailed physics, such as the boundary conditions, the presence of obstacles, impacts or friction. The following constraints are introduced:

$$\text{(Equalities)} \quad a(q(S, t), S, t) = 0 \quad (3)$$

$$\text{(Inequalities)} \quad g(q(S, t), S, t) \geq 0 \quad (4)$$

The research of a solution for (2) is then performed in the admissible set \mathbf{A}_{dm} given by:

$$\mathbf{A}_{\text{dm}} = \left\{ \begin{pmatrix} v(S, t) \\ q(S, t) \end{pmatrix}, a(q(S, t), S, t) = 0, g(q(S, t), S, t) \geq 0, v \in \mathcal{RCBV}, q \in \mathcal{AC} \right\} \quad (5)$$

where the set of right continuous functions of bounded variations and the set of absolutely continuous functions are denoted by \mathcal{RCBV} and \mathcal{AC} .

Finite element procedure

A finite element procedure is derived for the system given by (2)-(5). Following previous work [18], the unconstrained system is written:

$$\mathbf{M}\dot{\mathbf{v}}(t) + \mathbf{C}\mathbf{v}(t) + \mathbf{K}(\mathbf{q}(t))\mathbf{q}(t) - \mathbf{f}(t) = \mathbf{0}, \quad (6)$$

where \mathbf{v} and \mathbf{q} are finite-dimensional vectors collecting the unknowns at nodes. The equality and inequality constraints and their Jacobians are written at each nodes such that :

$$\mathbf{a}(\mathbf{q}, t) = \mathbf{0} \quad ; \quad \nabla^\top \mathbf{a}(t) = \mathbf{A}(t) \quad (7)$$

$$\mathbf{g}(\mathbf{q}, t) \geq \mathbf{0} \quad ; \quad \nabla^\top \mathbf{g}(t) = \mathbf{G}(t) \quad (8)$$

The mechanical system at stake can be formulated as a nonlinear complementarity system as follows:

$$\begin{cases} \mathbf{M}\dot{\mathbf{v}}(t) + \mathbf{C}\mathbf{v}(t) + \mathbf{K}(\mathbf{q}(t))\mathbf{q}(t) - \mathbf{f}(t) = \mathbf{A}(t)^\top \lambda + \mathbf{G}(t)^\top \mu \\ \dot{\mathbf{q}} = \mathbf{v} \\ \mathbf{a}(\mathbf{q}(t), t) = \mathbf{0} \\ \mathbf{0} \leq \mathbf{g}(\mathbf{q}(t), t) \perp \mu \geq \mathbf{0} \end{cases} \quad (9)$$

where λ and μ are Lagrange multipliers which can be physically interpreted as reaction forces provided that the Jacobians are normalized.

Let us introduce the following index sets:

$$\mathcal{E} = \{\beta, a^\beta(\mathbf{q}, t) = 0\}, \quad (\text{index set of equality constraints}) \quad (10)$$

$$\mathcal{I} = \{\alpha, g^\alpha(\mathbf{q}, t) \geq 0\}, \quad (\text{index set of inequality constraints}) \quad (11)$$

$$(12)$$

and the following sets:

$$\mathcal{C}(t) = \{\mathbf{q}, \quad \mathbf{a}(\mathbf{q}, t) = \mathbf{0}, \quad \mathbf{g}(\mathbf{q}, t) \geq \mathbf{0}\} \quad (13)$$

$$\mathcal{N}_{\mathcal{C}}(\mathbf{q}) = \left\{ \mathbf{s} \in \mathbb{R}^n, \mathbf{s} = - \sum_{\beta \in \mathcal{E}} \lambda^\beta \mathbf{A}^\beta - \sum_{\alpha \in \mathcal{I}} \mu^\alpha \mathbf{G}^\alpha, \mu^\alpha \geq 0, \mu^\alpha g^\alpha(\mathbf{q}) = 0, \alpha \in \mathcal{I} \right\} \quad (14)$$

Time dependencies will be omitted in the following for conciseness. The dynamics given by (9) can be written as an inclusion into the normal cone $\mathcal{N}_{\mathcal{C}}$:

$$\begin{cases} \mathbf{r} = \mathbf{M}\dot{\mathbf{v}} + \mathbf{C}\mathbf{v} + \mathbf{K}(\mathbf{q})\mathbf{q} - \mathbf{f} \\ -\mathbf{r} \in \mathcal{N}_{\mathcal{C}}(\mathbf{q}) \\ \mathbf{q} = \mathbf{q}_0 + \int_0^t \mathbf{v} dt \end{cases} \quad (15)$$

for the smooth phase of the motion. If the motion is nonsmooth, a differential measure equality must be written as:

$$\begin{cases} \mathbf{M} d\mathbf{v} + [\mathbf{C}\mathbf{v} + \mathbf{K}(\mathbf{q})\mathbf{q} - \mathbf{f}] dt = d\mathbf{r} \\ d\mathbf{q} = \mathbf{v} dt \\ -d\mathbf{r} \in \mathcal{N}_{\mathcal{C}}(\mathbf{q}) \end{cases} \quad (16)$$

where dt is the Lebesgue measure and $d\mathbf{r}$ is a reaction force measure. See [14] for details about the decomposition of this measure. This equality means that the reaction force \mathbf{r} tends to pull the system back into the admissible set $\mathcal{C}(t)$. An illustration for this situation is provided in Figure 1. Finally, to favor the use of the Moreau–Jean time–stepping scheme[19, 14], a second order Moreau sweeping process is formulated:

$$\begin{cases} \mathbf{M} d\mathbf{v} + [\mathbf{C}\mathbf{v} + \mathbf{K}(\mathbf{q})\mathbf{q} - \mathbf{f}] dt = d\mathbf{r} \\ d\mathbf{q} = \mathbf{v} dt \\ -d\mathbf{r} \in \mathcal{N}_{T_{\mathcal{C}}(\mathbf{q})}(\mathbf{v} + e\mathbf{v}^-), \end{cases} \quad (17)$$

where e is the coefficient of restitution and $T_{\mathcal{C}}$ the tangent cone to \mathcal{C} .

Numerical treatment of this system of equations will be at the heart of the following considerations.

 Figure 1: Normal cone and possible reaction forces in \mathbf{q}_1 and \mathbf{q}_2

Numerical treatment

In the Moreau–Jean time–stepping scheme [19], a θ -method is endowed to approximate integral quantities over a time-step h . For an arbitrary function ζ , it reads:

$$\int_{t_0}^{t_1} \zeta(t) dt \approx h [\theta \zeta_1 + (1 - \theta) \zeta_0] \quad (18)$$

where the subscript \bullet_0 (resp. \bullet_1) denotes the evaluation of \bullet in t_0 (resp $t_1 = t_0 + h$). In case of the stiffness matrix \mathbf{K} , a linearized approximation is endowed as:

$$\mathbf{K}_1(\mathbf{q}_1) \approx \mathbf{K}_0(\mathbf{q}_0) + h\theta \nabla \mathbf{K}_0 \mathbf{v}_1 + h(1 - \theta) \nabla \mathbf{K}_0 \mathbf{v}_0 \quad (19)$$

At last, the constraints are taken fully implicitly in the formulation such that:

$$\int_{t_0}^{t_1} d\mathbf{r} \approx \mathbf{p}_1 + \mathbf{A}_1^\top \lambda_1 \quad (20)$$

where p_1 and λ_1 are homogeneous to impulses.

The equality and inequality constraints are considered at the velocity level and are linearized such that it reduces to:

$$\mathbf{A}_0^\beta \mathbf{v}_1^\beta = \mathbf{0}, \beta \in \mathcal{E} \quad (21)$$

$$\bar{g}_1^\alpha = g_0^\alpha + \frac{h}{2} \mathbf{G}_0^\alpha \mathbf{v}_0, \alpha \in \mathcal{I} \quad (22)$$

$$\begin{cases} \text{If } \bar{g}_1^\alpha \leq 0, 0 \leq \mu_1^\alpha \perp \mathbf{G}_0^\alpha (\mathbf{v}_1 + e\mathbf{v}_0) \geq 0 \\ \text{If } \bar{g}_1^\alpha > 0, \mu_1^\alpha = 0 \end{cases}$$

The satisfaction at previous time step is used to get the simplification in (21). Then the equality constraints are reduced to their first-order expand. The whole numerical scheme can be wrapped into the following system:

$$\begin{cases} \widehat{\mathbf{M}}(\mathbf{v}_1 - \mathbf{v}_0) - \widehat{\mathbf{f}} = \mathbf{p}_1 + \mathbf{A}_0^\top \lambda_1 \\ \mathbf{A}_0^\beta \mathbf{v}_1^\beta = \mathbf{0}, \beta \in \mathcal{E} \\ \bar{g}_1^\alpha \approx g_0^\alpha + \frac{h}{2} \mathbf{G}_0^\alpha \mathbf{v}_0, \alpha \in \mathcal{I} \\ \begin{cases} \text{If } \bar{g}_1^\alpha \leq 0, 0 \leq \mu_1^\alpha \perp \mathbf{G}_0^\alpha (\mathbf{v}_1 + e\mathbf{v}_0) \geq 0 \\ \text{If } \bar{g}_1^\alpha > 0, \mu_1^\alpha = 0 \end{cases} \\ \mathbf{q}_1 = \mathbf{q}_0 + h\theta \mathbf{v}_1 + h(1 - \theta) \mathbf{v}_0 \end{cases}$$

where

$$\begin{aligned} \widehat{\mathbf{M}} &= \mathbf{M} + h\theta \mathbf{C} + h^2 \theta^2 \nabla \mathbf{K}_0 \\ \widehat{\mathbf{f}} &= h\theta \mathbf{f}_1 + h(1 - \theta) \mathbf{f}_0 - h\mathbf{C} \mathbf{v}_0 \\ &\quad - h\mathbf{K}_0 \mathbf{q}_0 - h^2 \theta \nabla \mathbf{K}_0 \mathbf{v}_0. \\ \mathbf{p}_1 &= \sum_{\alpha} \mu_1^\alpha \mathbf{G}_0^{\alpha\top} \end{aligned} \quad (23)$$

In order to obtain a mixed linear complementarity problem (MLCP) in a canonical form, the "free" velocity, \mathbf{v}_f is computed for a given \mathbf{v}_0 solving the unconstrained system:

$$\mathbf{v}_f = \mathbf{v}_0 + \widehat{\mathbf{M}}^{-1}\widehat{\mathbf{f}} \quad (24)$$

The following iteration is referred as a one step nonsmooth problem (OSNSP) in the literature [14] which aims to obtain the correct impact estimation and the corrected velocity as the solution of:

$$(\text{OSNSP}) \begin{cases} \widehat{\mathbf{M}}(\mathbf{v}_1 - \mathbf{v}_f) = \mathbf{p}_1 + \mathbf{A}_0^\top \lambda_1 \\ \mathbf{A}_0 \mathbf{v}_1 = \mathbf{0} \\ \mathbf{U}_1^\alpha = \mathbf{G}_0^\alpha \mathbf{v}_1 \\ \mathbf{p}_1^\alpha = \mu_1^\alpha \mathbf{G}_0^{\alpha\top} \\ \widehat{\mathbf{U}}_1^\alpha = \mathbf{U}_1^\alpha + e \mathbf{U}_0^\alpha \\ 0 \leq \mu_1^\alpha \perp \widehat{\mathbf{U}}_1^\alpha \geq 0 \end{cases} \text{ for } \alpha \in \mathcal{A}_{\text{ct}} \quad (25)$$

where the active set, \mathcal{A}_{ct} , is, in practice, a prediction of the index set of active constraints which will correspond to a violation of the unilateral constraints :

$$\mathcal{A}_{\text{ct}} = \{\alpha \in \mathcal{I}, \quad \bar{g}_1^\alpha \leq 0\}, \quad (\text{index set of active inequality constraints}) \quad (26)$$

The problem (OSNSP) can be written in a canonical mixed linear complementarity problem (MLCP) as:

$$\begin{cases} \begin{bmatrix} \mathbf{A}_0 \widehat{\mathbf{M}}^{-1} \mathbf{A}_0^\top & \mathbf{A}_0 \widehat{\mathbf{M}}^{-1} \mathbf{G}_0^\top \\ \mathbf{G}_0 \widehat{\mathbf{M}}^{-1} \mathbf{A}_0^\top & \mathbf{G}_0 \widehat{\mathbf{M}}^{-1} \mathbf{G}_0^\top \end{bmatrix} \begin{bmatrix} \lambda_1 \\ \mu_1 \end{bmatrix} + \begin{bmatrix} \mathbf{A}_0 \mathbf{v}_f \\ \mathbf{G}_0 \mathbf{v}_f + e \mathbf{G}_0 \mathbf{v}_0 \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \widehat{\mathbf{U}}_1 \end{bmatrix} \\ \mathbf{0} \leq \mu_1 \perp \widehat{\mathbf{U}}_1 \geq 0 \end{cases} \quad (27)$$

Constrained modes

Although the concept of modes has been thoroughly studied, the idea of a constrained mode is not clear yet. Looking at the mode as a preferential response for the system when solicited, we can extend the research for a periodic response to a system subjected to unilateral and bilateral constraints. Assuming the response will be small around a static equilibrium, the dynamics can be investigated in (9) via introducing a perturbation of the static equilibrium given by:

$$(\text{Static}) \begin{cases} \mathbf{K}(\mathbf{q})\mathbf{q} - \mathbf{f} = \mathbf{A}^\top \lambda + \sum_{\alpha \in \mathcal{A}_{\text{ct}}} \mu^\alpha \mathbf{G}^{\alpha\top} \\ \mathbf{a}(\mathbf{q}) = \mathbf{0} \\ \mathbf{0} \leq \mathbf{g}(\mathbf{q}) \perp \boldsymbol{\mu} \geq \mathbf{0} \end{cases} \quad (28)$$

Considering $\tilde{\mathbf{q}}(t) = \mathbf{q} + \mathbf{d}(t)$, $\tilde{\lambda} = \lambda + \lambda_d$ and $\tilde{\mu} = \mu + \mu_d$ in (9) and expansion around \mathbf{q} combined with (28) yields:

$$\begin{cases} 0 = \mathbf{M}\ddot{\mathbf{d}} + \nabla[\mathbf{K}(\mathbf{q})\mathbf{q} - \mathbf{G}^\top \boldsymbol{\mu}]\mathbf{d} - \mathbf{A}^\top \lambda_d - \mathbf{G}^\top \boldsymbol{\mu}_d \\ 0 = \mathbf{A}\mathbf{d} \\ 0 = \mathbf{G}^\alpha \mathbf{d}^\alpha, \quad \alpha \in \mathcal{A}_{\text{ct}} \end{cases} \quad (29)$$

From the last two equations, suitable projections into the kernels of \mathbf{A} and \mathbf{G} should be done to obtain an eigenvalue problem. Let us consider \mathbf{B}_1 a basis of the kernel of \mathbf{A} (then $\mathbf{B}_1^\top \mathbf{A}^\top = 0$) and \mathbf{B}_2 a basis of the kernel of $\mathbf{G}^\top \mathbf{B}_1$ (then $\mathbf{B}_2^\top \mathbf{G}^\top \mathbf{B}_1^\top = 0$). Let us refer to the product $\mathbf{B}_1 \mathbf{B}_2$ as \mathbf{B} . One can manipulate (29) to obtain a classical evolution problem:

$$0 = \mathbf{B}^\top \mathbf{M} \mathbf{B} \ddot{\mathbf{d}} + \mathbf{B}^\top \nabla[\mathbf{K}(\mathbf{q})\mathbf{q} - \mathbf{G}^\top \boldsymbol{\mu}]\mathbf{B} \mathbf{d} \quad (30)$$

which becomes a classic eigenvalue problem when the assumption of harmonic behavior is made for $\mathbf{d} = \exp(i\omega t)\mathbf{d}_\omega$:

$$0 = \left(\widetilde{\mathbf{K}}(\mathbf{q}, \boldsymbol{\mu}) - \omega^2 \widetilde{\mathbf{M}} \right) \mathbf{d}_\omega \quad (31)$$

with $i^2 = -1$. This methodology allows to trace linear vibrations around a steady-state. Main assumptions is that oscillations are "small" so that the active set of constraint remains unchanged as proposed by de Veubeke and G  rardin [20].

Applications

Constrained mode veering

It is well known that the cable exhibits mode veering for some value of parameter [3, 21]. Here we are interested in the variation of modes for a suspended cable subjected to the presence of an intermediary obstacle of circular shape. That is to say we consider:

$$g(\mathbf{q}^\alpha)^\alpha = \|\mathbf{q}^\alpha - \mathbf{q}_R\| - R \quad (32)$$

where \mathbf{q}_R and R stand for the circle center and its radius. The obstacle is translated along the x -axis as and the frequencies are computed for each equilibrium obtained as illustrated in Figure 4. We see that as one could expect in-plane (IP) modes or out-of-plane (OP) modes are obtained. Veering phenomenon occurs for some obstacle position, creating some possible scenarios of high resonances. We also see that the obtained modes are not single span modes and that an oscillation on the left of the obstacle can be accompanied with oscillation on its right, see Figure 2-3 which is opening the debate for a better physical description of multi-span cable systems.

Constrained dynamics

To account for the time stepping scheme (27) possible applications, we look at the dynamics of cable which only hanged at one end. The cable falls and may hit a vertical wall located at a given position, that is to say:

$$g(\mathbf{q}) = \mathbf{B}(\mathbf{q} - \mathbf{q}_0) \quad (33)$$

where \mathbf{B} is a diagonal matrix with 1 for arrays $(3j+1, 3j+1)$. Solving the MLCP (27) at each time step allows to compute the dynamics given by (9). Siconos is used to obtain the time response of the system depicted in Figure 5. A cable is falling from an initial catenary position and impacts a wall located on the edge of its initial support.

Conclusion

The global procedure to compute the dynamics of a nonlinear cable subjected to unilateral and bilateral constraints have been presented with several applications. Modes taking into account various types of constraints can be considered and provides interesting features of resonance and dynamical scenarios. The dynamics of an arbitrary system may be computed according to the nonsmooth contact dynamics and open the discussion about the influence of impact on the cable profile and tension.

Summary. This work concerns the trajectory tracking control for Linear Complementarity Systems (LCS) with continuous solutions. Such systems are strongly nonsmooth and nonlinear. The tracking issue is solved using passivity tools that yield conditions which can be solved with Linear Matrix Inequalities (LMI). Circuits with ideal diodes illustrate the theoretical developments.

1 Introduction

Trajectory tracking is a major problem in Automatic Control. It is well understood for linear time-invariant systems (see [1] and references therein) and some classes of nonsmooth systems [2, 3]. In this study, we study the LCS given by

$$\begin{cases} \dot{x}(t) = Ax(t) + B\lambda(t) + Eu(t), \\ 0 \leq \lambda(t) \perp Cx(t) + D\lambda(t) + Fu(t) \geq 0, \\ x(0) = x_0, \end{cases} \quad (1)$$

where $x(t) \in \mathbb{R}^n, u(t) \in \mathbb{R}^m, \lambda(t) \in \mathbb{R}^p$ with $D = 0, D \succeq 0$, and $D \succ 0$. In case $D \succeq 0$, we restrict to positive semidefinite matrices D of the form $\begin{pmatrix} D_1 & 0 \\ 0 & 0 \end{pmatrix}$, where $D_1 \succ 0$ is square of dimension $q < p$. Our goal is to design the controller u such that $\|x(t) - x_d(t)\| \rightarrow 0$ as $t \rightarrow \infty$, where x_d is a desired state trajectory. Generally, to find a controller satisfying a given reference is a hard problem. Thus our ambition is only to deal with some sub-classes of problems which we can handle.

1.1 Main Results

Let us first make the following assumptions.

Assumption 1 *There exists a multiplier λ_d such that desired trajectory x_d satisfies*

$$\begin{cases} \dot{x}_d(t) = Ax_d(t) + B\lambda_d(t) + Eu_d(t) \\ 0 \leq \lambda_d(t) \perp Cx_d(t) + D\lambda_d(t) + Fu_d(t) \geq 0, \end{cases}$$

for a given input $u_d \in L^1_{\text{loc}}(\mathbb{R}_+; \mathbb{R}^m)$.

Assumption 2 *There exists a matrix K such that the quadruple $(A + EK, B, C + FK, D)$ is strictly passive.*

Then the following result holds.

Proposition 1 *Suppose that Assumptions 1 and 2 hold. Then the closed-loop system (1) with the state feedback controller*

$$u(t) = K[x(t) - x_d(t)] + u_d(t)$$

has a unique global solution $x(\cdot)$, and $\|x(t) - x_d(t)\| \rightarrow 0$ as $t \rightarrow +\infty$.

The proof is led with the Lyapunov function $V(z) = z^\top Pz$, $z = x - x_d$, and $P = P^\top \succ 0$ is a solution of the passivity LMI [4, Lemma 3.16, Theorem 4.73]. The controller gain K is calculated by solving the LMI:

$$\begin{pmatrix} QA^\top + AQ + L^\top E^\top + EL + \varepsilon Q & B - QC^\top - L^\top F^\top \\ B^\top - CQ - FL & -(D + D^\top) \end{pmatrix} \preceq 0. \quad (2)$$

This gives an LMI feasibility problem in the new variables $Q = Q^\top \succ 0$ and L . After solving this LMI, the feedback gain K can be recovered from $K = LQ^{-1}$. It may happen that the above LMI has no solutions (see [5, section 2.5.1] for an example). This can be solved by changing the controller structure. Namely, we allow for not only a state feedback, but also that the multiplier $\lambda(t)$ be measurable and part of the controller. In practice the multiplier may be voltages or currents (for circuits) or contact forces (for mechanical systems) and could be measured.

Assumption 3 *There exist matrices K, G such that the quadruple $(A + EK, B + EG, C + FK, D + FG)$ is strictly passive and $D + FG$ is either a zero matrix, or a positive definite matrix, or a matrix in the form $\begin{pmatrix} D_1 & 0 \\ 0 & 0 \end{pmatrix}$ with $D_1 \succ 0$.*

Proposition 2 *Suppose that Assumptions 1 and 3 hold. Then the closed-loop system (1) with the controller*

$$u(t) = K[x(t) - x_d(t)] + G[\lambda(t) - \lambda_d(t)] + u_d(t)$$

has a unique global solution $x(\cdot)$ and $\|x(t) - x_d(t)\| \rightarrow 0$ as $t \rightarrow +\infty$.

2 Example and Simulations

Let us consider the circuit in Figure 1 with an ideal diode, having the dynamics:
$$\begin{cases} \dot{x}_1(t) = x_2(t) \\ \dot{x}_2(t) = -\frac{1}{LC}x_1(t) + \frac{\lambda(t)}{L} + \frac{u_2(t)}{L} \\ 0 \leq \lambda(t) \perp \frac{\lambda(t)}{R} + x_2(t) - \frac{u_1(t)}{R} \geq 0. \end{cases}$$

From Proposition 1, we get the controller $u^1 = K(x - x_d) + u_d$ with $K = \begin{pmatrix} -1.554224 & -0.261066 \\ -3.228662 & -3.663074 \end{pmatrix}$, and from Proposition 2, the controller $u^2 = K(x - x_d) + G(\lambda - \lambda_d) + u_d$ with $K = \begin{pmatrix} -2.833123 & -1.041382 \\ -4.568759 & -3.291980 \end{pmatrix}$, $G = \begin{pmatrix} -0.500000 \\ 5.121218 \end{pmatrix}$.

Figure 1: RLCD circuit with two voltage sources.

The matrices are obtained by using YALMIP (<https://yalmip.github.io/>) with 6-digit accuracy, and using the INRIA code SICONOS (<https://nonsmooth.gricad-pages.univ-grenoble-alpes.fr/siconos/index.html>) to get the numerical results of this problem. The results are depicted in Figure 2, where x_i^j is the i th component of the closed-loop system's state with controller u^j , and initial conditions $(0.5, 0.5)$.

3 Conclusions

A detailed presentation of this work is made in the report [5] where well-posedness issues are presented, as well as several circuits examples with simulations, and all the codes needed to compute the controller gains (MATLAB, YALMIP and SICONOS).

Identification and validation of impact models

Maarten Jongeneel*, Nathan van de Wouw* and Alessandro Saccon *

**Department of Mechanical Engineering, Eindhoven University of Technology (TU/e), The Netherlands*

Summary. Predicting the outcome of an impact event is of high importance for proper execution of many robotic tasks. Rigid-body contact models are extensively used in planning and control due to their simplicity and computational efficiency. However, there exists little literature that shows a comparison and verification of these models with real-life experiments, and it is therefore unclear how well these models approximate frictional impact events. In this study, we formulate an identification approach to find the parameters of commonly used contact, friction, and impact models using an experimentally obtained data-set of impact events using a single rigid-body, where the focus lies specifically on spatial frictional impact events. In future work, we will measure, using the identified parameters, the performance of the used models in terms of long-horizon prediction performance by comparing simulated and measured rest poses of a rigid-body tossed on a surface.

Introduction

Many robotic tasks rely on accurate dynamical models of the robot as well as models of the interactions the robot has with its environment or the object it is handling. Detailed understanding of the frictional impact events that occur when dynamic manipulation tasks are executed are important for proper task execution. Quantitative modeling these non-smooth dynamics related to such stick/slip transitions and impacts events is highly challenging. Various models have been presented in literature and in this study the focus lies on rigid contact models, where the Newton-Euler equations of motion are coupled with ideal unilateral contact constraints (Signorini's contact law), Newton's impact law, and Coulomb's friction law [1, 2]. Newton's and Coulomb's law rely on parameters known as the coefficient of restitution (COR) and coefficient of friction (COF), denoted by e_N and μ , respectively. Identifying these parameters from an experimental data-set requires expertise in both mechanics and optimization, and ultimately gives an approximation of the real physical behavior of the object, as also addressed in [3]. In this study, the goal is to determine to what extent rigid-body dynamics can be used to describe real world physical behavior. More specifically, we focus on a single body impacting a surface and compare measurements with rigid-body simulations to quantify the predictive capacity of these models. The main contribution is that our focus lies on spatial frictional impact events, instead of the planar impact events considered in, for example, [4, 5].

Obtaining impact events from experiments

An experimentally obtained data-set is used to estimate the COR and COF for an uniformly filled carton box impacting a surface, which in our case is the box shown in Figure 1b. Experiments are executed on a robotic setup using a OptiTrack motion capture system to record at 360fps the poses of rigid-objects with sub-millimeter accuracy, see Figure 1a for a picture of the setup. This setup is representing a typical scenario in a logistic application, which sets the context of the project in which the experiments were executed ¹. From the tracking data it is possible to extract the exact configuration of the box and the surface with which the object is impacting and we compute the velocity of the box using a central differencing scheme. Figure 2 shows the twist of the box around a single impact event (happening at the time instance $t = 0$, where the time is normalized around the impact time), where Figure 2a shows the linear velocity component and Figure 2b shows the angular velocity component of the twist. Due to noise in the measurement system, fitted velocities are used to determine the pre-impact velocity (at $t = -1$) and post-impact velocity (at $t = 1$), which will serve as the basis for the identification of the impact map.

Parameter Identification based on post-impact velocity comparison

A total of 129 impact events were collected experimentally, from which we determine the pre- and post-impact velocity of the rigid body, where the pre-impact velocity serves as the input to a model-based simulation. We then let the simulator compute the post-impact velocity of the rigid-body given a certain value for e_N and μ and we compare the simulated post-impact velocity $\tilde{\mathbf{v}}^+$ to the post-impact velocity computed from the measurement data \mathbf{v}^+ . By performing a grid-based search over the parameter space, we are then able to find the optimum parameters. Mathematically, we define the optimization problem as

$$(\mu^*, e_N^*) = \arg \min_{\mu, e_N, e_T} \frac{1}{N} \sum_{k=1}^N \left(\left\| \text{diag}(\mathbf{w}) (\mathbf{v}^+ - \tilde{\mathbf{v}}^+) \right\|_k \right), \quad (1)$$

$$\text{s.t. } 0 \leq \mu \leq \mu_s, \quad 0 \leq e_N \leq 1, \quad (2)$$

¹This work was partially supported by the Research Project I.A.M. through the European Union H2020 program under GA 871899.

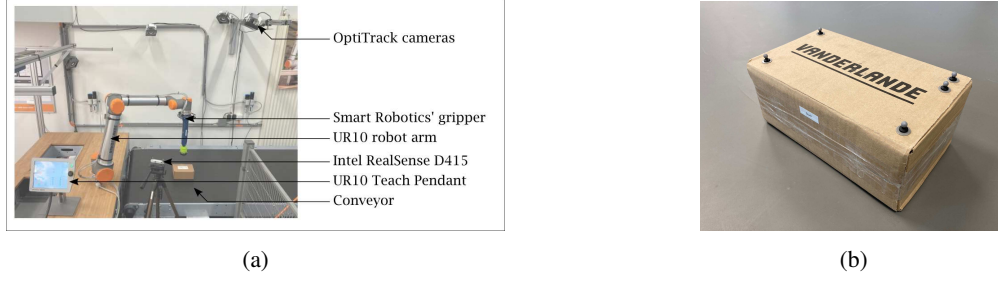

Figure 1: Experimental setup. Picture of the lab (a) and picture of the carton box (b).

Figure 2: Linear and angular hybrid velocities obtained from measurements. Fitted hybrid velocities shown as black dotted lines.

Figure 3: Sum of computed costs from all 129 combined impact events as obtained for simulations with different parameters (a) and evolution of parameter values for increasing number of impact events (b).

where the simulated post-impact velocity $\tilde{\mathbf{v}}^+$ is a function of the pre-impact pose and velocity and the chosen values for the parameters μ and e_N . Furthermore, in (1), N denotes the total number of impact events and \mathbf{w} is a weighting vector. As a result, the sum of all computed costs can be seen in Figure 3a, while Figure 3b shows the convergence behavior of the values e_N and μ as function of the number of impact events, with the optimum values found as $\mu = 0.48$ and $e_N = 0.38$.

Conclusions

In this study, an experimentally obtained data-set is used for parameter identification of a nonsmooth impact model by comparing post-impact velocities from measurements to those obtained from simulations in a cost function. In future work, the identified parameters will be used for the long-horizon prediction of the objects state and the performance of the nonsmooth models will be measured by comparing simulation results to experimental data.

Summary. We study multiple impacts in a chain of beads using the Kuwabara-Kono (KK) contact model [1], a nonsmooth (not Lipschitz continuous) extension of Hertz contact that accounts for viscoelastic damping. For this purpose, we introduce new numerical schemes which approximate dissipative impacts with good accuracy without including the nonsmooth KK viscoelastic component in the contact force. These schemes are derived using the technique of modified equations, which allows us to construct time-discretizations of the nondissipative Hertz law matching numerical dissipation with KK dissipation at different consistency orders. In addition, analytical approximations of wave profiles are derived using asymptotic expansions, in the limit when the exponent of the contact force becomes close to unity. Numerical tests are performed for the simulation of impacts in Newton's cradle and on alignments of free beads.

1 Introduction

In this work, we introduce a new method for the numerical simulation of granular chains which allows to approximate the KK contact model without explicitly including the nonsmooth viscoelastic term in the contact force, *i.e.*, $\gamma = 0$ in (1):

$$f(\delta) = k \left(\delta_+^\alpha + \gamma \frac{d}{dt} \delta_+^\alpha \right), \quad (1)$$

where $f(\delta)$ is the spring/dashpot contact force, δ is the indentation, and $\alpha = 3/2$ corresponds to the usual KK model [1]. Our approach is based on the technique of modified (or equivalent) equations, in which effects induced by time-discretization (such as numerical dissipation) are analyzed by considering suitable perturbations of the initial differential equation. In addition, analytical approximations of propagating fronts (generated for example by an impacting piston) are obtained using asymptotic expansions, by considering $\alpha - 1$ as a small parameter.

2 KK numerical dissipation

We consider a Newton's cradle, including local attachments consisting of strings or plates. The dynamical equations including local restoring forces, where the attachment of the n th bead is represented by a spring with linear stiffness K_n , are :

$$m_n \ddot{x}_n = -K_n x_n + k_n \delta_{(n-1)+}^{3/2} - k_{n+1} \delta_{n+}^{3/2}, \quad 1 \leq n \leq N, \quad (2)$$

with $\delta_n = x_n - x_{n+1}$ and $k_1 = k_{N+1} = 0$. In model (2), collisions are assumed nondissipative. Setting $x = (x_1, \dots, x_N)$, $v = (\dot{x}_1, \dots, \dot{x}_N)$ and $y = (x, v)$, system (2) can be reformulated as

$$\dot{y} = f(y) = \begin{pmatrix} v \\ g(x) \end{pmatrix}, \quad (3)$$

where the components of $g(x) \in \mathbb{R}^N$ are given by $g_n(x) = \frac{1}{m_n} (-K_n x_n + k_n \delta_{(n-1)+}^{3/2} - k_{n+1} \delta_{n+}^{3/2})$. In order to approximate solutions of (10), we introduce the implicit one-step method

$$\begin{aligned} \frac{X_n^{k+1} - X_n^k}{h} &= \theta V_n^{k+1} + (1 - \theta) V_n^k, \\ \frac{V_n^{k+1} - V_n^k}{h} &= \frac{1}{m_n} \left[-(1 - \mu) K_n X_n^{k+1} + \theta \left(k_n (\Delta_{n-1}^{k+1})_+^{3/2} - k_{n+1} (\Delta_n^{k+1})_+^{3/2} \right) \right] \\ &\quad + \frac{1}{m_n} \left[-\mu K_n X_n^k + (1 - \theta) \left(k_n (\Delta_{n-1}^k)_+^{3/2} - k_{n+1} (\Delta_n^k)_+^{3/2} \right) \right], \end{aligned} \quad (4)$$

where $\Delta_n^k = X_n^k - X_{n+1}^k$, h denotes the time step and $Y_k = (X_1^k, \dots, X_N^k, V_1^k, \dots, V_N^k)$ approximates $y(kh)$. We consider a modified (or equivalent) equation (see *e.g.*, [3, 4] and references therein) corresponding to the scheme (4) :

$$\dot{Y} = f(Y) + h F_1(Y) + O(h^2), \quad (5)$$

where the coefficient F_1 needs to be determined. After some manipulations the modified equation (5) can be rewritten

$$\dot{X}_n = V_n + h \left(\theta - \frac{1}{2} \right) g_n(X) + O(h^2), \quad (6)$$

$$m_n \ddot{X}_n + K_n (h(\theta - \mu) \dot{X}_n + X_n) = k_n \left(\Delta_{(n-1)+}^{3/2} + 3 \left(\theta - \frac{1}{2} \right) h \Delta_{(n-1)+}^{1/2} \dot{\Delta}_{n-1} \right) - k_{n+1} \left(\Delta_{n+}^{3/2} + 3 \left(\theta - \frac{1}{2} \right) h \Delta_{n+}^{1/2} \dot{\Delta}_n \right) + O(h^2), \quad (7)$$

with $\Delta_n = X_n - X_{n+1}$, where a KK dissipation term clearly appears. Setting

$$\theta = \frac{1}{2} + \frac{\gamma}{2h} = \mu \quad (8)$$

in (7) and neglecting $O(h^2)$ terms, one recovers the KK model

$$m_n \ddot{X}_n + K_n X_n = k_n \Delta_{(n-1)+}^{3/2} + \frac{3}{2} \gamma k_n \Delta_{(n-1)+}^{1/2} \dot{\Delta}_{n-1} - k_{n+1} \Delta_{n+}^{3/2} - \frac{3}{2} \gamma k_{n+1} \Delta_{n+}^{1/2} \dot{\Delta}_n. \quad (9)$$

This observation leads us to the concept of *tailored numerical dissipation*. In this framework, one discretizes the nondissipative model (2) with the dissipative scheme (4)-(8) in order to approximate the dissipative model (9).

3 Analytical approximations of wave profiles

We consider system (9) with a generalized elastic exponent $\alpha > 1$, without local springs (i.e., $K_n = 0$) and for identical beads, so that m_n and k_n are constant and rescaled to unity :

$$\ddot{X}_n = \Delta_{(n-1)+}^\alpha + \alpha \gamma \Delta_{(n-1)+}^{\alpha-1} \dot{\Delta}_{n-1} - \Delta_{n+}^\alpha - \alpha \gamma \Delta_{n+}^{\alpha-1} \dot{\Delta}_n. \quad (10)$$

We consider the limit case of an infinite chain, assume $\Delta_n \geq 0$ (absence of gaps between beads) and set

$$\Delta_n(t) = \delta y(\xi, \tau)^{1/\alpha}, \quad (11)$$

with $\xi = \varepsilon(n - ct)$, $c = \delta^{(\alpha-1)/2}$, $\tau = \frac{\gamma}{2} \varepsilon^2 c^2 t$, and $\varepsilon = \frac{\alpha-1}{\alpha \gamma c}$. The new variable y can be interpreted as a rescaled force variable. Substituting the Ansatz (11) in the dynamical equations (10), and performing an asymptotic expansion with respect to the small parameter ε , one arrives to a logarithmic Burgers equation

$$\partial_\tau y + \partial_\xi (y \ln y) = \partial_\xi^2 y. \quad (12)$$

The expansion is valid for α close enough to unity, and the logarithmic nonlinearity originates from the approximation $(y - y^{1/\alpha})/(1 - \frac{1}{\alpha}) \approx y \ln y$.

Alternatively, modifying the Ansatz as follows :

$$\Delta_n(t) = \delta y(s, \tau)^{1/\alpha}, \quad (13)$$

with $s = 2\sqrt{3}\varepsilon(n - ct)$, $\tau = \sqrt{3}\varepsilon^3 ct$, $\varepsilon = (1 - \frac{1}{\alpha})^{1/2}$ and c defined as above, one obtains the logarithmic KdV-Burgers equation

$$\partial_\tau y + \partial_s (y \ln y) + \partial_s^3 y = \mu \partial_s^2 y, \quad (14)$$

where $\mu = c 2\sqrt{3} \gamma (1 - \frac{1}{\alpha})^{-1/2}$. This expansion is valid when $\alpha \rightarrow 1^+$ and assuming $\mu = O(1)$, hence γ has to be small. The amplitude equations (12) and (14) both possess stationary front solutions, which can approximate the asymptotic response of a chain impacted by a piston. They are valid in different regimes regarding the amount of contact damping, and the logarithmic KdV-Burgers equation allows to approximate more general underdamped (oscillatory) fronts.

These approximations are tested by performing direct numerical simulations of the KK model. One observes a convergence of the numerical solutions towards analytical profiles when α is close to unity. In addition, the analytical approximations remain meaningful for $\alpha = 3/2$, i.e. rather far from the asymptotic limit where the amplitude equations have been derived.

4 Conclusions

New approaches for the numerical simulation of granular matter *via* the approximation of the Kuwabara-Kono model by suitable numerical dissipation or the derivation of adapted amplitude equations are presented. More details can be found in [2] and [5].

Summary. An extension of the drill-string dynamics model for drilling in heterogeneous rock formations is presented to study the heterogeneity effect on both the axial and torsional dynamics.

Introduction

According to [1], the total loads acting on the Polycrystalline-Diamond-Compact (PDC) bit in rotary drilling systems (see Figure 1-left) are changed abruptly when the bit blades drill into interchangeably harder and softer layers of heterogeneous rock formations. This fast load-change condition due to the formation heterogeneity can affect the dynamic response of the system and therewith the vibrational signature at the bit, which in turn may influence the durability of the PDC bit and drilling efficiency. To this end in this study, the drill-string system model as presented in [2, 3] is extended for vertical drilling scenario in interbedded formations, particularly for the transitional part of the motion of the bit in two heterogeneous layers (see Figure 1-middle). The latter requires a novel bit-rock interaction model of the forces and torques acting on the bit in such transitional phase.

Figure 1: Drilling system schematic for heterogeneous formations (left); the bit transition (middle); model of drill-string system (right).

Dynamic model of drill-string systems in heterogeneous formations

Following the modeling framework in [3] (as depicted in Figure 1-right), the dynamics model of drill-string system incorporating the heterogeneity effect of distinct rock layers is modelled in (scaled) dimensionless form as follows:

$$\mathcal{M}\mathbf{z}'' - \mathcal{H}(\tau, \mathbf{z}, \mathbf{z}', \mathbf{z}_{\tau_n}) = \mathcal{W}\mathcal{L}. \quad (1)$$

Herein, \mathbf{z} is the dimensionless generalized coordinates of the systems and composed by u_b for the axial position of the bit and ϕ_b for the angular position, and all are functions of dimensionless time τ . The matrices in (1) are given by,

$$\mathcal{M} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad \mathbf{z} = [u_b(\tau) \quad \phi_b(\tau)]^\top, \quad \mathcal{W} = \begin{bmatrix} \bar{\psi} & 0 \\ 0 & 1 \end{bmatrix}, \quad \mathcal{L} = [\mathcal{L}_{k,ba}^{tot}(\rho_b) \quad \mathcal{L}_{k,bt}^{tot}(\rho_b, \mathcal{L}_{k,ba}^{tot})]^\top, \quad (2)$$

$$\mathcal{H} = \begin{bmatrix} -\gamma u'_b \\ (-\gamma_\phi \phi'_b - (\phi_b - \omega_0 \tau)) \end{bmatrix} + \begin{bmatrix} -\bar{\psi} n \delta_n \bar{g}_k^\varepsilon \left(g_k^\varepsilon (1 - \eta_\zeta^l(\rho_b)) + \eta_\zeta^l(\rho_b) \right) \\ -n \delta_n \bar{g}_k^\varepsilon (g_k^\varepsilon (1 - \rho_b^2) + \rho_b^2) \end{bmatrix} + \begin{bmatrix} \bar{\psi} \mathcal{W}_a \\ 0 \end{bmatrix}. \quad (3)$$

The number of layers, with each specific thickness, is K (thus the index of each layer is denoted by $k \in \{2, 3, \dots, K\}$). The single and double prime symbols denote for the time derivatives of \mathbf{z} . \mathbf{z}_{τ_n} stores the delayed coordinates of \mathbf{z} (i.e., $u_b(\tau - \tau_n)$, $\phi_b(\tau - \tau_n)$). τ_n is the (state-dependent) time-delay appearing in the rock cutting process. \mathcal{M} is the mass matrix, and n is the number of bit-blades. Furthermore, one of the pivotal elements in the model is the bit-rock interaction that couples the axial and torsional dynamics of the drill-string and has two main components related to cutting and contact. Matrix \mathcal{H} consists of the generalized forces and torques (except from the components related to the wear-flat contact force and frictional torque), i.e., from the stiffness and damping processes, cutting, gravity and the hook-load imposed by the hoisting/top-drive system at the surface. Thus, we have the torsional damping (γ_ϕ), the axial damping (γ), the angular velocity imposed at the surface rotary table (ω_0), and the resultant of the submerged weight of the drill-string and hook-load (\mathcal{W}_a). Moreover, the cutting and contact components are extended for encapsulating the rock heterogeneity effect of two distinct horizontal layers in which the bit may be simultaneously drilling. The lithology

parameters influencing these bit force and torque components are the ratio of the intrinsic specific energies between upper and lower layers (g_k^ε), the ratio of the frictional coefficients for the contact between upper and lower layers (g_k^μ), the ratio of the contact pressures at the bit-rock interface between upper and lower layers (g_k^σ), and the ratio between the intrinsic specific energy at the associated layer and its mean values (\bar{g}_k^ε). In addition, these bit force and torque components are also affected by the bit parameters related to cutting (η_ζ^l) and contact (η_ζ^l), and drill-string design ($\bar{\psi}$). These bit parameters are adapted to the formation layer(s) in which the bit is currently engaged. We use the radius ratio of the bit at the layer boundary (ρ_b as defined in Figure 1-middle) to segregate the portion of the bit engaged in the upper ($(k-1)^{th}$) and lower (k^{th}) layers during the transition. We note that the bit is designed with a particular blade profile ($z(r)$) as a function of its radius r (with maximum radius a). In (3), the depth-of-cut δ_n and the time-delay τ_n are given by,

$$\delta_n = u_b(\tau) - u_b(\tau - \tau_n), \quad \phi_b(\tau) - \phi_b(\tau - \tau_n) = \frac{2\pi}{n}. \quad (4)$$

Vector \mathcal{L} stores the dimensionless wear-flat contact force ($\mathcal{L}_{k,b_a}^{tot}$) and the associated frictional torque ($\mathcal{L}_{k,b_t}^{tot}$) acting on the bit wear-flats and is affected by the heterogeneity of the layer(s) in which the bit engages (this dependence is indicated by index k). The generalized directions of these forces and torques are contained in matrix \mathcal{W} . These forces and torques obey set-valued force laws (reflecting a unilateral contact law in (5) and a Coulomb friction law in (6)) using a proximal-point formulation on velocity level:

$$\begin{aligned} \mathcal{L}_{k,b_a}^{tot}(\rho_b) &= \text{prox}_{\bar{C}_a}(\mathcal{L}_{k,b_a}^{tot} - r_1 u'_b), \quad \bar{C}_a = \{\mathcal{L}_{k,b_a}^{tot}(\rho_b) \mid -n g_{k,\rho_b}^\sigma \bar{\mathcal{L}}_{k,b_a} \leq \mathcal{L}_{k,b_a}^{tot}(\rho_b) \leq 0\}, \\ \mathcal{L}_{k,b_t}^{tot}(\rho_b, \mathcal{L}_{k,b_a}^{tot}) &= \text{prox}_{\bar{C}_t}(\mathcal{L}_{k,b_t}^{tot} - r_2 \phi'_b), \quad \bar{C}_t = \{\mathcal{L}_{k,b_t}^{tot}(\rho_b) \mid -\beta_{k,\rho_b} \mathcal{L}_{k,b_a}^{tot}(\rho_b) \leq \mathcal{L}_{k,b_t}^{tot}(\rho_b) \leq \beta_{k,\rho_b} \mathcal{L}_{k,b_a}^{tot}(\rho_b)\}. \end{aligned} \quad (5)$$

$$(6)$$

$\bar{\mathcal{L}}_{k,b_a}$ is the nominal contact force for the associated rock layer, while g_{k,ρ_b}^σ is the value of g_k^σ affected by the bit-geometry at the layer boundary (associated to ρ_b). β_{k,ρ_b} is the bit-design parameter that is also affected by the formation heterogeneity and mainly influences the frictional torque. r_1 and r_2 are some positive arbitrary constants.

Preliminary Simulation Results

The simulation results of the dimensionless model of drill-string system for vertical drilling in heterogeneous formations are shown in Figure 2. Under the influence of the heterogeneity, the torque and weight on bit are fluctuating and not reaching the steady-state limit cycles (associated to the responses in homogeneous rock formulations) while the bit moves in heterogeneous and thin layers, i.e., each layer thickness equal to the bit height. The green area is the soft layer, while the red area is for the hard one. These responses show that in the case of heterogeneous formations, the drill-string dynamics can no longer be described through homogeneous models and the developed heterogeneous model is indeed required.

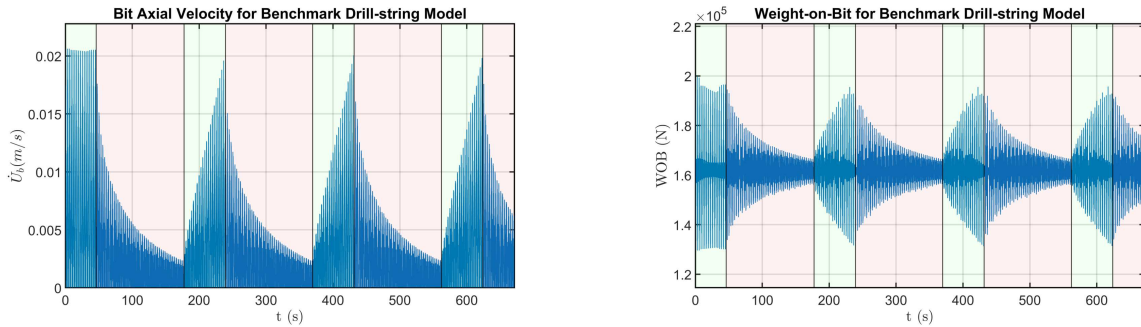

Figure 2: Bit axial velocity/rate-of-penetration in drilling heterogeneous formations (left); weight-on-bit (right).

Conclusion

This abstract presents a drill-string dynamics model with a PDC bit for drilling vertically in the heterogeneous formations with an emphasis on the characterization of the bit-rock interaction during the transition of the bit between two distinct horizontal layers. Next we aim to analyze the drilling efficiency in terms of ROP and to examine the total torsional power losses that can lead to the onset of (torsional) stick slip vibrations in heterogeneous formations.

Nonlinear granular damping of structures with cavities from additive manufacturing

Sebastian Tatzko*, Tobias Ehlers†, Gleb Kleyman* and Roland Lachmayer†

**Institute of Dynamics and Vibration Research, Leibniz University Hannover, Hannover, Germany*

†*Institute of Product Development, Leibniz University Hannover, Hannover, Germany*

Summary. Additively manufactured parts are often created with cavities for weight reduction or other mechanical purposes. These cavities offer the optimal base for granular damping. Unfused raw material particles can be left inside the structure or another granular material can be filled in to increase structural damping. In this paper, a simple mechanical model is developed based on measurements of a basic experiment for granular damping with only a small amount of particles.

Additive manufacturing for lightweight structures

Today, the term additive manufacturing characterizes a multitude of different processes with which almost all materials from metals to plastics to ceramics, glass and concrete can be processed. The potential of additive manufacturing offers new possibilities to realize optimized solutions in the development process. This includes in particular the manufacture of components with a high degree of complexity and shape variance.

The possibility of integrating cavities into components is particularly attractive for lightweight construction. The overall weight is reduced while lattice structures can be added easily to provide the necessary stability. A major drawback of these lightweight integral structures is their susceptibility to vibrations and noise emissions. A common additive manufacturing process for metals is laser powder bed fusion (LPBF). Smallest particles of the raw material are melted with a laser and formed into a structure in layers. A CT-scan of a LPBF-printed beam with unfused material in the cavity is shown in Fig.1a). The raw granular material is removed from the cavities at the end of the manufacturing process. The obvious idea is to leave the unfused granules inside the structure to make use of the granular damping effect [1], [2]. In order to keep the weight low, the raw material can be replaced by another granule with a lower density [3]. The simpler way is to leave only a small part of the granules in the cavity.

Figure 1: a) Additively manufactured beam with unfused granules in cavity; b) Experimental set up of steel pipe hanging on strings

Fundamental investigations on granular damping

For first investigations on increased damping through a small amount of particles a standard steel pipe is tested with sand as granular medium. Sand can have a strong damping effect on mechanical structures [4]. The pipe hangs freely on strings as shown in Fig.1b). Free decay from impact excitation is recorded with a microphone and then analyzed by applying a short-time Fourier transform (STFT). Fig.2a) shows the results for the unfilled pipe in the frequency range around the first bending mode. Due to a slight asymmetry two close frequencies are recognized. Repeating the measurement with a small amount of sand inside the pipe, see Fig.1b), a strongly increased damping is noticeable. After a certain time, the damping effect disappears with a distinct frequency shift., cp. Fig.2b). The structure then vibrates at significantly lower amplitudes with low damping.

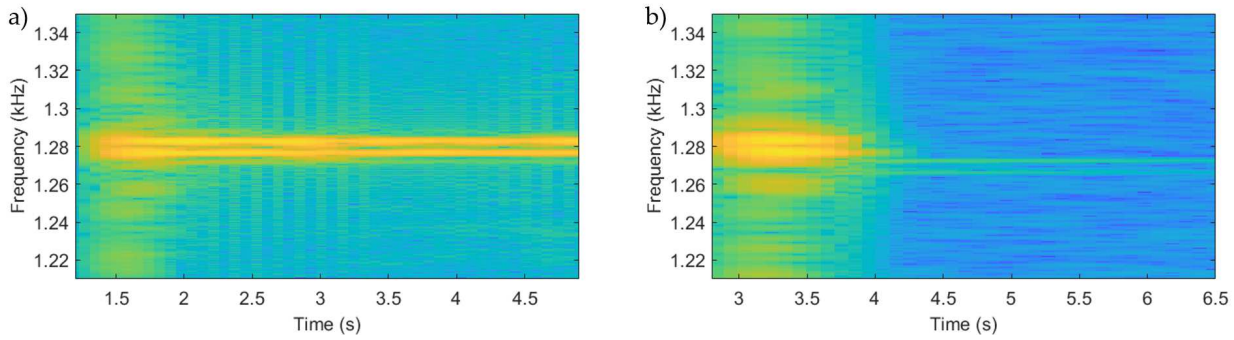

Figure 2: STFT results after impact excitation: a) unfilled pipe ; b) pipe filled with a small amount of sand

Minimal model showing observed phenomena

Motivated by the measurement results, a minimal model is developed to reproduce the observed vibration phenomena. A strongly increased damping with a shift to a lower vibration frequency are approached by the dual mass model shown in Fig.3a). An unbound mass m_2 is connected via Coulomb friction to a single degree of freedom (SDOF) oscillator with mass m_1 . The frictional force depends on the relative velocity of the two masses and the factor μF_n . In the case of an impact excitation of the lower mass, it will initially move independently. The upper mass stays at rest due to its inertia and resulting friction forces provide increased vibration damping. After a certain amount of time, the upper mass will move synchronously with the lower mass and practically increase the mass of the SDOF-system. This leads to a sudden reduction of the vibration frequency clearly visible in the spectral analysis result in Fig.3b). Numerical results are obtained by time step integration for which a Matlab/Simulink model of the system is set up. The natural frequency of the system is tuned to match the first bending mode of the pipe. All remaining parameters are manually set in order to obtain a qualitative characteristic close to the measurements. The acoustic measurement results for a single vibration mode could be very well reproduced with the presented minimal model. If it is possible to find a physical interpretation of the model parameters and to identify these parameters from measurements, the minimal model could be used for a simple first approach in granular damping design.

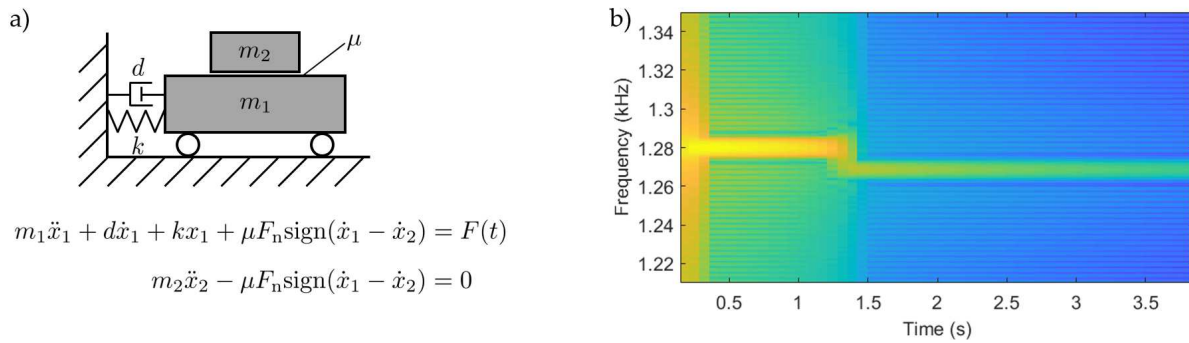

Figure 3: a) Dual mass model and equations of motion; b) STFT result after impact excitation from numerical time integration

Conclusion

Granular damping of structures is a promising and cost-effective method for vibration reduction. Additively manufactured components with cavities of various types open up new possibilities for placing granules. For weight reasons, partially filled cavities are of particular interest. In this work experimental studies are carried out and observed phenomena are modelled using a mechanical oscillator. The model shows the same characteristic as found in measurements and maybe helpful for granular damping design with only a small amount of particles.

A Nonsmooth Approach for Generating Convex Relaxations of Dynamic Systems

Yingkai Song and Kamil A. Khan

Department of Chemical Engineering, McMaster University, Hamilton, ON, Canada

Summary. We propose a new approach for generating convex and concave relaxations for the solutions of parametric ordinary differential equations (ODEs), for use in global dynamic optimization and reachability analysis. These relaxations are described as the solutions of an auxiliary nonsmooth ODE system with embedded convex optimization problems. The resulting relaxations are indeed valid relaxations, are convex, and converge rapidly to the original system as the parametric subdomain shrinks. The new approach is compatible with any relaxations for the original right-hand side, and tighter such relaxations will necessarily translate into tighter relaxations for state variables. Especially, if generalized McCormick relaxations are used, the new approach is guaranteed to yield tighter relaxations than a state-of-the-art ODE relaxation approach [1], and thus may reduce the number of iterations for overarching global dynamic optimization. Further implications and examples are discussed.

Background and Motivation

Global dynamic optimization is useful in a wide variety of engineering applications such as parameter estimation, global optimal control, and optimization-based worst-case uncertainty analysis. Compared with stochastic methods for global optimization, deterministic global optimization methods have the advantage that a globally optimal solution is guaranteed to be found within a predefined tolerance in finite computation time. However, current deterministic global dynamic optimization methods based on branch-and-bound [2] can only solve problems of modest size. Thus, improved techniques are sought to extend these methods to problems of practical interest.

One computational bottleneck for global dynamic optimization is generating convex and concave relaxations for state variables with respect to decision variables, termed *state relaxations* [1]. These relaxations are useful for computing lower bounds for the global optimal objective value, which are required in deterministic global optimization algorithms. Moreover, state relaxations could also help construct convex enclosures for the reachable set which is useful in applications involving reachability analysis such as fault detection and robust optimal control. Hence, there is a need in global dynamic optimization to develop efficient and accurate computational tools for generating state relaxations automatically.

State relaxations should have desirable convergence and tightness properties. The relaxations supplied to a branch-and-bound global optimization method must converge rapidly to the underlying model as the decision space is subdivided or else the overall global optimization method will be impeded by cluster effects, in which the method will branch many times on intervals that either contain or are near a global minimum [3]. This notion of rapid convergence has been formalized as *second-order pointwise convergence* [4]. Tighter state relaxations could construct tighter lower bounds for the global optimal objective value, and thus may reduce the overall computational time by reducing the number of required iterations. In reachability analysis, tighter enclosures of the reachable set could reduce the sets' conservatism, which could lead to earlier detection of faults or less conservative control inputs.

New Relaxation Approach

Consider a parametric ODE system of the form

$$\begin{aligned}\dot{\mathbf{x}}(t, \mathbf{p}) &= \mathbf{f}(t, \mathbf{p}, \mathbf{x}), \quad \forall t \in (t_0, t_f], \\ \mathbf{x}(t_0, \mathbf{p}) &= \mathbf{x}_0(\mathbf{p}),\end{aligned}$$

where \mathbf{x} denotes dependent state variables and \mathbf{p} denotes system parameters.

We propose a new approach for constructing state relaxations $\mathbf{x}^{cv}(t, \mathbf{p})$ and $\mathbf{x}^{cc}(t, \mathbf{p})$ for states $\mathbf{x}(t, \mathbf{p})$ with respect to \mathbf{p} . These relaxations are described as the solutions of an auxiliary ODE system whose right-hand side comprises convex optimization problems with embedded relaxations for \mathbf{f} . The auxiliary system is nonsmooth because of the nonsmooth nature of optimal-valued functions. The advantages of this approach are presented as follows. First, if the relaxations for \mathbf{f} have second-order pointwise convergence, then the resulting state relaxations inherit this desirable convergence property which could help avoid cluster effects. Secondly, the new approach is compatible with various relaxations for \mathbf{f} , such as α BB relaxations [5] and generalized McCormick relaxations [6], while previously established approaches are typically limited by one particular type of relaxations. Thirdly, tighter relaxations for \mathbf{f} necessarily translate into tighter state relaxations. Thus, it is worthwhile from a dynamic optimization or reachability analysis standpoint to seek tighter relaxation methods for closed-form functions since doing so necessarily translates into superior descriptions of reachable sets for dynamic systems. Especially, if the generalized McCormick relaxations are employed, the new approach necessarily yields tighter state relaxations than a state-of-the-art ODE relaxation approach by Scott and Barton [1], and thus may reduce the number of required iterations for overarching global dynamic optimization.

Proof-of-concept Implementation

Two numerical examples are presented to illustrate the convergence and tightness properties of the new state relaxations. The examples are implemented in MATLAB, using the ODE solver `ode15s` and the local optimization solver `fmincon`.

Example 1

Consider the following parametric ODE system:

$$\dot{x}(t, p) = p(x^2 - 1), \quad x(0, p) = -2,$$

with $t_f = 0.15$ and $-1 \leq p \leq 1$. State relaxations are constructed by the new approach using α BB relaxations of the right-hand side function. Figure 1 shows that the resulting relaxations have second-order pointwise convergence, where X^C denotes the enclosure formed by state relaxations, and P denotes the parametric subdomain.

Figure 1: A log-log plot of width of the enclosure formed by state relaxations at $t := t_f$ versus width of the parameter's domain (circles) and a reference line with a slope of 2 (dashed).

Example 2

The following example is modified from a bioreaction model in [7] by adding more nonlinearities:

$$\begin{aligned} \dot{x}_1(t, p) &= \left(\frac{1.2x_2}{px_2^2 + x_2 + 7.1} - 0.18 \right) x_1, & x_1(0, p) &= 0.82, \\ \dot{x}_2(t, p) &= 0.36(5.7 - x_2) - \frac{12.636x_2x_1}{px_2^2 + x_2 + 7.1} + \frac{1}{x_1} - x_2^2 + x_1^2x_2, & x_2(0, p) &= 0.8, \end{aligned}$$

with $t_f = 15$ and $0.4 \leq p \leq 0.6$. State relaxations are constructed by the new approach using generalized McCormick relaxations and by the approach of Scott and Barton [1]. Figure 2 shows that the new state relaxations are tighter than Scott–Barton relaxations for this example.

Figure 2: The final state $x_2(t_f, p)$ vs. p (black-solid), along with corresponding Scott–Barton relaxations (blue-circled) and new relaxations (red-dashed), plotted as functions of p at $t := t_f$.

Nonsmooth Modal Analysis of Varying Cross-section Bar

Tianzheng Lu and Mathias Legrand

Structural Dynamics and Vibration Laboratory, McGill University, Montreal, Québec, Canada

Summary. The nonsmooth modal analysis of a simple one-dimensional bar of constant cross-section has already been successfully performed using a Finite Volume formulation and the Frequency-Domain Boundary Element Method (FD-BEM). Both strategies took advantage of the existence of d'Alembert solution for such problem. The present contribution extends the previous works to a bar of non-constant cross-section for which the d'Alembert solution no longer exists. The proposed scheme combines the finite element method in space to the harmonic balance technique in time. The solution satisfies the unilateral contact condition along with an energy-preserving implicit impact law in a weighted-residual sense. The partial backbone curve of the first mode shows the existence of internal resonances.

Introduction

Within the framework of structural dynamics, modal analysis is a practical tool to predict the occurrence of vibrational resonances, most commonly to prevent them. Various formulations have been proposed in the nonlinear framework where the governing equation contains smooth nonlinear function of the state of system. Nonsmooth modal analysis is one incarnation of nonlinear modal analysis in which the smoothness assumption does not hold, as for instance exhibited in unilaterally-constrained structural dynamics [1, 2]. In this context, a method combining the finite element method (FEM) and harmonic balance method (HBM) is proposed.

System of Interest

The system of interest, in Figure 1, is a one-dimensional bar of finite length L . The displacement field of straight cross-sections is denoted $u(x, t)$ where x is the space coordinate and t is time. The bar is clamped at $x = 0$ (Dirichlet condition) and subject to a unilateral contact condition at $x = L$ (Signorini condition). The cross-section area $A(x)$ is varying along the bar while the mass density ρ and Young's modulus E are constant. Given the initial gap g_0 between the bar at rest and the rigid foundation, the gap function reads $g(t) = g_0 - u(L, t)$. The dynamics of the bar is governed by the Partial Differential Equation

Figure 1: One-dimensional bar system of interest

$$EA_x u_x + EA u_{xx} + \rho A u_{tt} = 0 \quad (1)$$

where \bullet_η denotes a partial differentiation with respect to η . Clamping at $x = 0$ reads $u(0, t) = 0$ while unilateral contact at $x = L$ is expressed as

$$-\lambda(t) + \max[\lambda(t) - \alpha g(t), 0] = 0 \quad (2)$$

where $\lambda(t)$ is the contact force and α is a strictly positive real number.

Solution method: Fourier Transform+Finite Elements+Harmonic Balance

The sought families of periodic solutions defining the modal motions are computed through a numerical scheme which assumes that no impact law is explicitly required, in contrast to common practises. First, a Fourier Transform is applied on the unknowns of the problem:

$$\mathcal{F}\{u(x, t)\} = \hat{u}(x, \omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} u(x, t) \exp(-i\omega t) dt \quad \text{and} \quad \mathcal{F}\{\lambda(t)\} = \hat{\lambda}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \lambda(t) \exp(-i\omega t) dt. \quad (3)$$

This leads to the two governing equations in the frequency domain

$$EA \hat{u}_{xx} + EA_x \hat{u}_x - \omega^2 \rho A \hat{u} = 0 \quad \text{and} \quad -\hat{\lambda}(\omega) + \mathcal{F}\{\max[\lambda(t) - \alpha g(t), 0]\} = 0 \quad (4)$$

where the last term $\mathcal{F}\{\dots\}$ can unfortunately not be explicitly expressed in terms of \hat{u} and $\hat{\lambda}$. Spatial semi-discretization is applied via the standard FEM with N two-node linear elements and the corresponding $N + 1$ nodes. The Dirichlet boundary condition is directly enforced in the discretized weak form of (4) which reads

$$\mathbf{H}(\omega) \hat{\mathbf{u}}(\omega) = \hat{\mathbf{f}}(\omega) \quad (5)$$

with $\mathbf{H}(\omega) = \mathbf{K} - \omega^2 \mathbf{M}$ where \mathbf{K} and \mathbf{M} are the classical stiffness and mass matrices. Also, vector $\hat{\mathbf{f}}(\omega) = [0, \dots, 0, \hat{\lambda}(\omega)]^\top$ stores the contact force while vector $\hat{\mathbf{u}}(\omega) = [\hat{u}_0(\omega), \dots, \hat{u}_{N-1}(\omega), \hat{u}_N(\omega)]^\top$ stores the response nodal displacements, both in the frequency domain. Inverting $\mathbf{H}(\omega)$ yields the relation

$$\hat{u}_N(\omega) = \gamma(\omega) \hat{\lambda}(\omega) \quad (6)$$

where $\gamma(\omega)$ is the last entry of the inverse of $\mathbf{H}(\omega)$. Since periodic solutions are targeted, the time-domain nodal displacements and companion contact force are approximated as

$$\lambda(t) = a_0 + \sum_{k=1}^M a_{2k-1} \sin k\Omega t + a_{2k} \cos k\Omega t, \quad u_i(t) = b_{i0} + \sum_{k=1}^M b_{i2k-1} \sin k\Omega t + b_{i2k} \cos k\Omega t, \quad i = 1, \dots, N. \quad (7)$$

Given the form of $\hat{\mathbf{f}}$, the only unknowns of the problem actually are the Fourier coefficients of $u_N(t)$ and $\lambda(t)$, that is the coefficients (a_k, b_{Nk}) for $k = 0, \dots, 2M$. Accordingly, it is required to establish the corresponding equations to solve for. First, inserting (7) into (6) leads to

$$b_{Nk} = \gamma(k\Omega)a_k, \quad k = 0, \dots, 2M. \quad (8)$$

Second, noting $\beta(t) \stackrel{\text{def}}{=} \max(\lambda(t) - \alpha g(t), 0)$ and $T = 2\pi/\Omega$, the HBM version of condition (2) implies

$$a_0 - \frac{1}{T} \int_0^T \beta(t) dt = 0 \quad (9)$$

along with

$$a_{2k} - \frac{2}{T} \int_0^T \beta(t) \cos k\Omega t dt = 0 \quad \text{and} \quad a_{2k-1} - \frac{2}{T} \int_0^T \beta(t) \sin k\Omega t dt = 0, \quad k = 1, \dots, M \quad (10)$$

where Expressions (7) are first inserted into the above integrals which can then be numerically evaluated using basic quadrature schemes. Continuous families of periodic solutions are built via a classical sequential continuation technique [3, 4] on the frequency parameter Ω , which is thus not treated as an unknown. The resulting system of $4M + 2$ equations (8) to (10) in $4M + 2$ unknowns can be solved using a nonlinear solver. Since autonomous periodic solutions are targeted, it seems justified to say that the classically required energy-preserving impact law is here embedded implicitly in the above integrals. However, we do not have a formal proof of this statement.

Results

The selected cross-section area is $A(x) = 1.5 - x$ with $L = 1$ and the initial gap is $g_0 = 0.001$. The discretization is chosen to be $M = 40$ and $N = 4000$. Results on the first nonsmooth mode are depicted in Figure 2. The backbone

Figure 2: First nonsmooth mode: backbone curve (left) and displacement field at $\Omega = 1.907$ (right).

curve shows the frequency-energy dependency of the modal response and internal resonance mechanisms with higher modes. Unlike the displacement field of the constant cross-section bar which consists of piecewise affine segments, the displacement field found here seems to have smoother functional properties, even with a fine approximation.

Conclusion

A numerical scheme combining FEM and the HBM is proved capable of capturing nonsmooth modes for a one-dimensional varying cross-section bar. The main feature of the proposed scheme is that neither explicit energy-preserving impact laws nor regularization techniques are required at the contact interface even-though classical finite-elements are employed. Instead, the Signorini condition and companion impact law are satisfied in a weighted-residual sense.

Summary. We present a theory for the dispersion of generated harmonics in a traveling nonlinear wave. The harmonics dispersion relation—derived by the theory—provides direct and exact prediction of the collective harmonics spectrum in the frequency-wavenumber domain, and does so without prior knowledge of the spatial-temporal solution. The new relation is applicable to a family of initial wave functions characterized by an initial amplitude and wavenumber. We demonstrate the theory on nonlinear elastic waves in a homogeneous rod and demonstrate an extension to periodic rods.

Wave motion lies at the heart of many disciplines in the physical sciences and engineering. For example, problems and applications involving light, sound, heat or fluid flow are all likely to involve wave dynamics at some level. In this work, we consider strongly nonlinear wave propagation [1,2] in elastic solids, although the theory presented is in principle applicable to other types of waves such as waves in fluids, gases, and plasma.

We investigate a thick elastic rod admitting longitudinal motion. In the linear limit, this rod is dispersive due to the effect of lateral inertia. The nonlinearity is introduced through either the stress-strain relation and/or the strain-displacement gradient relation. Using a formulation we have developed earlier and demonstrated on thin rods and beams [3], we derive an exact nonlinear dispersion relation for the thick rod. Equation (1) provides the governing nonlinear differential equation considering a linear stress-strain relation and a Green-Lagrange nonlinear relationship between strain and displacement gradient:

$$\partial_{tt}\bar{u} - \partial_{xx}(\alpha\bar{u} + \beta\mathcal{N}(\bar{u}) + \gamma\partial_{tt}\bar{u}), \quad (1)$$

where $\gamma = r^2\nu^2$, r is the polar radius of gyration, and ν is the Poisson's ratio. The Green-Lagrange strain measure is introduced by setting $\alpha = \beta = c^2$ and $\mathcal{N}(\bar{u}) = 3\bar{u}^2/2 + \bar{u}^3/2$ where c is the longitudinal speed of sound in the rod. Equation (2) is a statement of the derived nonlinear dispersion relation, and Figure 1 presents it in graphical form with and without accounting for lateral inertia.

$$\omega = c\kappa\sqrt{(2 + 3B\kappa + B^2\kappa^2)/(2 + 2\gamma\kappa^2)}, \quad (2)$$

where ω and κ denote the frequency and wavenumber, respectively, and B represents the wave amplitude.

Figure 1. Nonlinear dispersion relation for elastic waves propagating in a thick rod with a radius of gyration r . A non-zero value of r represents the presence of lateral inertia which gives rise to dispersion even when there is no nonlinearity in the system. The wave amplitude is denoted by B . Solid red curves represent dispersion curves for $B = 0.05$ and dashed black curve represent the linear nondispersive case, i.e., very small value of B .

The derived relation is validated by direct time-domain simulations, examining both instantaneous dispersion (by direct observation) and short-term, pre-breaking dispersion (by Fourier transformations). Figure 2 shows a multi-window overlay of the frequency-wavenumber response obtained by performing a space-time Fourier transform of the

simulation field for a collection of hyperbolic secant signals all with an initial amplitude of $B = 0.025$. Specifically, the contour plot shown is obtained by superimposing the energy spectra of thirty separate simulations for distinct initial wave packets, each following a hyperbolic secant spatial profile and sharing the same amplitude but covering the range of excitation wavenumbers $\kappa_e = 1$ to 30, with increments of 1. What emerges from this exercise is a profile of the fundamental harmonic spanning the various simulations. On the same plot, nonlinear dispersion relation of Eq. (2) is overlaid demonstrating perfect prediction of the simulated nonlinear response [4].

Figure 2. Superposition of harmonics spectra from thirty distinct simulations covering a range of excitation wavenumbers is shown to match perfectly with the general nonlinear dispersion relation of Eq. (2) for the selected value of wave amplitude. Results are for $B = 0.025$ and $r = 0.15$.

The study is then extended to a continuous thin rod with a periodic arrangement of material properties [5]. For this problem we introduce a new method that is based on a standard transfer matrix augmented with a nonlinear enrichment at the constitutive material level. This method yields an approximate band structure that accounts for the finite wave amplitude. Finally, we present an analysis on the condition required for the existence of spatial invariance in the wave profile.

Shocks and solitary waves in series connected discrete Josephson transmission lines

Eugene Kogan

Department of Physics, Bar-Ilan University, Ramat-Gan 52900, Israel

Summary. We analytically study the running waves propagation in the discrete Josephson transmission lines (JTL), constructed from Josephson junctions (JJ) and capacitors. Due to the competition between the intrinsic dispersion and the nonlinearity, in the dissipationless JTL there exist running waves in the form of supersonic kinks and solitons. The velocities and the profiles of the kinks and the solitons are found. We also study the effect of dissipation in the system and find that in the presence of the resistors, shunting the JJ and/or in series with the ground capacitors, the only possible stationary running waves are the shock waves, whose velocities and the profiles are also found.

Introduction

The concept that in a nonlinear wave propagation system the various parts of the wave travel with different velocities, and that wave fronts (or tails) can sharpen into shock waves, is deeply imbedded in the classical theory of fluid dynamics [1]. The methods developed in that field can be profitably used to study signal propagation in nonlinear transmission lines [2, 3, 4, 5, 6, 7, 8, 9, 10, 11]. In the early studies of shock waves in transmission lines, the origin of the nonlinearity was due to nonlinear capacitance in the circuit [12, 13, 14].

Interesting and potentially important examples of nonlinear transmission lines are circuits containing Josephson junctions (JJ) [15] - Josephson transmission lines (JTL) [16, 17, 18, 19]. The unique nonlinear properties of JTL allow to construct soliton propagators, microwave oscillators, mixers, detectors, parametric amplifiers, and analog amplifiers [17, 19, 18]. Transmission lines formed by JJ connected in series were studied beginning from 1990s, though much less than transmission lines formed by JJ connected in parallel [20]. However, the former began to attract quite a lot of attention recently [21, 22, 23, 24, 25, 26, 27, 28], especially in connection with possible JTL traveling wave parametric amplification [29, 30, 31].

The interest in studies of discrete nonlinear electrical transmission lines, in particular of lossy nonlinear transmission lines, has started some time ago [32, 33, 34], but it became even more pronounced recently [35, 36, 37]. These studies should be seen in the general context of waves in strongly nonlinear discrete systems [38, 39, 40, 41, 42, 43, 44].

In our previous publication [45] we considered shock waves in the continuous JTL with resistors, studying the influence of those on the shock profile. Now we want to analyse wave propagation in the discrete JTL, both lossless and lossy. The rest of the paper is constructed as follows. In Section we formulate quasi-continuum approximation for the discrete lossless JTL. In Section we show that the problem of a running wave is reduced to an effective mechanical problem, describing motion of a fictitious particle. In Section the velocity and the profile of the kink, and in Section - of the soliton are found from the solution of the effective mechanical problem. In Section we rigorously justify the quasi-continuum approximation for the kinks and solitons in certain limiting cases. In Section we discuss the effect of dissipation on the waves propagation in the discrete JTL. In Section we briefly mention possible applications of the results obtained in the paper and opportunities for their generalization. We conclude in Section . In the Appendix we propose the integral approximation to the discrete equations.

The quasi-continuum approximation

Consider the model of JTL constructed from identical JJ and capacitors, which is shown on Fig. 1. We take as dynamical variables the phase differences (which we for brevity will call just phases) φ_n across the JJ and the charges q_n which have passed through the JJ. The circuit equations are

$$\frac{\hbar}{2e} \frac{d\varphi_n}{dt} = \frac{1}{C} (q_{n+1} - 2q_n + q_{n-1}) , \quad (1a)$$

$$\frac{dq_n}{dt} = I_c \sin \varphi_n , \quad (1b)$$

where C is the capacitor, and I_c is the critical current of the JJ.

Everywhere in this paper we'll treat $q_n(t)$ ($\varphi_n(t)$) as a function of two continuous variables (z, t) , where $z = n\Lambda$, and will make the simplest assumption,

$$q_{n+1} - 2q_n + q_{n-1} = \Lambda^2 \frac{\partial^2 q}{\partial z^2} + \frac{\Lambda^4}{12} \frac{\partial^4 q}{\partial z^4} . \quad (2)$$

(To keep in (2) only the first term would be an even simpler assumption, but the effects we'll be talking about are absent in this approximation.) We will call (2) the quasi-continuum approximation and will see later that in certain limiting cases it can be rigorously justified.

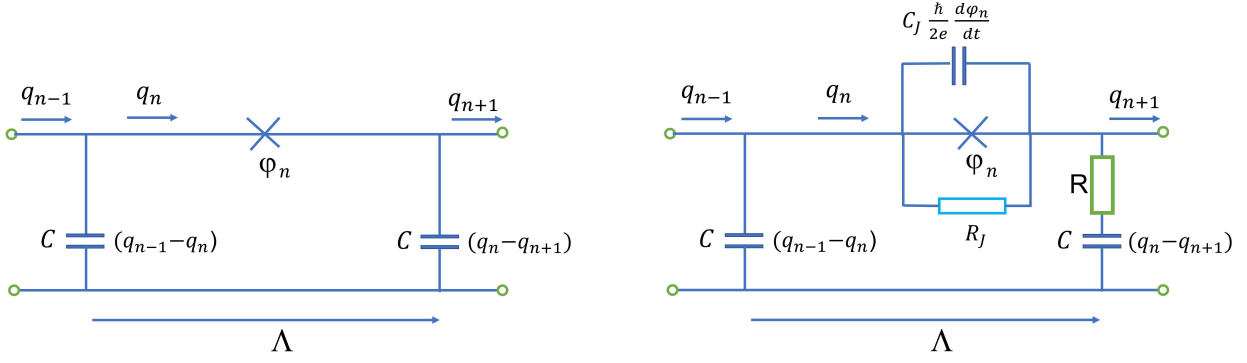

Figure 1: Discrete JTL (left) and discrete JTL with the capacitor and the resistor shunting the JJ and another resistor in series with the ground capacitor (right).

Newtonian equation

The running wave solutions are of the form

$$\varphi(z, t) = \varphi(x), \quad q(z, t) = q(x), \quad (3)$$

where $x = Ut - z$, and U is the running wave velocity. For such solutions, and after the truncation, Eq. (1) becomes the ordinary differential equation

$$\bar{U}^2 \frac{d\varphi}{dx} = \frac{d \sin \varphi}{dx} + \frac{\Lambda^2}{12} \frac{d^3 \sin \varphi}{dx^3}; \quad (4)$$

in this paper, for any velocity V , $\bar{V} \equiv V\sqrt{L_J C}/\Lambda$, and $L_J = \hbar/(2eI_c)$. Integrating with respect to x we obtain

$$\frac{\Lambda^2}{12} \frac{d^2 \sin \varphi}{dx^2} = -\sin \varphi + \bar{U}^2 \varphi + F, \quad (5)$$

where F is the constant of integration. Multiplying Eq. (5) by $d \sin \varphi / dx$ and integrating once again we obtain

$$\frac{\Lambda^2}{24} \left(\frac{d \sin \varphi}{dx} \right)^2 + \Pi(\sin \varphi) = E, \quad (6)$$

where

$$\Pi(\sin \varphi) = \frac{1}{2} \sin^2 \varphi - \bar{U}^2 (\varphi \sin \varphi + \cos \varphi) - F \sin \varphi, \quad (7)$$

and E is another constant of integration. Equation (6) can be integrated in quadratures in the general case.

We can think about x as time and about $\sin \varphi$ as coordinate of the fictitious particle, thus considering (5) as the Newtonian equation. We are interested in the propagation of the waves characterised by the boundary conditions

$$\lim_{x \rightarrow -\infty} \varphi = \varphi_1, \quad \lim_{x \rightarrow +\infty} \varphi = \varphi_2, \quad (8)$$

Thus the problem of finding the profile of the wave is reduced to studying the motion of the particle which starts from an equilibrium position, and ends in an equilibrium position.

Using the expertise we acquired in mechanics classes, we come to the conclusion that the initial position corresponds to maxima of the "potential energy" $\Pi(\sin \varphi)$, and so does the final position. Either these are two different maxima, or the same maximum. In the latter case the particle returns to the initial position after reflection from a potential wall. (See Figs. 2 (above) and 3.) In the first case the solution describes the kink, in the second - the soliton.

One should compare the running wave velocity with the velocity $u(\varphi_1)$ of propagation along the JTL of small amplitude smooth disturbances of φ on a homogeneous background φ_1 [45]

$$\bar{u}^2(\varphi_1) = \cos \varphi_1 \quad (9)$$

(in this paper we consider only the solutions which lie completely in the sector $(-\pi/2, \pi/2)$.) From the fact that there is a maximum of the "potential energy" at the point φ_1 , follows that

$$\left. \frac{d^2 \Pi(\varphi)}{d\varphi^2} \right|_{\varphi=\varphi_1} < 0. \quad (10)$$

Calculating the derivatives we obtain

$$\bar{U}^2 > \cos \varphi_1, \quad (11)$$

that is the running wave is supersonic.

The kinks

In the case of the kink, going in Eq. (5) to the limits $x \rightarrow +\infty$ and $x \rightarrow -\infty$ we obtain

$$\bar{U}^2 \varphi_1 = \sin \varphi_1 - F, \quad (12a)$$

$$\bar{U}^2 \varphi_2 = \sin \varphi_2 - F. \quad (12b)$$

Solving (12) relative to \bar{U}^2 and F we obtain we obtain

$$\bar{U}^2 = \frac{\sin \varphi_1 - \sin \varphi_2}{\varphi_1 - \varphi_2} \equiv \bar{U}_{\text{sh}}^2(\varphi_1, \varphi_2), \quad (13a)$$

$$F = \frac{\varphi_1 \sin \varphi_2 - \varphi_2 \sin \varphi_1}{\varphi_1 - \varphi_2}; \quad (13b)$$

the reason, why we have chosen subscript sh for the velocity in (13a), will become clear in Section .

The result for the kink velocity (13a) is more robust than it looks. In fact, summing up (1a) from far to the left of the kink up to far to the right of the kink we obtain

$$\frac{\hbar}{2e} \frac{d}{dt} \sum_n \varphi_n = \frac{1}{C} [(q_{n+1} - q_n)_1 - (q_{n+1} - q_n)_2]. \quad (14)$$

From the running wave ansatz follows

$$\frac{d}{dt} \sum_n \varphi_n = \frac{U}{\Lambda} (\varphi_1 - \varphi_2). \quad (15)$$

To deal with the r.h.s. of (14) we need to approximate the finite difference only far away from the kink, where everything changes slowly, and the continuum approximation

$$q_{n+1} - q_n = \Lambda \frac{\partial q}{\partial z} \quad (16)$$

is enough. From (16) and the running wave ansatz follows

$$(q_{n+1} - q_n)_i = \frac{\Lambda}{U} \left(\frac{dq_n}{dt} \right)_i = \frac{\Lambda}{U} \sin \varphi_i. \quad (17)$$

Substituting into (14) we recover (13a).

Returning to (13) and taking into account additionally the equality

$$E = \Pi(\sin \varphi_1) = \Pi(\sin \varphi_2), \quad (18)$$

we obtain

$$\varphi_2 = -\varphi_1. \quad (19)$$

Thus the kinks which can propagate in JTL are very special. We also obtain

$$F = 0, \quad (20a)$$

$$\bar{U}^2 = \bar{U}_{\text{sh}}^2(\varphi_1, -\varphi_1) = \frac{\sin \varphi_1}{\varphi_1} \equiv \bar{U}_k^2(\varphi_1). \quad (20b)$$

$$\Pi(\sin \varphi) - E = \frac{1}{2} (\sin \varphi - \sin \varphi_1)^2 - \frac{\sin \varphi_1}{\varphi_1} [\cos \varphi - \cos \varphi_1 - (\varphi_1 - \varphi) \sin \varphi]. \quad (20c)$$

Equation (20c) and the results of integration of Eq. (6) for this "potential energy" are graphically presented on Fig. 2 (above).

Consider specifically the limiting case $|\varphi_1| \ll 1$. Expanding the "potential energy" with respect to φ and φ_1 and keeping only the lowest order terms we obtain the approximation to Eq. (6) in the form

$$\Lambda^2 \left(\frac{d\varphi}{dx} \right)^2 = (\varphi_1^2 - \varphi^2)^2. \quad (21)$$

The solution of Eq. (21) is

$$\varphi(x) = -\varphi_1 \tanh \frac{\varphi_1 x}{\Lambda}. \quad (22)$$

Equations (22) coincides with that obtained by Katayama et al. [36]. So does Eq. (20b), being expanded in series with respect to φ_1 and truncated after the first two terms:

$$\bar{U}_k^2(\varphi_1) = 1 - \frac{\varphi_1^2}{6}. \quad (23)$$

Figure 2: The "potential energy" (20c) (left) and the kink profile calculated with this energy according to Eq. (6) (right). We have chosen $\varphi_1 = .5$.

The solitons

For the soliton $\varphi_2 = \varphi_1$, and two equations of (12) become one equation. As an additional parameter we take the amplitude of the soliton (maximally different from φ_1 value of φ), which we will designate as φ_0 . Adding to (12) the equation

$$E = \Pi(\sin \varphi_0) = \Pi(\sin \varphi_1) \quad (24)$$

and solving the obtained system we obtain

$$\bar{U}_{sol}^2(\varphi_1, \varphi_0) = \frac{(\sin \varphi_1 - \sin \varphi_0)^2}{2[\cos \varphi_0 - \cos \varphi_1 - (\varphi_1 - \varphi_0) \sin \varphi_0]}, \quad (25a)$$

$$\Pi(\sin \varphi) - E = \frac{1}{2} (\sin \varphi_1 - \sin \varphi)^2 - \bar{U}_{sol}^2(\varphi_1, \varphi_0) [\cos \varphi - \cos \varphi_1 - (\varphi_1 - \varphi) \sin \varphi]. \quad (25b)$$

Equation (25b) is graphically presented on Fig. 3 (left).

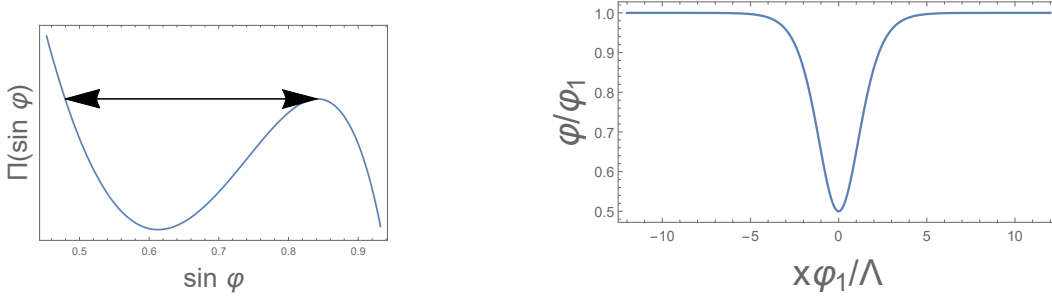

Figure 3: The "potential energy" (25b) (left) and the soliton profile according to Eq. (27) (right)

Considering the limiting case $|\varphi_1|, |\varphi_0| \ll 1$, expanding Eq. (25b) with respect to all the phases and keeping only the lowest order terms we obtain Eq. (6) in the form

$$\Lambda^2 \left(\frac{d\varphi}{dx} \right)^2 = (\varphi - \varphi_1)^2 (\varphi - \varphi_0) (\varphi + 2\varphi_1 + \varphi_0). \quad (26)$$

Equation (26) can be integrated in elementary functions

$$\varphi = \varphi_1 - \frac{(4\bar{\varphi} + \Delta\varphi)\Delta\varphi}{4\bar{\varphi} \cosh^2 \Phi + \Delta\varphi}, \quad (27)$$

where $\Delta\varphi \equiv \varphi_1 - \varphi_0$, $\bar{\varphi} \equiv (\varphi_1 + \varphi_0)/2$, $\Phi \equiv \sqrt{(3\varphi_1 + \varphi_0)\Delta\varphi} x / (2\Lambda)$. Equation (27) is graphically presented on Fig. 3 (right).

In an another limiting case of weak soliton ($\Delta\varphi \cot \varphi_1 \ll 1$), Eq. (6) takes the form

$$\Lambda^2 \left(\frac{d\varphi}{dx} \right)^2 = 4 \tan \varphi_1 \cdot (\varphi - \varphi_1)^2 (\varphi - \varphi_0). \quad (28)$$

The solution of Eq. (28) is

$$\varphi = \varphi_1 - \Delta\varphi \operatorname{sech}^2 \left(\sqrt{\Delta\varphi \tan \varphi_1} x / \Lambda \right). \quad (29)$$

Velocity of the soliton in this approximation is

$$\bar{U}_{sol}^2(\varphi_1, \varphi_0) = \cos \varphi_1 - \frac{\sin \varphi_1}{2} \Delta\varphi. \quad (30)$$

The controlled quasi-continuum approximation

Let us return to Eq. (2). Looking at Eqs. (22) and (27) we realize that in the description of the kinks and solitons with $|\varphi_1| \ll 1$, the expansion parameter is φ_1^2 ; thus the quasi-continuum approximation (2) can be rigorously justified. However, strictly speaking, truncation of the expansion should be performed in accordance with the truncation of the series expansion of the sine function, and Eq. (4) in the consistent approximation should be written as

$$\bar{U}^2 \frac{d\varphi}{dx} = \frac{d\varphi}{dx} - \frac{1}{6} \frac{d\varphi^3}{dx} + \frac{\Lambda^2}{12} \frac{d^3\varphi}{dx^3}. \quad (31)$$

Equation (31) clearly shows the competition between the nonlinearity, described by the second term in the r.h.s. of the equation, and the intrinsic dispersion, caused by the discreteness of the line, described by the third term. Note that (22) is the exact solution of Eq. (31) (with \bar{U} given by (23)).

Looking at Eq. (29) we realize alternatively, that the quasi-continuum approximation can be rigorously justified when it is applied to the description of the solitons with $\tan \varphi_1 \cdot (\varphi_1 - \varphi_0) \ll 1$. The latter quantity is the expansion parameter in the r.h.s. of Eq. (2) in this case. So in the consistent approximation, Eq. (2) should be written as

$$\bar{U}^2 \frac{d\psi}{dx} = \cos \varphi_1 \frac{d\psi}{dx} - \frac{\sin \varphi_1}{2} \frac{d\psi^2}{dx} + \cos \varphi_1 \frac{\Lambda^2}{12} \frac{d^3\psi}{dx^3}, \quad (32)$$

where $\psi = \varphi - \varphi_1$. Note that Eq. (29) is the exact solution of Eq. (32) (with \bar{U} given by (30)).

Here we would like to attract the attention of the reader to the following issue. Common wisdom says that the continuum approximation and the small amplitude approximation are independent - there could be a wave with small amplitude, which allows to expand the sine function, but which varies fast in space (wavelength comparable to lattice spacing), so the continuum limit is not justified. And there could be the opposite situation (large amplitude, long wavelength), in which the sine needs to be retained but the continuum limit is allowed.

However, for the kinks and the solitons these approximations are not independent. Parametrically, the length scale of the waves is of the order of the lattice spacing Λ , so, naively, the continuum (or even the quasi-continuum) limit is not justified. What we have shown above, is that for the waves with small amplitude $|\varphi_1|$ ($\tan \varphi_1 (\varphi_1 - \varphi_0)$), the length scale is $\Lambda/|\varphi_1|$ ($\Lambda/(\tan \varphi_1 (\varphi_1 - \varphi_0))$), thus justifying the quasi-continuum approximation.

The shocks

Consider JTL with the capacitor and resistor shunting the JJ and another resistor in series with the ground capacitor, shown on Fig. 1 (right). As the result, Eq. (1) changes to

$$\frac{\hbar}{2e} \frac{d\varphi_n}{dt} = \left(\frac{1}{C} + R \frac{\partial}{\partial t} \right) (q_{n+1} - 2q_n + q_{n-1}), \quad (33a)$$

$$\frac{dq_n}{dt} = I_c \sin \varphi_n + \frac{\hbar}{2eR_J} \frac{d\varphi_n}{dt} + C_J \frac{\hbar}{2e} \frac{d^2\varphi_n}{dt^2}, \quad (33b)$$

where R is the ohmic resistor in series with the ground capacitor, and C_J and R_J are the capacitor and the ohmic resistor shunting the JJ.

Considering again the running wave solutions we obtain the generalization of Eq. (5)

$$\frac{\Lambda^2}{12} \frac{d^2 \sin \varphi}{dx^2} + \left(\frac{C_J}{C} + \frac{R}{R_J} \right) \bar{U}^2 \Lambda^2 \frac{d^2 \varphi}{dx^2} + \left(\frac{R}{Z_J} \cos \varphi + \frac{Z_J}{R_J} \right) \bar{U} \Lambda \frac{d\varphi}{dx} = -\sin \varphi + \bar{U}^2 \varphi + F, \quad (34)$$

where $Z_J \equiv \sqrt{L_J/C}$ is the characteristic impedance of the JTL, and we discarded the terms with the derivatives higher than of the forth order.

We impose the boundary conditions (8) and try to understand what part of the analysis of Section can be transferred to the present case. The results (12) are determined only by the r.h.s. of Eq. (5), so are (4), following from (12). Since the r.h.s. of Eqs. (5) and (34) are identical, these equations are valid in the present case also. In particular, we obtain

$$\bar{U}^2 = \bar{U}_{sh}^2(\varphi_1, \varphi_2), \quad (35)$$

which explains the subscript we introduced in Eq. (13a).

On the other hand, the resistors, by introducing the effective "friction force", break the "energy" conservation law, which means that the stationary kinks and the solitons we considered previously are no longer possible, however weak the dissipation is. However in the lossy JTL the solutions with $|\varphi_2| \neq |\varphi_1|$ (the shocks) are possible.

The continuum approximation

Looking at Eq. (34) we understand, that when C_J and/or R are large enough, and/or R_J is small enough the first term in the l.h.s. of (34) (the second term in (2)) can be discarded, hence the continuum approximation is valid, and (34) acquires Newtonian form [45]

$$\left(\frac{C_J}{C} + \frac{R}{R_J}\right) \frac{d^2\varphi}{d\tau^2} + \left(\frac{R}{Z_J} \cos \varphi + \frac{Z_J}{R_J}\right) \frac{d\varphi}{d\tau} = -\sin \varphi + \bar{U}^2 \varphi + F, \quad (36)$$

where we have introduced the dimensionless time $\tau = x/(\bar{U}\Lambda)$. In distinction from case of the kinks and the solitons, now the fictitious particle trajectory connects the "potential energy" maximum with the "potential energy" minimum, The shocks in the framework of the continuum approximation were studied in our previous publication [45]. In particular, in the simple case when $C_J = 0$, $R = 0$ (when (36) is similar to equation describing the motion of a fluxon in biased long JJ [42]) and for weak shock ($\Delta\varphi \cdot \cot \varphi_1 \ll 1$), where $\Delta\varphi \equiv (\varphi_1 - \varphi_2)/2$, Eq. (36) takes the form

$$\frac{Z_J}{R_J} \frac{d\psi}{d\tau} = \sin \bar{\varphi} (\psi^2 - \Delta^2 \varphi), \quad (37)$$

where $\bar{\varphi} \equiv (\varphi_1 + \varphi_0)/2$ and $\psi \equiv \varphi - \bar{\varphi}$. The solution of (37) is

$$\psi = -\Delta\varphi \tanh\left(\frac{R_J}{Z_J} \Delta\varphi \sin \bar{\varphi} \cdot \tau\right). \quad (38)$$

The qualitative analysis

For qualitative analysis of Eq. (34) in the general case, it is better to present it as a system of two first order differential equations

$$\left[\frac{\cos \varphi}{12} + \left(\frac{C_J}{C} + \frac{R}{R_J}\right) \bar{U}^2\right] \Lambda \frac{d\chi}{dx} = \frac{\sin \varphi}{12} \chi^2 - \left(\frac{R}{Z_J} \cos \varphi + \frac{Z_J}{R_J}\right) \bar{U} \chi - \sin \varphi + \bar{U}^2 \varphi + F, \quad (39a)$$

$$\Lambda \frac{d\varphi}{dx} = \chi. \quad (39b)$$

Now, one important feature of shocks can be understood immediately. We are talking about the direction of shock propagation. Linearising Eq. (39) in the vicinity of the fixed points $(\chi, \varphi) = (0, \varphi_1)$ and $(\chi, \varphi) = (0, \varphi_2)$ we obtain

$$\Lambda \begin{pmatrix} d\chi/dx \\ d\varphi/dx \end{pmatrix} = \begin{pmatrix} M_i & K_i \\ 1 & 0 \end{pmatrix} \begin{pmatrix} \varphi - \varphi_i \\ \chi \end{pmatrix}, \quad i = 1, 2 \quad (40)$$

where

$$K_i = \frac{\bar{U}^2 - \cos \varphi_i}{\cos \varphi_i / 12 + (C_J/C + R/R_J) \bar{U}^2}, \quad (41)$$

and here we are not interested in M_i . From the fact that φ_1 is the unstable fixed point, and φ_2 is the stable fixed point we obtain

$$\cos \varphi_2 > \bar{U}_{\text{sh}}^2(\varphi_1, \varphi_2) > \cos \varphi_1. \quad (42)$$

The inequalities (42) allow only one direction of shock propagation - from larger $\cos \varphi$ to smaller $\cos \varphi$. Taking into account (9), we can present (42) as

$$\bar{u}^2(\varphi_2) > \bar{U}_{\text{sh}}^2(\varphi_1, \varphi_2) > \bar{u}^2(\varphi_1), \quad (43)$$

thus establishing the connection with the well known in the nonlinear waves theory fact: the shock velocity is lower than the sound velocity in the region behind the shock, but higher than the sound velocity in the region before the shock [1].

Let us write down inequalities (42) explicitly

$$\cos \varphi_2 > \frac{\sin \varphi_1 - \sin \varphi_2}{\varphi_1 - \varphi_2} > \cos \varphi_1. \quad (44)$$

We will combine the case we studied up to now, when φ_1 was the phase before the shock and φ_2 - behind the shock, with the opposite case, which corresponds to indices 1 and 2 in (44) being interchanged. The points in the phase space of the shock boundary conditions (φ_1, φ_2) , for which neither (44), nor its interchanged version are satisfied, has very simple geometric property. The point (φ_1, φ_2) belongs to that region, if the secant of the curve $\sin \varphi$ between the points φ_1 and φ_2 crosses the curve, like it is shown on Fig. 4 (below). Because $\sin \varphi$ is concave downward for $0 < \varphi < \pi/2$, and concave upward for $-\pi/2 < \varphi < 0$, it never happens if φ_1, φ_2 have the same sign. Hence the shock can exist between

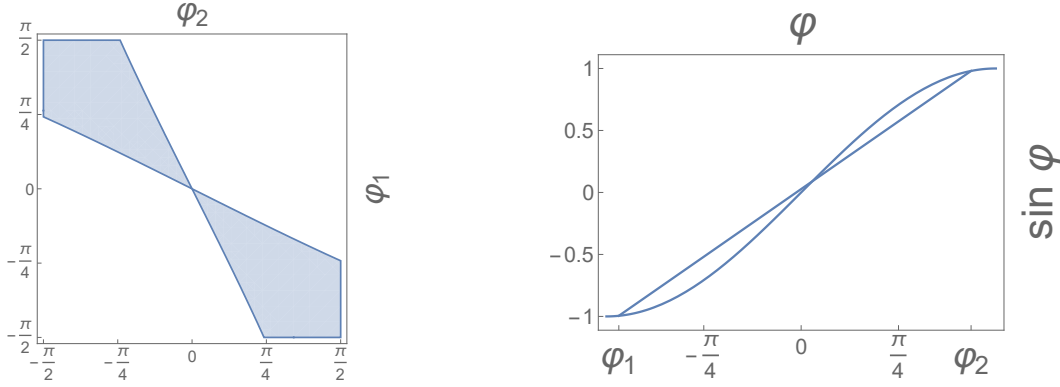

Figure 4: The phase space of the boundary conditions on the ends of the JTL φ_1 and φ_2 . The region, which corresponds to the forbidden shock boundary conditions, is shaded (left). The geometric property of the points belonging to the shaded region (right).

any such points. It is not so for φ_1 and φ_2 having opposite signs. We present the phase space of shock boundary conditions on Fig. 4 (above). The forbidden region is shaded.

When the asymptotic phases on the two sides of the JTL belong to the shaded region, probably there exists some intermediate φ_{in} in between, such that the shocks between φ_1 and φ_{in} , and between φ_2 and φ_{in} are allowed. Say, when the phases are φ_1 and $-\varphi_1$, the system can chose the intermediate value $\varphi_{in} = 0$. In this hypothetical case, the shocks move in the opposite directions, and the central part with the phase $\varphi_{in} = 0$ expands with the velocity $2U_{sh}(\varphi_1, 0)$. However, the case of multiple shocks being simultaneously present in the system demands further studies.

The numerical integration

Equation (34) can be easily integrated numerically. For aesthetical reasons let us simplify it by putting $R = 0$ and $C_J = 0$. (Actually, the physical meaning and the relevance of the resistor in series with the ground capacitor is not obvious. We included it because we were able to do it for free. The capacitance of the JJ is certainly physically relevant. Anyhow, when $C_J/C \ll 1$, it can be ignored.) After the simplification and substitution of the results for \bar{U} and F from (4), the equation becomes

$$\frac{\cos \varphi}{12} \Lambda^2 \frac{d^2 \varphi}{dx^2} = \frac{\sin \varphi}{12} \left(\frac{d\varphi}{dx} \right)^2 - \frac{Z_J}{R_J} \bar{U} \Lambda \frac{d\varphi}{dx} - \frac{(\sin \varphi - \varphi_2)(\varphi_1 - \varphi) - (\sin \varphi_1 - \sin \varphi)(\varphi - \varphi_2)}{\varphi_1 - \varphi_2}.$$

The result of the numerical integration are shown on Fig. 5 (compare with Figs. 2 (below) and ??).

Figure 5: The shock profile according to Eq. (45). We have chosen $\varphi_1 = 1$, $\varphi_2 = .5$, $Z_J/R_J = .005$.

Dissipation is always present in real experiments. And yet we can observe solitary waves (though they are nonstationary, but practically identical to the corresponding stationary solitons at any given moment of time) in case if dissipation is weak enough. Looking at Fig. 5 we realize that weak dissipation does not completely kill solitary waves, it just makes them nonstationary/attenuating. Such solitary waves are observed in numerical calculations and in experiments, as was the case with granular chains [41, 43]. On the other hand, there is a critical rate of dissipation which transforms oscillating stationary shock waves into monotonous [47].

Discussion

Recently, quantum mechanical description of JTL in general and parametric amplification in such lines in particular started to be developed, based on quantisation techniques in terms of discrete mode operators [48], continuous mode

operators [49], a Hamiltonian approach in the Heisenberg and interaction pictures [50], the quantum Langevin method [51], or on partitions a quantum device into compact lumped or quasi-distributed cells [52]. It would be interesting to understand in what way the results of the present paper are changed by quantum mechanics. Particularly interesting looks studying of quantum ripples over a semi-classical shock [53] and fate of quantum shock waves at late times [54]. Closely connected problem of classical and quantum dispersion-free coherent propagation in waveguides and optical fibers was studied recently in Ref. [55].

Finally, we would like to express our hope that the results obtained in the paper are applicable to kinetic inductance based traveling wave parametric amplifiers based on a coplanar waveguide architecture. Onset of shock-waves in such amplifiers is an undesirable phenomenon. Therefore, shock waves in various JTL should be further studied, which was one of motivations of the present work.

Conclusions

We analytically studied the running waves propagation in the discrete Josephson transmission lines (JTL), constructed from Josephson junctions (JJ) and capacitors. Due to the competition between the intrinsic dispersion in the discrete JTL and the nonlinearity, in the dissipationless JTL there exist running waves in the form of supersonic kinks and solitons. The velocities and the profiles of the kinks and the solitons were found. We also studied the effect of dissipation in the system and find that in the presence of the resistors, shunting the JJ and/or in series with the ground capacitors, the only possible stationary running waves are the shock waves, whose velocities and the profiles were also found. We have proposed the integral approximation, which is alternative to the quasi-continuum approximation.

Acknowledgments

The main idea of the present work was born in the discussions with M. Goldstein. We are also grateful to J. Cuevas-Maraver, A. Dikande, M. Inc, P. Kevrikidis, B. A. Malomed, V. Nesterenko, T. H. A. van der Reep, and B. Ya. Shapiro for their comments (some of which were crucial for the completion of the project).

Summary. In this work, we study locally resonant acoustic chains with inerters. Topological properties are investigated on the example of one-dimensional chain with diatomic mass-in-mass unit cells based on the band structure and eigenstate analysis. The existence of interface modes in finite chains is confirmed through natural frequencies and frequency response function analysis. Tuning of interface modes due to introduced inertia amplification effect is observed and investigated in details.

Introduction

The interest for investigation of topologically protected interface states in acoustic and mechanical metamaterials has significantly grown over the past years. Inspired by the phenomena from solid states physics such as the valley and quantum Hall effects, researchers discovered a number of equivalent phenomena in mechanical systems based on acoustic and elastic wave propagation analysis [1]. Since the beginning there was a need to control wave propagation properties in such periodic systems based on approaches that can be divided into two main groups. The first group encompasses active approaches where different external fields such as magnetic or electric field are employed for wave propagation control purposes [2]. The second group encompasses passive or semi-passive strategies that are often based on application of external passive damping devices [3]. Since their discovery, inerters have been widely accepted as efficient vibration attenuation devices [4]. Based on the inertia amplification effect, they are able to reduce the frequency and change properties of periodic structures and other mechanical systems [5]. Here, we apply ideal inverter elements to change the band structure of the locally resonant acoustic chain and at the same time keep the topological properties of the original lattice without inerters.

Figure 1: Illustration of one-dimensional locally resonant acoustic chain with interface.

Mathematical model

Let us consider a one-dimensional locally resonant acoustic chain with an interface, for which the equation for the unit cell in the general case can be expressed as

$$m_a \ddot{u}_{(\zeta)a}^p + (k_\zeta + k_{\zeta+1}) u_{(\zeta)a}^p - k_\zeta u_{(\zeta-1)a}^p - k_{\zeta+1} u_{(\zeta+1)a}^p + k_b (u_{(\zeta)a}^p - u_{(\zeta)b}^p) + j_a (2\ddot{u}_{(\zeta)a}^p - \ddot{u}_{(\zeta-1)a}^p - \ddot{u}_{(\zeta+1)a}^p) + j_b (\ddot{u}_{(\zeta)a}^p - \ddot{u}_{(\zeta)b}^p) = 0, \quad (1)$$

and

$$m_b \ddot{u}_{(\zeta)b}^p + k_b (u_{(\zeta)b}^p - u_{(\zeta)a}^p) + j_b (\ddot{u}_{(\zeta)b}^p - \ddot{u}_{(\zeta)a}^p) = 0, \quad (2)$$

where $\zeta = 2, 3, \dots, \mathcal{N}-1$, $u_{(\varepsilon)a}$ and $u_{(\varepsilon)b}$, $\varepsilon = 1, 2, \dots, \mathcal{N}$ are displacements of outer m_a and inner m_b masses, respectively k_ε , k_b are the springs stiffnesses, while j_a , j_b are the inverter parameters connecting outer and inner masses, respectively. It should be noted that for the adopted notation, the repeating unit cell of the last outer mass is connected to the next unit cell through the spring $k_{\mathcal{N}+1} = k_1$, where equations for the first and the last mass-in-mass sub-systems can be written accordingly. We note that the values of outer and inner masses, inverter parameters and stiffness of inner mass springs are assumed to be the same for different mass-in-mass sub-systems. Size of a unit cell depends on the number of different springs and mass-in-mass sub-units. The system of equations for the one-dimensional finite chain constructed from two sub-lattices connected at interface can be obtained by following the notations given in (Fig.1).

Results and discussion

Topological properties of locally resonant acoustic lattice can be examined through dispersion and eigenstate analysis of a representative unit cell based on the topological invariant called the winding number (here denoted as w) or by using

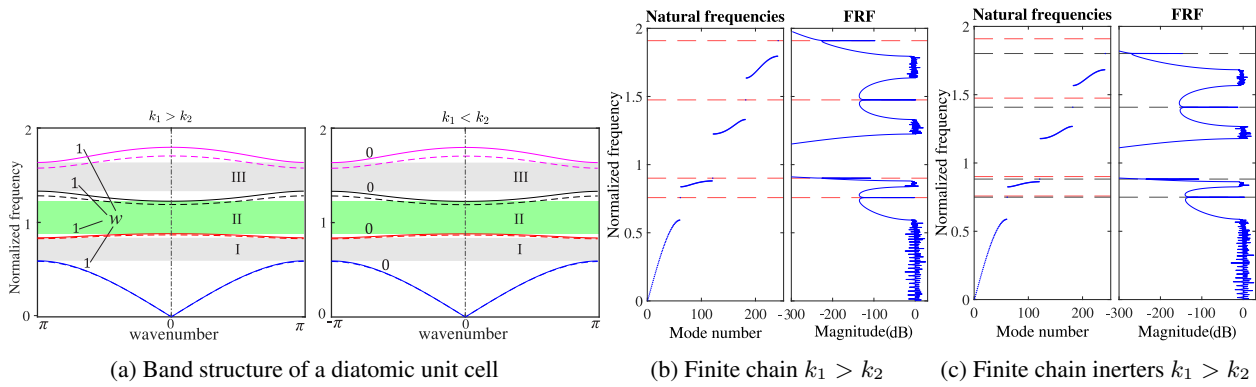

Figure 2: Band structure, natural frequencies and frequency response function of the one-dimensional locally resonant acoustic chain with diatomic mass-in-mass unit cells.

the the bulk-edge correspondence. Dispersion curves for the representative unit cell can be obtained as a solution of the eigenvalue problem based on Eqs.1 and 2 by considering the stiffnesses $k_1 = k(1 + \gamma)$ and $k_2 = k(1 - \gamma)$, with k denoting the mean stiffness and γ is the dimensionless parameter. Natural frequencies and frequency response function of the finite chain can be obtained from the corresponding system of equations by considering the $N = 30$ unit cell on each side of the interface. Fig. 2a shows dispersion curves of a diatomic unit cell with (dashed lines) and without (full lines) inerters when $\gamma = 0.5$, $m_2/m_1 = 0.5$, $m_2/m_1 = 0.5$, $k = 10 \times 10^3$ [N/m], $k_b = 8 \times 10^3$ [N/m] and $j_a = j_b = 0.02$. Four bands and three band gaps can be noticed, where II band gap highlighted in green is of locally resonant origin. By comparing the lattices when $k_1 > k_2$ and $k_1 < k_2$ does not change the band structure but it changes the topology of eigenvectors i.e. the winding number of individual bands change its value from $w = 1$ to $w = 0$. This change physically means that interface modes can appear between the two lattice types. For the finite chain, we can confirm the existence of interface modes within the band gaps by observing its natural frequencies and frequency response function (Figs. 2b and 2c). In the diagram showing the natural frequencies, normalized with respect to the frequency of the local resonator, one can observe four interface modes. The presence of these modes is confirmed in the frequency response function diagram of the outer interface mass. Interface modes that appear inside the band gap II and above the last band are trivial since they will disappear if we change lattice configuration to low stiffness springs ($k_1 < k_2$) at the interface (see Fig. 1). The other two interface modes will remain in both configurations and they are robust and topologically protected. In this case, the effect of inertia amplification on interface states can be seen by comparing the interface mode frequencies of chains with (black dashed lines) and without (red dashed lines) inerters in Fig. 2b. The results reveal the shift of interface mode frequencies to lower values. This effect is especially pronounced at higher frequencies while shifting at lower frequency band gaps is smaller. The similar analysis can be performed for one-dimensional lattices with triatomic mass-in-mass unit cells with and without inerters, where quantized topological invariant winding number can be recovered only in the case when one of the springs connecting the outer masses is different from others.

Conclusions

Recent advances in discovering exotic metamaterials have provided a new insight for understanding the essential processes that create unique wave propagation phenomena and they have initiated a wide range of possible applications in industry and other fields of science. This study is a step forward towards a better understanding of the role of inerters in passive control and tuning of interface modes in locally resonant acoustic chains. Parametric study has demonstrated a significant shifting of interface states when inertia amplification effect is introduced while the topological properties of bands were preserved. This opens new possibilities for application of inerters in more complex lattices or periodic structures capable of generating interface modes.

Summary. Phononic media with contact nonlinearity enable unique wave responses, which brings new capabilities in controlling the propagation of mechanical energy both passively and actively. Our previous studies of phononic media with periodic “rough” contacts have demonstrated different wave responses under *zero* or *strong* precompression, however, wave dynamics of these system under *weak* precompression is yet to be understood. Such understanding can help improve the dynamic response of these materials for wave propagation control. Here, we numerically study nonlinear wave propagation through phononic material with rough contacts such that the contacts are weakly compressed and exhibit a strong nonlinear response at high amplitude excitations. Different from uncompressed and strongly compressed media, this system disintegrates the excited waves into constant amplitude compression pulses followed by an oscillatory tail of decaying amplitudes. These two wave profiles are linked through a transition zone in the form of a rarefaction front. Such wave response is attributed to the mechanics of weakly-compressed contact that transmits tension-compression forces at low amplitudes but only compression forces at high amplitudes. We also demonstrate the tunability of the amplitude, speed, and energy of compression pulses via external precompression. Further, owing to the band gap characteristics of the underlying linear phononic media, these materials display spectral filtering of the harmonic waves. Overall, the capability of these materials to transfer information or energy via compression pulses, amplitude-dependent material response, energy transfer from the excitation frequency to other frequency-wavenumber regimes, and tunability through precompression could pave the way for the development of mechanical devices for advanced wave control.

Introduction

Phononic materials are periodic media that allow spatial and temporal control over mechanical waves. Specifically, Bragg scattering [1] and local resonance [2] phenomenon in these materials have enabled band gaps, which are frequencies of strong wave attenuation. These materials also exhibit unprecedented characteristics such as mode conversion [3], Anomalous polarization [3, 4] and wave directionality [5] by virtue of their unit cell geometry. While these studies are within the linear regime, incorporating nonlinearity further enhances dynamic properties in the form of amplitude-dependent response, irreversibility, and frequency conversion (see the review of [6]). All of these exotic properties make nonlinear phononic materials potential candidates for designing engineering materials and devices with advanced functionalities.

A route to achieve nonlinearity within phononic media is via contact interfaces. Phononic media with contact nonlinearity demonstrate excellent flexibility as they can be tuned from linear to a strongly nonlinear regime, through externally applied precompression. When uncompressed, these phononic materials does not support propagation of linear waves, essentially behaving as “sonic vacuum” [7]. On the other hand, high amplitude wave excitations can enable strongly nonlinear wave signatures. This has been demonstrated in granular crystals, which are ordered ensembles of particles (or grains) exhibiting *Hertzian* contact nonlinearity [8] and in continuum phononic materials with *rough* contacts [9]. While the type of contact nonlinearity and modeling of contacting bodies as discrete or continuum reveals interesting differences, the contact-based phononic media, in general, have shown excellent promise in enriching the wave dynamics.

Importantly, the combined effects of periodicity and nonlinearity in contact-based phononic media support different forms of nonlinear waves. For example, uncompressed (strongly nonlinear) granular crystals support the propagation of solitary waves, which are localized traveling waves with a hump-type wave profile propagating with constant speed and amplitude [7, 10]. Depending upon the mass of the striker, the system can support trains of solitary waves as well [11]. On the other hand, strongly compressed (weakly nonlinear) granular crystals support the propagation of harmonic (of oscillatory nature) waves. As a result, the system exhibits amplitude-dependent band diagrams with propagating and attenuation frequency zones [12]. Within a weakly nonlinear regime, granular crystals support energy transfer between frequencies due to harmonic generation [12]. The system can even support discrete breathers [13], which are spatially localized and temporally periodic modes, at band gap frequencies. Damped granular crystals support shock waves that gradually decay in time [14]. Beyond the elastic regime, asymmetric nonlinearity of elastic-plastic Hertzian contacts support the propagation of “signoton”, which is a shock wave causing an instantaneous change in the deformation direction [15]. Our recent studies on continuum phononic media with rough contacts reported the emergence of stegotons (a different form of solitary waves with stepwise spatial profile) and acoustic resonances, when uncompressed (i.e. strongly nonlinear interfaces) [9], and frequency conversion from wave self-interactions when strongly compressed (i.e. weakly nonlinear interfaces) [16]. These recent studies further suggest the role of contact nonlinearity in phononic media in enabling unique wave responses with no analog in linear theory.

Despite these studies, nonlinear wave propagation through phononic media with *weakly-compressed rough contacts* is yet to be understood. There are open questions such as (1) how the reported nonlinear responses of these phononic media (acoustic resonances, stegotons and harmonic generation) change when non-zero precompression and high amplitude excitation is involved and (2) whether both strongly and weakly nonlinear wave responses co-exist together. Further, weak precompression may in fact support additional nonlinear responses not possible with uncompressed or strongly

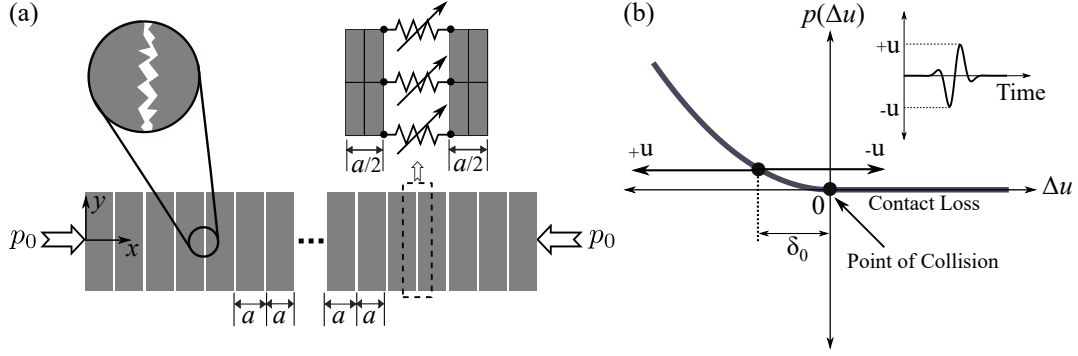

Figure 1: (a) Compressed phononic material with periodic contacts having rough features at the microscale. Schematic of dashed rectangle shows contact modeling as nonlinear springs between elastic layers. (b) Nonlinear contact pressure-gap relationship at rough contacts. The contacts exhibit strongly nonlinear responses as wave displacements, u , are larger than static predeformation, δ_0 . Inset is a temporal schematic of the excited wave pulse.

compressed media.

In this paper, we numerically study nonlinear wave propagation through continuum phononic material with weakly compressed rough contacts. We excite wave pulse with amplitude larger than static predeformation to enable strong non-linearity. We report the evolution of excited waves with propagation distance demonstrating the generation of localized traveling waves and subsequently their separation from low-amplitude harmonic waves. We study the wave response at different center frequency pulses and discuss the frequency-filtering abilities of the phononic material due to its dispersion characteristics. Finally, we also compare the speed and amplitude of generated pulses with the one formed in the uncompressed system, and show the tunability of propagation properties through precompression. The focus of the study is to illustrate nonlinear wave responses achievable in the weakly compressed system, different from uncompressed and strongly compressed configurations.

The paper is organized as follows: First, we describe the phononic material system and corresponding numerical setup. Then, we illustrate the transformation of input waves into waves of different forms due to nonlinearity and dispersion. The tunability of wave propagation is discussed later. Finally, we conclude the paper and provide potential future directions.

Phononic material with weakly compressed rough contacts

The studied phononic material is a one-dimensional system consisting of linear elastic layers of aluminum ($E = 69$ GPa, $\nu = 0.33$, $\rho = 2700$ kg/m³) of identical length, a , with roughness on either side at the microscale [Fig. 1(a)]. These layers are compressed externally under a precompression, p_0 , thus forming a continuum with periodic rough contacts. The layers and contact are assumed to be infinite in the y -direction. The study assumes the wavelength of propagating waves to be three orders of magnitude larger than the rough features of the contacts, allowing contacts to be modeled as nonlinear springs [17]. However, we study wave propagation at wavelengths comparable to layer thickness, thus capturing the effects of continuum layers as well. Due to the inherent feature of contacting bodies, this material does not support any tensile forces during a loss of contact. We assume the roughness on the contacting surface such that the asperities (uneven features on nominal surfaces) are uniformly distributed and that hysteresis associated with their plastic deformation is already removed through multiple loading-unloadings. Under these assumptions, the contacts follow a purely quadratic nonlinear relation between contact pressure, $p(\Delta u)$, and gap, Δu [Fig. 1(b)] [18]. Thus, the contact nonlinearity within our system is as follows:

$$p(\Delta u) = \begin{cases} 0, & \Delta u > 0, \\ \frac{C^2 \Delta u^2}{4}, & \Delta u \leq 0. \end{cases} \quad (1)$$

where $C = 6 \times 10^{10} \sqrt{\text{Pa}}/\text{m}$ [18]. Since $u > \delta_0$ in our analysis (i.e. wave displacement is larger than the predeformation caused by p_0), the dynamics of rough contacts is non-smooth (strongly nonlinear) as contact surfaces can collide and separate [Fig. 1(b)].

To study nonlinear wave propagation through these phononic materials, we construct a finite element (FE) model using COMSOL Multiphysics 5.5a with solid mechanics module based on our previous work [16, 9]. The layers are considered as continua while the contacts are modeled through spring elements with nonlinear characteristics as defined in Eq. 1. The numerical simulation is conducted in two stages: first, the model solves the static problem of external precompression to determine the deformed state of the phononic material and predeformation in the springs. Then, a wave propagation study is conducted through transient analysis. The output of the static analysis is considered as the initial conditions for the wave propagation problem. We model a larger number of unit cells than what we analyze to avoid the effect of end reflections, essentially simulating a phononic material infinite in the positive x -direction. A longitudinal wave pulse [wave schematic in Fig. 1(b)] of amplitude, U , and center frequency, f , with a Gaussian modulation (parameters, $\zeta = 2/f$, $\sigma = 0.5/f$ for Eq. 4 of [9]) was excited from the entire left edge of the FE geometry. Note that the maximum displacement of the

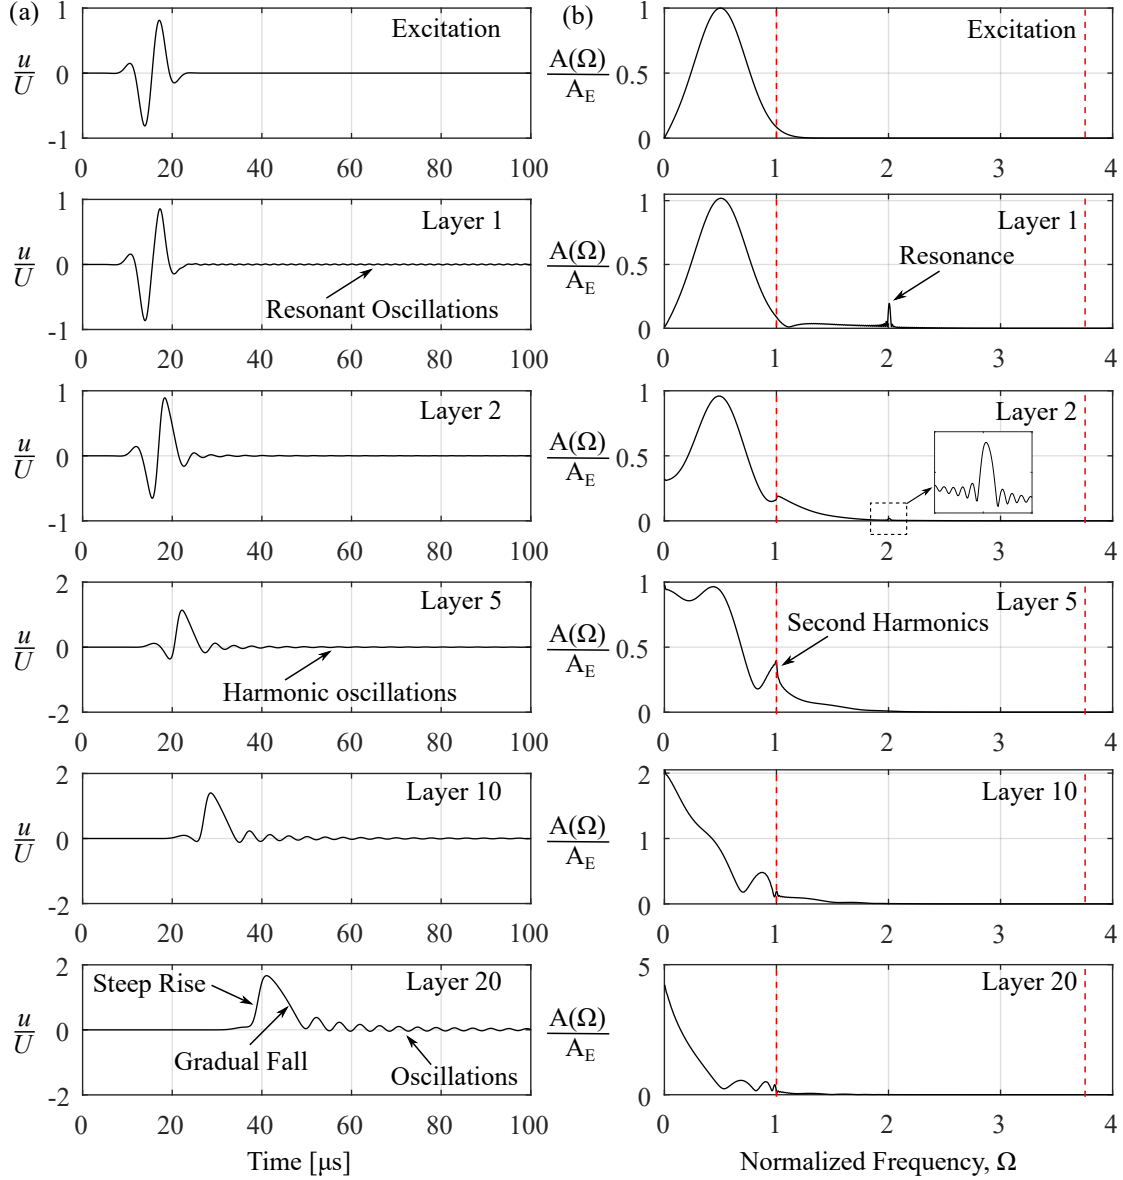

Figure 2: Evolution of input pulse wave with center frequency at $\Omega = 0.5$. (a) Displacement-time profile and (b) frequency content of the propagating wave at multiple locations inside the phononic material. Wave displacements, u , are normalized by pulse excitation amplitude, U , and spectral amplitudes are normalized by spectral excitation amplitude, A_E . input pulse $[\max(|+u|, |-u|)]$ is smaller than excitation amplitude, U , due to Gaussian modulation. This specific wave profile corresponds to the typical response of a broadband ultrasonic contact transducer.

Nonlinear wave disintegration

In this section, we study the evolution of the input wave profile in the phononic material with weak external precompression and high amplitude excitation. Specifically, we discuss an example case of $\delta_0/u \approx 0.83$, which allows us to enable strong nonlinearity as well as study the effect of external compression. To inform the selection of frequencies for analysis, we obtained the linearized dispersion of the phononic material [16]. A non-dimensional frequency, Ω , is introduced such that the frequencies are normalized by the lower-edge frequency of the first band gap of the linearized phononic media for the applied p_0 (i.e. band gap starts at $\Omega = 1$). We study two representative cases of input pulse: (1) with center frequency in pass band ($\Omega = 0.5$) and (2) with center frequency at band edge ($\Omega = 1$). The first pulse, consisting of wide band of frequencies within $0 < \Delta\Omega < 1$, was excited to analyze nonlinear wave propagation in a highly dispersive frequency regime of the linearized phononic media. On the other hand, the second pulse, consisting of wide band of frequencies within $0 < \Delta\Omega < 2.5$, was excited to analyze the effect of band gaps on nonlinear wave propagation.

The wave profile changes as the wave propagates through the phononic material [Fig. 2(a)]. Particularly, the input pulse that originally consists of both compression and extension displacement, gradually transforms to a profile which is predominantly in compression only [compare wave profile in layer 1 vs in layer 20 in Fig. 2(a)]. As the wave propagates, the tensile portion of the pulse vanishes with each layer [note gradual reduction in negative displacements from layer 2

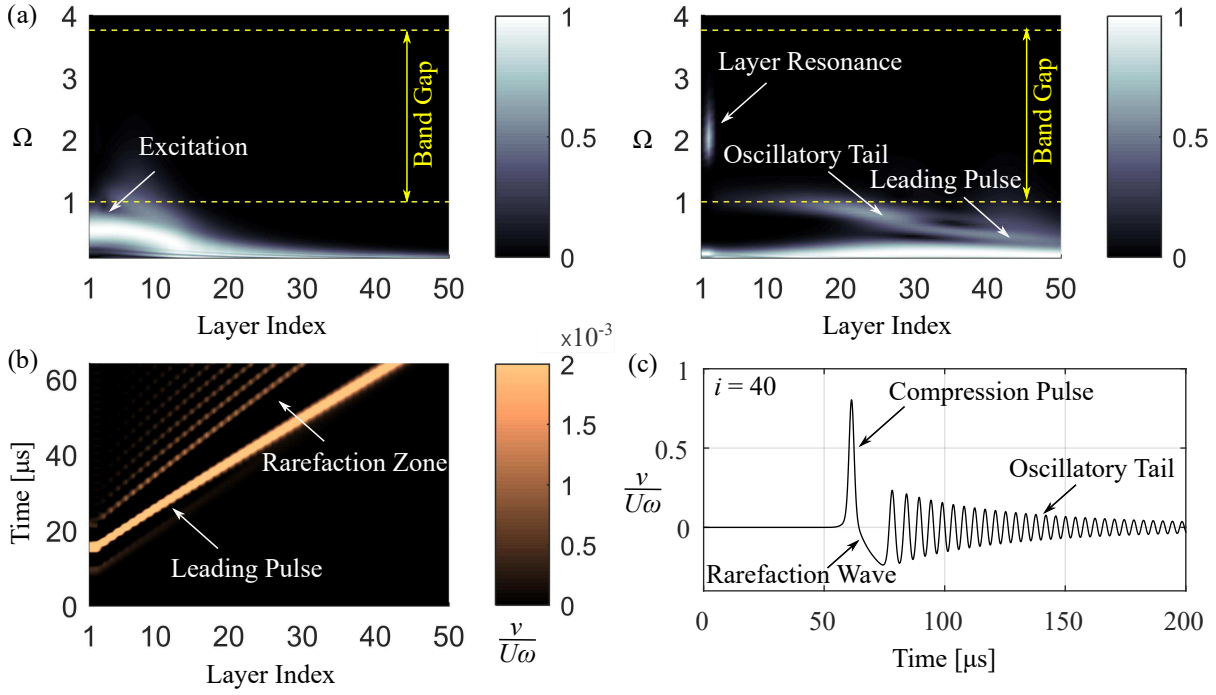

Figure 3: (a) Spatio-spectral and (b) spatio-temporal plots of nonlinear wave propagation for excitation at $\Omega = 0.5$. Spatio-spectral plot (normalized by its maximum value) is shown at an instant when the leading pulse is between the 10th and 20th layer (left) and between the 40th and 50th layer (right). Dashed yellow lines are linearized band gap edges. Layer indices are marked from the excitation boundary. (c) Temporal profile of the disintegrated wave inside the 40th layer. Wave amplitude is denoted in terms of particle velocity, v , normalized by excitation amplitude, U , and angular frequency, ω .

to 20 in Fig. 2(a)]. Moreover, the transmitted compression part is followed by small-amplitude oscillatory waves. The Gaussian input pulse eventually evolves into a waveform that contains three distinct features: (1) a steep increase in profile at the wave front, followed by (2) a gradual amplitude reduction, and (3) an oscillatory tail. This transformation can be understood as follows: The profile of the pulse transmitted across a contact is a combined effect of contact nonlinearity and weak compression. The contacts transmit all compressive forces, whereas only tensile forces that are just enough to counteract the external precompression are transmitted. As a result, once tensile forces exceed external precompression, a contact loss takes place. Therefore, the only harmonic waves supported inside the phononic material are those that contain small amplitude displacements.

This wave evolution also causes frequency conversions, meaning that energy is transferred within the spectral domain. In fact, both strongly and weakly nonlinear effects occur within the phononic material. Specifically, layer 1 resonates at a frequency, $\Omega = 2$ [note resonant oscillations in Fig. 2(a) and a spectral peak in Fig. 2(b) for layer 1]. This resonance corresponds to the mode of the layer under the fixed-fixed boundary condition. Note that layer 1 is held fixed at the left end by virtue of excitation profile whereas the right end is a rough contact. This mode is at a frequency slightly higher compared to the first fixed-free mode of the layer, i.e. acoustic resonance given by $\Omega_r = 1.876$ ($\Omega_r = c_0/4a$, where c_0 is the wave speed of the bulk material). This is because, unlike the uncompressed system, the weakly compressed system experiences a non-zero spring force at the contact end, which pushes the mode of the layer to a higher frequency. Even, layer 2 shows a spectral peak at the same frequency [refer inset in Fig. 2(b) for layer 2]. This is surprising since, in an uncompressed system, the second layer from the excitation boundary resonates at a frequency twice the resonance of layer 1 [9]. This is because layer 2 loses its contact with adjacent layers after wave interaction and the contact loss remains in effect due to the lack of external precompression. As a result, layer 2 resonates under free-free boundary conditions. In the current system, however, both layers (1 and 2) are in contact due to external precompression - a state not possible in an uncompressed system. Due to their persistent contact even after the wave-contact interactions, the resonant energy of layer 1 is partly transmitted to layer 2 causing a spectral peak at $\Omega = 2$. In subsequent layers, second harmonics are generated, i.e. $\Omega = 1$ [refer to the spectral peak at Fig. 2(b) for layer 5] - a feature typical of weakly nonlinear systems. These harmonics, however, lie on the band gap edge and beyond. Thus, they do not propagate and therefore their spectral amplitude vanishes at later layers, for example, layers 10 and 20. Frequencies within the pass band propagate while those close to the band gap edge propagate with extremely slow speed. Eventually, the propagating frequency components consist primarily of low frequencies close to 0 Hz, i.e. a localized traveling wave.

One can think of the transformation of the input wave profile and its frequency content as a “disintegration” of the input pulse. Here, we refer to disintegration as a transformation of input pulse into (1) leading pulses of compressive nature, (2) transitioning zone of rarefaction nature, and (3) tails of decaying amplitudes of harmonic nature. This can be seen in terms of the spatial distribution of frequency content [Fig. 3(a)] and temporal dependence of particle velocity [Figs. 3(b) and (c)]. Despite exciting energy in the system around $\Omega = 0.5$, the energy content within phononic material spreads spatially

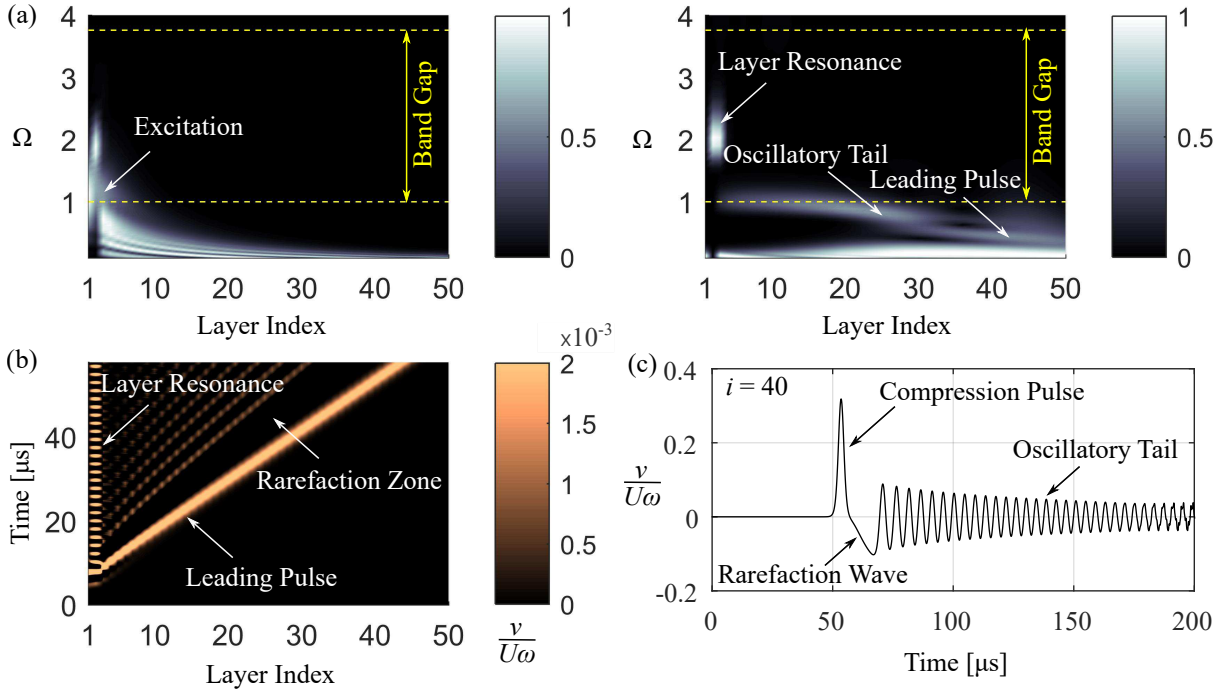

Figure 4: (a) Spatio-spectral and (b) spatio-temporal plots of nonlinear wave propagation for excitation at $\Omega = 1$. Spatio-spectral plot (normalized by its maximum value) is shown at an instant when the leading pulse is between the 1st and 10th layer (left) and between the 40th and 50th layer (right). Dashed yellow lines are linearized band gap edges. Layer indices are marked from the excitation boundary. (c) Temporal profile of the disintegrated wave inside the 40th layer.

due to dispersion while some remains trapped in the form of layer resonances [Fig. 3(a)]. The oscillations correspond to frequencies near the band edge that propagate at a much slower speed. The leading pulse propagates faster than the oscillatory tails and thus overtakes them, causing disintegration, which is clearly visible away from the excitation boundary. The pulse and oscillatory wave profiles are linked through a rarefaction front [Fig. 3(c)]. As a result, the duration over which a rarefaction wave exists in a layer increases with propagation distance [Fig. 3(b)]. This shows that phononic material with contact nonlinearity can support rarefaction waves given non-zero external precompression. Interestingly, similar wave disintegration has been reported in nonlinear metamaterials but with softening-type nonlinearity, i.e. where the exponent of power-law nonlinearity is < 1 [19, 20]. Specifically, these studies reported that an excited compression pulse transforms into a leading rarefaction pulse in tensegrity [19] and origami metamaterials [20].

A similar wave disintegration occurs even in the case when the center frequency of the excited pulse is at the linearized band gap edge, i.e. $\Omega = 1$ (Fig. 4). Importantly, the frequencies $\Omega > 1$ do not propagate through the phononic material, indicating that the band gap exists at these frequencies in this strongly nonlinear regime. In this case, oscillatory tails consist of frequencies within the pass band only. Since the excitation frequency is closer to the resonance frequency of layer 1, there are stronger resonant oscillations of layer 1 compared to when the excitation center frequency is $\Omega = 0.5$ [Compare oscillations at layer index = 1 in Fig. 4(b) and Fig. 3(b)]. The generated compression pulses in these phononic materials are in fact localized traveling waves that propagate with constant speed and amplitude. Due to the hybrid nature of the phononic material, which is continua connected through discrete nonlinearity, these compression pulses are in the form of stegotons showing a step-wise spatial profile [9].

Tunability of compression pulses

In this section, we characterize the dependence of propagation properties of nonlinear waves on external precompression. Specifically, we discuss how external precompression can be used to tune and control the leading compression pulses. The ability to control the speed and amplitude of these pulses can allow greater flexibility and feasibility in utilizing these phononic materials for engineering applications.

By controlling external precompression while keeping the input amplitude the same, we can control the amplitude of the generated compression pulse. The absolute amplitude of these pulses increases with an increase in precompression [Fig. 5(a)]. This is surprising since as precompression increases, the ratio between predeformation and wave amplitude (δ_0/u) increases. As a result, the strength of nonlinearity decreases, which in turn is expected to cause relatively weaker momentum transfer across the contacts. In other words, increasing precompression is expected to generate compression pulses with decreasing amplitudes. However, keeping the same excitation displacement amplitude in the analysis requires larger external work to be done on the system for larger precompressions. This is because the dynamic excitation has to work against the stronger contact forces developed from increased precompressions. Overall, increasing precompression draws more input energy for the same excitation frequency and amplitude, which subsequently generates compression pulses

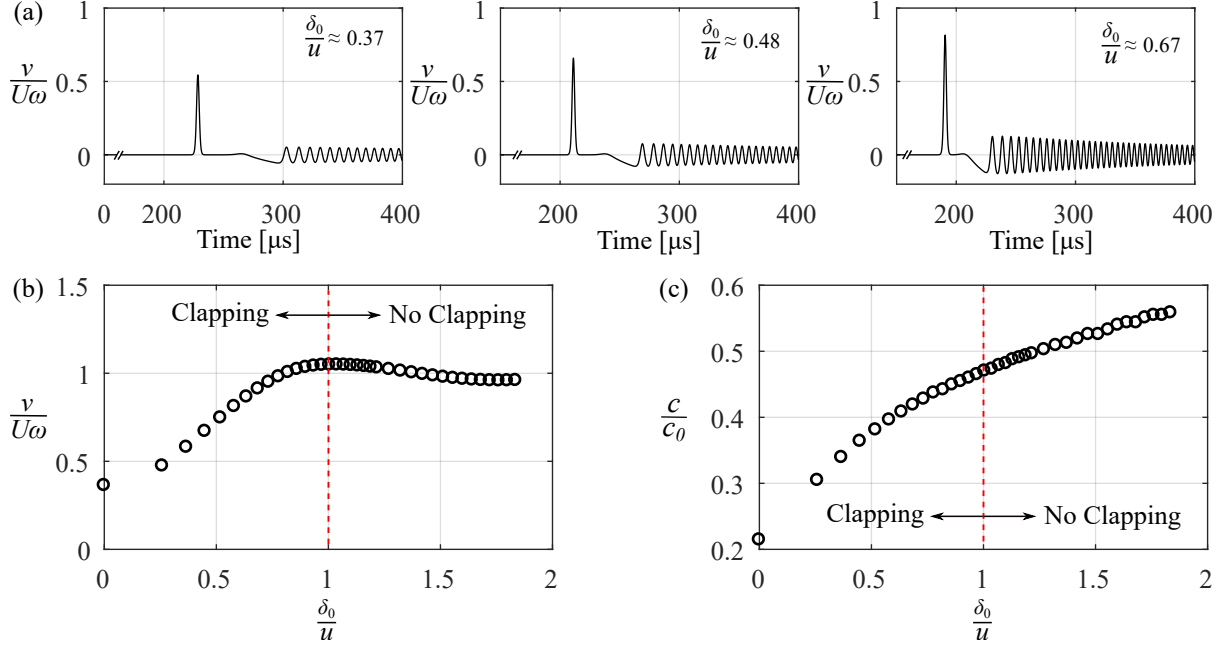

Figure 5: Tunability of nonlinear waves through precompression. (a) Disintegrated wave profile inside the 150th layer for three different precompressions. Dependence of pulse (b) amplitude and (c) wave speed on precompression. Red dashed line is the precompression threshold below which contact clapping occurs.

with larger amplitudes. The rarefaction and harmonic wave amplitudes also increase with compression pulse amplitudes. In other words, stronger precompression supports tensile waves of high amplitudes. Based on these observations, we can conclude that weakly compressed systems exhibit nonlinear wave responses that are a mix of uncompressed and strongly compressed systems, and further allow control over these responses. Specifically, the high amplitude portion of the excitation contributes to strongly nonlinear responses (i.e. compression pulses) as seen in the uncompressed system and low amplitudes contribute to weakly nonlinear responses (i.e. frequency filtering and harmonic waves) as seen in the strongly compressed systems. However, the transition zone from compression pulse to harmonic oscillations is seen only in weakly compressed systems. As waves propagate, compression pulses separate from the rarefaction waves. It is worth noting that the time delay between the compression pulse and rarefaction front can also be controlled through precompression [Fig. 5(a)].

As discussed, the compression pulses are in fact solitary waves as these pulses propagate with constant speed and amplitude. Next, we discuss how the amplitude and speed of these pulses depend on precompression and the threshold value of precompression that can still generate these strongly nonlinear responses. Interestingly, the compression pulses are generated even for the cases where contact clapping is restricted, i.e. when predeformation is larger than the excitation amplitude ($\frac{\delta_0}{u} > 1$) [Fig. 5(b)]. Despite the lack of clapping, this regime is not necessarily weakly nonlinear since excitation amplitudes are not small enough. Note that there exists quadratic nonlinearity between contact force and displacement due to the deformation of rough asperities. This is possibly causing the balance between nonlinearity and dispersion to form a compressive pulse. Further, the amplitude of generated pulses decreases beyond $\frac{\delta_0}{u} > 1$ - a threshold beyond which no clapping is possible. The change in amplitude of compression pulses is less sensitive to $\frac{\delta_0}{u} > 1$ compared to $\frac{\delta_0}{u} < 1$ [note the change in pulse amplitude dependence on precompression before and after the red dashed line in Fig. 5(b)]. The maximum amplitude of the compression pulse is attained at $\frac{\delta_0}{u} = 1$. This is the threshold where clapping is possible and energy added to the system is more than the energy added for $\frac{\delta_0}{u} < 1$.

Contrary, the wave speed of the compression pulses, c , (normalized by bulk wave dilatational wave speed, c_0) increases monotonically with precompression [Fig. 5(c)]. This is consistent with Fig. 5(b) for $\frac{\delta_0}{u} < 1$ since the amplitude and speed of these waves are proportional to each other. We also observe that wave speed changes dramatically for low precompression and depends linearly on precompression at larger values. For $\frac{\delta_0}{u} > 1$, wave speed increases despite a decrease in amplitude. This indicates that the pulses generated beyond $\frac{\delta_0}{u} > 1$ have a different speed-amplitude relationship than solitary waves generated from clapping.

As expected, the fraction of energy carried by the compression pulses as a function of total energy in the system decreases with an increase in precompression (Fig. 6). In fact, the energy carried by the pulses is almost negligible (two orders smaller) for precompressions $u/\delta_0 > 1.5$. This indicates the region of precompression where the phononic material behavior changes into a weakly compressed system.

Conclusions

In this paper, we studied high amplitude nonlinear wave propagation through phononic material with weakly compressed rough contacts. The source of nonlinearity within the material comes from two mechanisms: (1) contact separation and

Figure 6: Dependence of the energy carried by the compression pulses (E_p) as a fraction of total energy (E_T) on precompression.

collision at high amplitudes and (2) quadratic contact force-displacement relationship during the contact. Application of non-zero precompression during analysis revealed that both strongly and weakly nonlinear wave responses can coexist. Specifically, the phononic material supports both solitary waves as well as frequency filtering. Importantly, an additional wave signature in the form of wave disintegration is observed in the weakly compressed system. The input pulse breaks down in three different wave forms: (1) a localized traveling wave in the form of compression pulse, (2) a rarefaction wave front, and (3) an oscillatory tail of decaying amplitude. A compression pulse initially leads the wave propagation before separating from other wave forms due to its greater wave speed. Oscillatory tails are associated with the periodic waves at frequencies in the vicinity of band gap and therefore spread spatially. Finally, the propagation properties of the compression pulse, i.e. their amplitude and speed, can be tuned through external precompression.

Contact-based phononic materials would practically require non-zero precompression to keep all surfaces in contact. The results presented in this paper give an idea of how a slight deviation in system parameters dramatically changes the behavior of the phononic material. The effect not only influences the values of propagation parameters but in fact introduces new types of waves. From an application perspective, these weakly compressed phononic materials can be used for developing mechanical sensors and delay switches. Particularly, the rate at which information is carried from one end to the other can be simply controlled in-situ through external precompression. The combined ability of information transfer and frequency filtering could help develop new imaging devices to isolate spurious scattering while transmitting captured data.

While we elucidated wave responses from weak compression, a detailed study of the effects of excitation frequency, pulse bandwidth, and different contact laws is necessary to fully understand the capability of the system. Higher frequency excitation may cause stronger momentum transfer across contacts generating strong compression pulses while different contact laws may dictate the speed-amplitude relationship. Wave excitation with narrow bandwidth may help study higher harmonic generation while wide band excitation could cause wave mixing within input frequencies. These complex behavior may help advance the understanding of how contacts can be exploited to manipulate the propagation of mechanical energy in an unprecedented way.

Summary. The Partitioned Finite Element Method introduced in [7] provides a structure-preserving discretization for the solution of systems of boundary controlled and observed Partial Differential Equations (PDEs), formulated as distributed-parameter port-Hamiltonian systems (pHs). In particular, the energy balance is preserved at the discrete level. This method, already well-developed for linear systems, is also suitable for nonlinear systems with polynomial nonlinearity, such as the 2D Shallow Water Equations, or the full von-Kármán plate equations.

Port-Hamiltonian systems (pHs)

These are dynamical systems ruled by a Hamiltonian function and conservation laws, together with interaction ports for control u through actuators, and observation or measurements y via sensors; this modelling tool proves very useful for the analysis and control of multiphysics systems: see e.g. [8] for a general presentation. PHs can be finite dimensional (i.e. described by Ordinary Differential Equations (ODEs) with a finite number of d.o.f), or infinite dimensional (i.e. described by Partial Differential Equations PDEs), see [13]. In both cases, all the variables involved in the description do have a clear physical meaning, in contrast with many methods available in the mathematical literature: in particular, anisotropic and heterogeneous media can be accounted for in a very natural way, with no extra complication w.r.t the isotropic and homogeneous cases.

General setting [3]

Let \mathcal{H} the Hamiltonian functional, and (α_1, α_2) the energy variables in the domain Ω . The co-energy variables are defined as the variational derivatives of the Hamiltonian w.r.t. these energy variables: $e_i := \delta_{\alpha_i} \mathcal{H}$. The dynamical system reads:

$$\partial_t \begin{pmatrix} \alpha_1 \\ \alpha_2 \end{pmatrix} = \begin{bmatrix} 0 & -\mathcal{L}^* \\ \mathcal{L} & 0 \end{bmatrix} \begin{pmatrix} e_1 \\ e_2 \end{pmatrix}, \quad \begin{aligned} u_\partial &= \gamma_0 e_1, \\ y_\partial &= \gamma_\perp e_2, \end{aligned} \quad (1)$$

and the differential operator \mathcal{L} and its adjoint \mathcal{L}^* satisfy the following abstract Green's formula:

$$\langle e_2, \mathcal{L} e_1 \rangle_{L^2(\Omega, \mathbb{A}_2)} - \langle \mathcal{L}^* e_2, e_1 \rangle_{L^2(\Omega, \mathbb{A}_1)} = \langle \gamma_0 e_1, \gamma_\perp e_2 \rangle_{\partial\Omega}. \quad (2)$$

The energy variables $\alpha_i \in L^2(\Omega, \mathbb{A}_i)$, where the sets \mathbb{A}_i are either scalar, vectorial or tensorial quantities. The co-energy variables e_i belong to some appropriate Sobolev spaces, namely: $e_1 \in H^\mathcal{L} := \{v_1 \in L^2(\Omega, \mathbb{A}_1) \mid \mathcal{L} v_1 \in L^2(\Omega, \mathbb{A}_2)\}$, and $e_2 \in H^{\mathcal{L}^*} := \{v_2 \in L^2(\Omega, \mathbb{A}_2) \mid \mathcal{L}^* v_2 \in L^2(\Omega, \mathbb{A}_1)\}$. Then, the evolution of the Hamiltonian is given by:

$$\frac{d}{dt} \mathcal{H}(\alpha_1(t), \alpha_2(t)) = \langle u_\partial(t), y_\partial(t) \rangle_{\partial\Omega}, \quad (3)$$

corresponding to a lossless open system, a generalization of a conservative closed system.

Worked-out examples in structural, fluid mechanics and electromagnetism

The practical cases dealt with so far are:

- $\mathcal{L} = \text{div}$ and $\mathcal{L}^* = -\text{grad}$, for vectorial and scalar fields in 2D in [12] and [5],
- $\mathcal{L} = \text{Div}$ and $\mathcal{L}^* = -\text{Grad}$, for tensorial and vectorial fields in 2D in [1] and [4],
- $\mathcal{L} = \text{curl}$ and $\mathcal{L}^* = \text{curl}$, for vectorial fields in 3D in [9],
- $\mathcal{L} = \text{div Div}$ and $\mathcal{L}^* = \text{Grad grad} = \text{Hess}$ for tensorial and scalar fields in 2D in [2].

In each case, the energy and co-energy variables are defined in accordance with continuum mechanics and physics.

The Partitioned Finite Element Method (PFEM)

This method makes use of the finite element method to open systems of conservation laws, i.e. with collocated boundary controls and observations; it was first introduced in [6], fully detailed in [7], and extended to damped systems in [10].

Principle

The Partitioned Finite Element Method boils down to 3 steps: first provide a weak formulation of the coupled first order system, second perform an integration by parts on one of the two lines as to highlight the desired boundary control, and third apply a Galerkin procedure by choosing finite element families for each component including the boundary, giving rise to large sparse matrices.

Let us denote the shape functions φ_i^1 for the first variables, φ_j^2 for the second variable and ψ_k for the boundary variables, set the vectors $\Phi_1 := [\varphi_1^1 \cdots \varphi_{N_1}^1]$, $\Phi_2 := [\varphi_1^2 \cdots \varphi_{N_2}^2]$ and $\Psi := [\psi_1 \cdots \psi_{N_\partial}]$, and define the discrete Hamiltonian as $H(\alpha_1, \alpha_2) := \mathcal{H}(\Phi_1 \alpha_1, \Phi_2 \alpha_2)$, we end up with the following finite-dimensional port-Hamiltonian system:

$$\begin{aligned} \begin{bmatrix} M_1 & 0 \\ 0 & M_2 \end{bmatrix} \frac{d}{dt} \begin{pmatrix} \alpha_1 \\ \alpha_2 \end{pmatrix} &= \begin{bmatrix} 0 & -L^T \\ L & 0 \end{bmatrix} \begin{pmatrix} e_1 \\ e_2 \end{pmatrix} + \begin{bmatrix} 0 \\ B_2 \end{bmatrix} u_\partial, & M_1 e_1 &:= \nabla_{\alpha_1} H, \\ & & M_2 e_2 &:= \nabla_{\alpha_2} H, \\ M_\partial y_\partial &= \begin{bmatrix} 0 & B_2^T \end{bmatrix} \begin{pmatrix} e_1 \\ e_2 \end{pmatrix}. \end{aligned} \quad (4)$$

The mass matrices M_i of dimension $N_i \times N_i$ are symmetric and positive definite. Matrix L is $N_2 \times N_1$, and the boundary control matrix B_2 is $N_2 \times N_\partial$. Then, mimicking (3), the power balance for open systems is preserved at the discrete level:

$$\frac{d}{dt} H(\alpha_1(t), \alpha_2(t)) = u_\partial^T M_\partial y_\partial. \quad (5)$$

Linear examples

When the Hamiltonian is a quadratic and separable functional of the energy variables, the co-energy variables are linear w.r.t. the energy variables, and an explicit closed-form for (4) can be easily obtained, either in terms of α_i , or of e_i . This strategy has been fully developed and worked out on the anisotropic heterogeneous 2D wave equation in [12], on the Reissner-Mindlin thick plate in [1], on the Kirchhoff-Love thin plate in [2] and also on Maxwell's equations in 3D in [9].

Nonlinear examples

Now the same strategy applies to nonlinear models, keeping the energy and co-energy variables apart. In this case though, the link between the co-energy variable e_i and the energy variables α_i is no more linear and requires some special care. However, in the case of a polynomial nonlinearity, explicit relations can be provided at the discrete level, and more important, these relations can be computed off-line (i.e. an extra application of the FEM does not prove necessary at each time step). This has been worked out on the irrotational 2D Shallow Water in [5] with a nonlinear and non-separable Hamiltonian, on the heat equation with internal energy as Hamiltonian in [11]. The full von-Kármán plate model in [4] is another candidate.

Summary: The most common type of human snoring is characterized by vibrations of the soft-palate, induced by passing air during respiration. Despite being a widespread disorder, its occurrence is poorly understood and, consequently, clinical treatment is often ineffective. This physical system can be characterized, in its essence, by a cantilevered beam subjected to axial flow in a confined passage. These type of fluid-structure interaction systems have been a subject of research for many years, as its fundamental behavior is found in many other practical applications. Most studies are concerned solely with the conditions for linear stability and do not explore the ensuing nonlinear behavior of the system. This is particularly delicate as fluttering beams in confined flows are known to often result in dynamics with intermittent impacts between the beam and the side-walls. Here we present a nonlinear analytical resolution to a simplified 1-D model, based on a modal beam and bulk-flow equations. The model accounts for dissipation through distributed (frictional) and localized head-loss terms. The latter are imposed at the boundary conditions and aims to describe the complex effects occurring outside the domain (turbulence, vortex shedding, etc.). The present analytical resolution leads to a compact system for linear stability analysis, but also to a nonlinear formulation of the fluid-structure interaction. The inclusion of a regularized contact model allows for the computation of the full nonlinear dynamics, including intermittent impacts. Linear stability results are compared to previously published results using 2-D CFD models, and the relative merits of the model are discussed. A series of limit cycles with intermittent impacts between the beam and side-walls are presented to illustrate the nature of the post-instability oscillations. To the authors knowledge, the proposed formulation presents, for the first time, a framework for the comprehensive understanding of the nonlinear dynamics associated with flexible beams in confined axial flow.

Introduction

Recent studies suggest that no less than 30% of the adult population snores habitually. However, due its inherent complexity, the underlying physics and their relation to the type and degree of the disorder remain poorly understood and, consequently, treatment responses are often ineffective [1] [2]. The most common form of snoring is that of palatal snoring, where the vibration of the soft-palate/uvula (see Figure 1-(a)) is induced by the passage of air during respiration. This system can be categorized as a flow induced vibration problem. More specifically, it can be modelled as a flexible cantilever beam in confined axial flow [3] [4].

The static and dynamic instabilities associated with flexible beams/plates subject to axial flow occur also in different contexts from enhanced heat transfer [5], energy harvesting devices [6] or wind musical instruments [7]. The subject has been studied extensively [8], particularly for the case of unconfined flows. In these systems, the typical instability is of the flutter type. In the work of Shoele & Mittal [9], for example, we find some elucidating results regarding the influence of relevant non-dimensional parameters like the fluid-beam mass ratio, the reduced velocity (inverse of Strouhal number) or the confinement ratio (channel height to beam length ratio). Their results show that, at low beam-fluid mass ratios, the instability is of the single-mode flutter type, involving the coupling of the first two in-vacuo beam modes. As mass ratios increase, the initial single-mode flutter ceases to be the principal instability, and successive “mode-transitions” occur, whereby multiple higher-order fluttering modes prevail. This type of instability is commonly referred to as coupled-mode flutter.

More recently, the advances in computational efficiency have enabled the possibility to simulate these fluid-structure interaction (FSI) systems numerically by solving the Navier-Stokes equations in 2D and 3D domains [10]. These FSI models allow a more accurate representation of the physics. However, they also require considerable computational time, which becomes a handicap when analyzing problems whose behavior depends on a wide variety of parameters. For a more thorough parameter mapping, 1D models, based on simplified equations of motion, are not only computationally more efficient but also more tractable, and may provide valuable insights into the core dynamics of the problem.

In the context of simplified approaches, we note the work of Nagakura & Kaneko [11] that have used leakage flow theory to model the linear stability of a cantilever beam in a confined passage. Based on the work by Inada & Hayama [12], they formulate a 1D problem where flow pressure and velocity are taken as cross-sectionally averaged. The confinement is restricted to symmetric channels of constant cross-section, viscous effects are accounted for by a distributed friction term and the energy losses at the trailing edge are encapsulated by a localized head-loss term, imposed at the boundary condition.

By and large, the analytical models developed so far deal solely with the conditions for instability, using linearized equations of motions to study the effect of various parameters on the stability boundaries. Although undeniably a crucial information about the system dynamics, this gives us little insight about the ensuing nonlinear behavior. The

analysis of the nonlinear dynamics might be of valuable interest to various applications, giving information about human snoring, but also working regimes in wind musical instruments or in energy harvesting devices, for example.

In the context of unbounded flows, a number of theoretical and experimental studies can be found, illustrating the array of possible limit cycles arising in this type of systems [13] [14]. However, for instabilities in a confined passage, nonlinear modelling results and experimental observations have demonstrated the regular occurrence of limit cycles with intermittent impacts between the beam and the side walls [15] [16].

In this paper, we deal with a simplified 1D model in the spirit of Nagakura & Kaneko's work [11]. Contrary to their work, we admit channel profiles of any shape. More importantly however, we present an analytical resolution, based on formal solutions of the flow pressure and velocity fields, that leads not only to a compact system for linear stability analysis but also to a fully nonlinear flow formulation. This formulation can be used to explore post-instability regimes at very low computational costs. Additionally, to overcome the previously mentioned limitations, we add the possibility of contact between the flexible beam and the channel walls, enabling the calculation of limit-cycle oscillations (LCO) with, potentially, intermittent impacts.

Model Description

The model presented here deals with the fluid-structure interaction of a flexible beam confined by flow on each upper and lower sides, as illustrated in Figure 1. The formulation presented in the following is generic, in that it can, in principle, be applied to beams with arbitrary boundary conditions. However, in this paper we will deal solely with the particular case of a cantilever beam.

Figure 1 (a) Cross-sectional view of a human upper airway; (b) Schematic representation of the model.

Structural dynamics

The dynamics of a flexible linear beam are defined in terms of N modes, decoupled from the fluid. The modal parameters: modal masses m_n , frequencies ω_n , damping ratios ζ_n and mode shapes $\phi_n(x)$ can be calculated analytically for a beam with uniform cross-section or numerically for beams of any geometry, through either the Euler-Bernoulli or Timoshenko 1D linear beam equations. The beam displacement is developed as

$$y(x,t) = \sum_{n=1}^N \phi_n(x) q_n(t) \quad (1)$$

and the beam motion is finally described by the following set of N modal equations

$$m_n \ddot{q}_n(t) + 2m_n \omega_n \zeta_n \dot{q}_n(t) + m_n \omega_n^2 q_n(t) = b \int_0^L (p_2(x,t) - p_1(x,t)) \phi_n(x) dx, \quad n = 1, 2 \dots N \quad (2)$$

where b is the beam width and the modal forces are given by the projection of the pressure fields $p_1(x,t)$ and $p_2(x,t)$ (associated with the flow in the upper and lower channels, respectively), unto the beam modes.

Fluid dynamics

To derive the incompressible bulk-flow equations, we first consider small-to-moderate fluctuating channel heights $h_c(x,t)$, defined in terms of the beam motion

$$h_1(x,t) = H_1(x) - y(x,t) \quad ; \quad h_2(x,t) = H_2(x) + y(x,t) \quad (3)$$

where $H_1(x)$ and $H_2(x)$ are the distances from each wall to the position of the beam at rest and the index $c = 1, 2$ corresponds to the upper and lower channels, respectively. Following the derivation by Antunes & Piteau [17], the flow variables are taken as cross-sectionally averaged, $p_c(x,t)$ and $u_c(x,t)$. The continuity and momentum equations of the fluid are given, respectively, for each channel $c = 1, 2$, by

$$\frac{\partial h_c}{\partial t} + \frac{\partial}{\partial x}(h_c u_c) = 0 \quad ; \quad \rho \left[\frac{\partial}{\partial t}(h_c u_c) + \frac{\partial}{\partial x}(h_c u_c^2) \right] + h_c \frac{\partial p_c}{\partial x} + \tau_c^w + \tau_c^b = 0 \quad (4)$$

where ρ is the fluid's density, τ_c^w and τ_c^b are the shear stresses at the two interfaces (fluid-wall and fluid-beam) in each channel. Following the bulk-flow approach, the tangential stresses will be formulated as a head-loss model, given by

$$\tau_c^{w,b} = \frac{1}{2} \rho u_c |u_c| f_c^{w,b} \quad (5)$$

where f_c^w and f_c^b are the Fanning friction coefficients for each interface. Additionally, we assume both interfaces have equivalent frictional properties, hence $f_c^w = f_c^b = f$.

Aside from the distributed losses, we include as well singular dissipative effects at the boundaries. These are enforced at the boundary conditions and aim to encapsulate, in a simplified manner, the energy losses (turbulence, vortex shedding, etc.) occurring outside the domain. The second order system (4) is then submitted to the following flow boundary conditions at $x = 0$ and $x = L$:

$$p_c(0, t) = P_0(t) - \rho \frac{1}{2} (u_c^2(0, t) - u_c(0, t) |u_c(0, t)| K_0) \quad ; \quad p_c(L, t) = P_L(t) - \rho \frac{1}{2} (u_c^2(L, t) + u_c(L, t) |u_c(L, t)| K_L) \quad (6)$$

where K_0 and K_L are the singular head-loss coefficients at the boundaries; $P_0(t)$ and $P_L(t)$ are the imposed pressures. For the particular case of a cantilevered beam, the head-loss coefficient K_0 is bound to have a minimal effect on the dynamics, as it acts on the clamped end of the beam. For steady inflow (in the positive x -direction), it acts simply as a control-valve, limiting the flow energy entering the domain. On the other hand, the turbulent effects expected at the trailing-edge suggest that K_L will probably have a significant effect on the coupling dynamics. Following reference models [11] [18], we will take $K_L = 1$ and $K_0 = 0$, which as shown to provide a reasonable representation in these types of FSI systems.

Nonlinear analytical approach using formal solutions

Integrating the continuity equation (4) with respect to x leads us to a formal solution for the velocity fields in each channel c :

$$u_c(x, t) = \frac{Q_c(t) - \int \dot{h}_c(x, t) dx}{h_c(x, t)} \quad (7)$$

where the “constants” of integration (actually, time domain functions) $Q_c(t)$ represent the global unsteady flow rates (per unit width) in each channel. After replacement of (7) in the momentum equation (4) and again integrating with respect to x , we obtain the formal solution for the pressure field in each channel,

$$p_c(x, t) = \rho \int \left[\frac{\int \ddot{h}_c dx}{h_c} - 2 \frac{\dot{h}_c \int \dot{h}_c dx}{h_c^2} + \frac{h_c' \left(\int \dot{h}_c dx \right)^2}{h_c^3} - \frac{1}{h_c} \dot{Q}_c(t) + 2 \left(\frac{\dot{h}_c}{h_c^2} - \frac{h_c' \int \dot{h}_c dx}{h_c^3} \right) Q_c(t) \right] dx + S_c(t) \quad (8)$$

$$+ \frac{h_c'}{h_c^3} Q_c(t)^2 + f \left(\frac{\left(\int \dot{h}_c dx - Q_c(t) \right) \left| \int \dot{h}_c dx - Q_c(t) \right|}{h_c^3} \right)$$

where spatial and temporal derivatives are denoted by an upper dash and dot, respectively. The new “constants” of integration $S_c(t)$ describe the pressure at the entrance of the channels $S_c(t) = p_c(0, t)$. From here on, to simplify notation, we define the following auxiliary variables describing the terms in the formal solutions

$$A_c(x, t) = -\frac{\int \dot{h}_c dx}{h_c} \quad ; \quad B_c(x, t) = \frac{1}{h_c} \quad ; \quad C_c(x, t) = \frac{\int \ddot{h}_c dx}{h_c} - 2 \frac{\dot{h}_c \int \dot{h}_c dx}{h_c^2} + \frac{\left(\int \dot{h}_c dx \right)^2}{h_c^3} \left(h_c' + f \operatorname{sign} \left(\int \dot{h}_c dx - Q_c(t) \right) \right) ;$$

$$D_c(x, t) = 2 \left(\frac{\dot{h}_c}{h_c^2} - \frac{\int \dot{h}_c dx}{h_c^3} \left(h_c' + f \operatorname{sign} \left(\int \dot{h}_c dx - Q_c(t) \right) \right) \right) ; \quad E_c(x, t) = \frac{1}{h_c^3} \left(h_c' + f \operatorname{sign} \left(\int \dot{h}_c dx - Q_c(t) \right) \right) ; \quad (9)$$

To enforce the boundary conditions, we replace the formal solutions (7)-(8) into expressions (6). After some algebra, we obtain two expressions for the constant of integration $S_c(t)$, in terms of $Q_c(t)$, $\dot{Q}_c(t)$ and the beam motion $A_c(x,t) - E_c(x,t)$. At the leading edge ($x = 0$) we have simply

$$S_c(t) = P_0 - \rho \frac{1}{2} (1 + \text{sign}(Q_c(t)) K_0) (B_c(0,t) Q_c(t))^2 \quad (10)$$

while at the trailing edge ($x = L$) we get

$$S_c(t) = P_L(t) - \rho \left(\begin{aligned} & - \left(\int B_c(L,t) dx \right) \dot{Q}_c(t) \\ & + \left(\int D_c(L,t) dx + A_c(L,t) B_c(L,t) [1 - \text{sign}(A_c(L,t) + B_c(L,t) Q_c(t)) K_L] \right) Q_c(t) \\ & + \left(\int E_c(L,t) dx + \frac{B_c^2(L,t)}{2} [1 - \text{sign}(A_c(L,t) + B_c(L,t) Q_c(t)) K_L] \right) Q_c^2(t) \\ & + \frac{A_c^2(L,t)}{2} [1 - \text{sign}(A_c(L,t) + B_c(L,t) Q_c(t)) K_L] + \int C_c(L,t) dx \end{aligned} \right) \quad (11)$$

Then, combining (11) and (10), we are able to remove the constant of integration $S_c(t)$ and obtain two (one for each channel) first-order nonlinear ODEs in terms of the unsteady flow rates $Q_c(t)$,

$$\begin{aligned} & - \left(\int B_c(L,t) dx \right) \dot{Q}_c(t) \\ & + \left(\int D_c(L,t) dx + A_c(L,t) B_c(L,t) [1 - \text{sign}(A_c(L,t) + B_c(L,t) Q_c(t)) K_L] \right) Q_c(t) \\ & + \left(\int E_c(L,t) dx - \frac{B_c^2(0,t)}{2} (1 + \text{sign}(Q_c(t)) K_0) \right. \\ & \quad \left. + \frac{B_c^2(L,t)}{2} [1 - \text{sign}(A_c(L,t) + B_c(L,t) Q_c(t)) K_L] \right) Q_c^2(t) \\ & + \frac{A_c^2(L,t)}{2} [1 - \text{sign}(A_c(L,t) + B_c(L,t) Q_c(t)) K_L] + \int C_c(L,t) dx + \frac{P_0(t) - P_L(t)}{\rho} = 0 \end{aligned} \quad (12)$$

Replacement of the formal solution for the pressure fields (8) into the beam modal equations (2), leads to a set of $2N$ nonlinear ODEs, in terms of the modal displacements $q_n(t)$, modal velocities $r_n(t) = \dot{q}_n(t)$ and the two unsteady flow rates $Q_1(t)$ and $Q_2(t)$. Together with the two flow rate ODEs (12), they form a closed set of first-order nonlinear differential equations describing the 1D fluid-structure model, in the form

$$[\mathbf{A}]\{\dot{\mathbf{x}}\} + [\mathbf{B}]\{\mathbf{x}\} = \{\mathbf{C}\} \quad (13)$$

where $\mathbf{x} = \{r_1(t), \dots, r_N(t), q_1(t), \dots, q_N(t), Q_1(t), Q_2(t)\}$, $[\mathbf{A}]$ and $[\mathbf{B}]$ are (dense) matrices of size $2N+2$, and $\{\mathbf{C}\}$ is a vector containing constant flow terms. Effectively, we are able to discretize our continuous 1D problem into a set of ODEs. However, there are nonlinear terms associated with beam motion (e.g. $\int A_c dx$) which contain modal summations in the denominator. As these terms cannot be simplified analytically, we do not reach “true” time-space separation, in the sense that the formulation does not contain time-independent spatial operators. During time-domain integrations, these terms need to be calculated at each time-step. Despite this fact, the formulation allows for temporal-integrations of the nonlinear system at very modest computational costs.

Results: linear stability and numerical validation

In this paper, for compactness, we have not shown the linearization of the above-mentioned system. It will suffice to say that linearization of the expressions above leads to a closed set of $2N+2$ ODEs (with constant spatial operators), which can then be formulated as an eigenvalue problem, from which we can infer the linear stability of the system under a set of given parameters.

In this section, with the aim of assessing the viability of the 1D simplified modelling approach and validating our results, we compare the linear stability results from our model to reference results. Even though the present modelling approach allows for channels of arbitrary shapes $H_c(x)$, we will consider only symmetric channels of constant section, i.e. $H_1(x) = H_2(x) = H$, on which most literature is based on. For the same reason, we will analyze configurations with flow in the positive direction only.

Following reference studies [9], we will present results in terms of the following non-dimensional parameters

$$U^* = U_0 L \sqrt{\frac{\rho_s e}{EI}} \quad ; \quad M^* = \frac{\rho_f L}{\rho_s e} \quad ; \quad H^* = \frac{H_0}{L} \quad (14)$$

where U^* is a reduced velocity (essentially the inverse of a Strouhal number), M^* is the fluid-beam mass ratio, and H^* is the confinement ratio. In our formulation, $H_0 = H_1(0) + H_2(0)$ and the fluid velocity U_0 is given by the steady component of the inlet velocity, i.e. $U_0 = (\bar{Q}_1 + \bar{Q}_2)/H_0$. Additionally, the Reynolds number Re is accounted implicitly by the Fanning friction coefficient f . To this end, we note the commonly used relation between Reynolds number Re and the friction coefficient f , established based on empirical data of steady flow [19], given by

$$\begin{cases} f = 12 Re^{-1} & \text{for } Re < Re_0 \quad (\text{laminar}) \\ f = 0.055 Re^{-0.25} & \text{for } Re > Re_0 \quad (\text{turbulent}) \end{cases} \quad (15)$$

where Re_0 is the Reynolds number separating laminar from turbulent flow ranges, taken here as $Re_0 = 2500$.

Comparison to results from a 2-D viscous model

Here we compare linear stability results from our simplified model to those obtained by a more realistic 2D viscous model developed recently by Cisoni et al. [20]. In their paper [20], a 2D model is used to solve the nonlinear Navier-Stokes equations in the time-domain, including viscous effects. Several parametric sweeps were carried out to obtain stability curves in the nondimensional $(U^* - M^*)$ plane, for several (H^*, Re) pairings. Figure 2 shows a typical stability map in the $(U^* - M^*)$ plane, calculated with the present model and with the 2-D viscous model. Here, an undamped beam was considered, $\zeta_n = 0$, the confinement ratio was set at $H^* = 1/10$ and the Reynolds number at $Re = 100$. Note that, in our formulation, the Reynolds number is set implicitly following relation (15), which leads to a friction coefficient $f \approx 0.14$. On the left are the stability boundaries in the $(U^* - M^*)$ plane and on the right the frequencies of the corresponding neutrally stable modes.

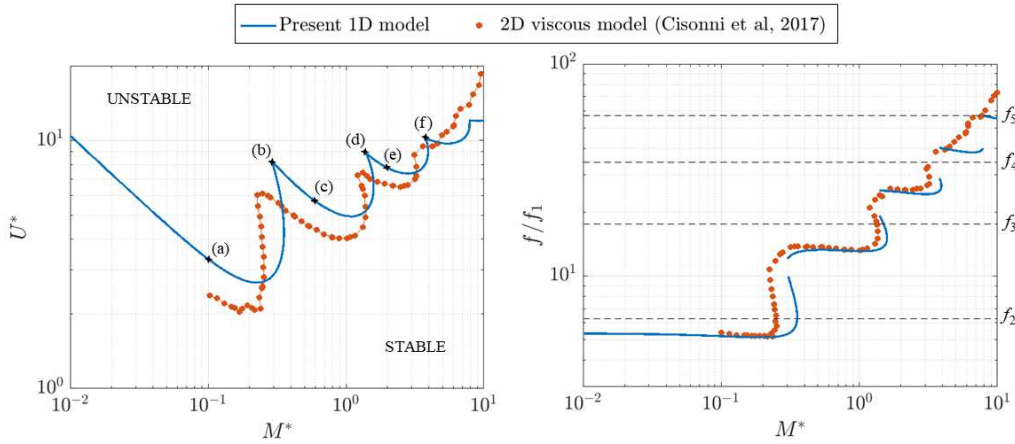

Figure 2 – Stability boundary in the $(U^* - M^*)$ plane (left) and the corresponding frequencies (right) for a system with confinement $H^* = 1/10$ and Reynolds number $Re = 100$. The 2-D model results were retrieved from those presented in [20].

The cascading stability boundary shown in Figure 2 is a typical result of cantilevered structures subject to axial flow, reported in many previous studies, including models which assume inviscid flow (see review in [9]). We note that results from the present model agree qualitatively well with those from the 2D model. Despite some minor quantitative differences, the overall stability behavior of the system is well encapsulated. Namely, the sharp transitions in the stability curves, associated with the well-known mode-switching behavior and illustrated clearly by the abrupt changes in the instability frequency, are well represented. This behavior occurs at increasing mass-ratios, whereby the first unstable mode in the system transitions from lower to higher order, i.e. the main unstable (coupled) mode is dominated by *in-vacuo* beam modes of progressively higher order. To clarify, Figure 3 illustrates the complex mode shapes associated with the various points (a)-(f) indicated in Figure 2. The minor quantitative differences (slight vertical and horizontal shifts in the $M^* - U^*$ plane), are likely explained by the inherent differences in the 1D and 2D modelling approaches, namely, the explicit vs. implicit account of viscous effects or the parabolic vs. constant velocity profiles stemming from explicit/implicit account of boundary layer effects.

Figure 3 – Complex mode-shapes of the neutrally-stable modes associated with the boundary points (a)-(f) indicated in Figure 2. The real and imaginary parts of the mode shapes are indicated in blue and red, respectively. The grey lines illustrate the actual beam motion associated with the corresponding complex mode shapes.

Results: time-domain integrations and nonlinear dynamics

In this section we aim to explore the nature of the nonlinear regimes associated with a linearly unstable system through numerical time-domain integration. The set of nonlinear ODEs described in above (13) was solved using MATLAB’s solver ode15i [21], an implicit scheme with variable time-stepping. Numerical simulations were started with the solutions of the steady configuration \bar{q}_n , \bar{Q}_c as initial conditions, and a small perturbation force was applied to all beam modes to induce eventually unstable dynamics.

Stability and impact boundaries

As a first step to characterize the nonlinear behavior of the system, we examine the role of impacts and when they are more likely to occur. To this end, a series of numerical time-domain integrations were performed in the non-dimensional parametric space (U^*, M^*) . We considered a symmetric configuration with confinement ratio $H^* = 1/10$, and friction coefficient $f = 0.14$. The simulations were run for several seconds until one of the following scenarios was encountered: (1) oscillations gradually decreased converging to the steady solution (linearly stable dynamics), (2) the oscillations grew until a stable limit cycle was reached, without the occurrence of impacts, or (3) oscillations grew until the beam eventually comes into contact with one of the walls, at which point the simulations were stopped. The difference between the latter two scenarios enabled us to estimate an “impact boundary”, that is, a frontier in the (U^*, M^*) plane separating limit cycles with and without impacts. Because contact was not accounted in this first study, the beam was described by only $N = 10$ modes. All modal damping coefficients were set to $\zeta_n = 0.01$. The resulting map is shown in Figure 4.

Figure 4 – Stability map of a system with confinement ratio $H^* = 1/10$ and friction coefficient $f = 0.14$, in the (U^*, M^*) plane. The linear stability boundary (black line) is compared to the limit cycle boundary found by the nonlinear simulations (orange circles). The impact boundary (blue line) illustrates the frontier in which unstable dynamics lead to contact between the beam and the confinement walls. The nonlinear limit cycles associated with the points marked (1a-c) will be shown in the following sections.

We see that the stability boundary predicted by the linearized system is coherent with the unstable dynamics observed in the nonlinear simulations. As for the impact boundary, we note that the regions in which limit cycles without impacts occur (grey area) are not extensive. Noticeably, we underline the fact that for small mass ratios (heavy beams or light fluids) these regions simply do not exist and the flutter instability, however weak, inevitably leads to large amplitude beam motions and eventual contact with the side walls. This seems physically plausible as, in these cases, the inertia of heavier beams will tend to outweigh the restoring forces from a light fluid.

Elastic impact model

Numerous experimental (and modelling) observations [3] [4] [14] [16] demonstrate that nonlinear motions of cantilevered plates in confined axial flow regularly present intermittent impacts between the beam and the side-walls. Consequently, previous attempts at modelling limit-cycle oscillations (LCO), eventually encountered limitations in their solutions, at regimes where the motion of the plate is large enough that collisions become inevitable.

In the current bulk-flow formulation, the addition of dynamic impact between the beam and the side walls is not a trivial task. One of the major challenges relates to the fact that the solutions for flow velocity and pressure fields present singularities at the moment of contact, i.e. when the channel height $h_c = 0$. Consequently, classical penalty methods, reliant on “interpenetration”, are incompatible with the current flow model. Without dealing with these delicate issues, here we present a pragmatic approach, based on a regularized impact formulation, that allows us to include impacts in a simple manner that is compatible with the flow formulation. Since the fluid equations do not allow for beam penetration, an impact force $F_i(x, t)$ is applied on the beam just before contact, in regions of the beam which have trespassed a small regularization parameter ε (Figure 5). In essence, we allow some flow leakage at the moments of “contact”, such that an impact force can be applied to the beam without fully restricting the flow dynamics.

Figure 5 – Illustration of the beam violation right before contact and corresponding impact force.

A simplified version of a classic Hertz model is considered, where the impact force is linearly proportional to a violation parameter $v(x, t)$, describing the penetration distance between the beam a “virtual” wall defined by $H_c(x) - \varepsilon$, as illustrated in Figure 5. Then, the impact force $F_i(x, t)$ is given by

$$F_i(x, t) = \begin{cases} k_i v(x, t) & \text{if } v(x, t) > 0 \\ 0 & \text{otherwise} \end{cases} \quad (16)$$

where k_i is an impact stiffness and the violation amplitude is given by $v(x, t) = \varepsilon - h_c(x, t)$. The sign of $F_i(x, t)$ is defined for each channel: $F_i > 0$ for $c = 2$; $F_i < 0$ for $c = 1$.

Illustrative examples of limit-cycle oscillations with intermittent impacts

Here we illustrate a few limit cycles that include intermittent impacts, namely, the solutions for the configurations indicated in Figure 4 by points (1a), (1b) and (1c). These configurations have a constant mass ratio of $M^* = 1$ and various reduced velocities $U^* = [7, 8.5, 10]$, respectively. For these simulations, a large number of beam modes was considered, $N = 40$, to ensure the impact dynamics are well represented. In the following simulations, the non-dimensional impact stiffness was taken as $k_i^* = k_i / m_1 \omega_1^2 = 10^6$ (normalized by the stiffness of the first beam mode) and the non-dimensional regularization parameter $\varepsilon / H = 10^{-3}$.

Figure 6 shows snapshots of the beam motion and Figure 7 the evolution of the modal velocities $r_n(t)$ and the unsteady flow rates $Q_c(t)$, for the three configurations (1a), (1b) and (1c). Moreover, in Figure 8 we show the phase-portrait of the beam tip, the evolution of the tip displacement $y(L, t)$, the spectra of the tip velocity and RMS-value of the modal displacements $q_n(t)$, for all three configurations. Finally, we show in Figure 9 the impact force applied on the beam throughout the limit cycles. The impact force is expressed as the spatial integral of $F_i(x, t)$, normalized by a reference force $F_0 = m f_1^2 H$, where m is the total mass of the beam and f_1 is the frequency of the first in-vacuo beam mode.

Figure 6 - Snapshots of the beam motion during one cycle for configurations (1a), (1b) and (1c).

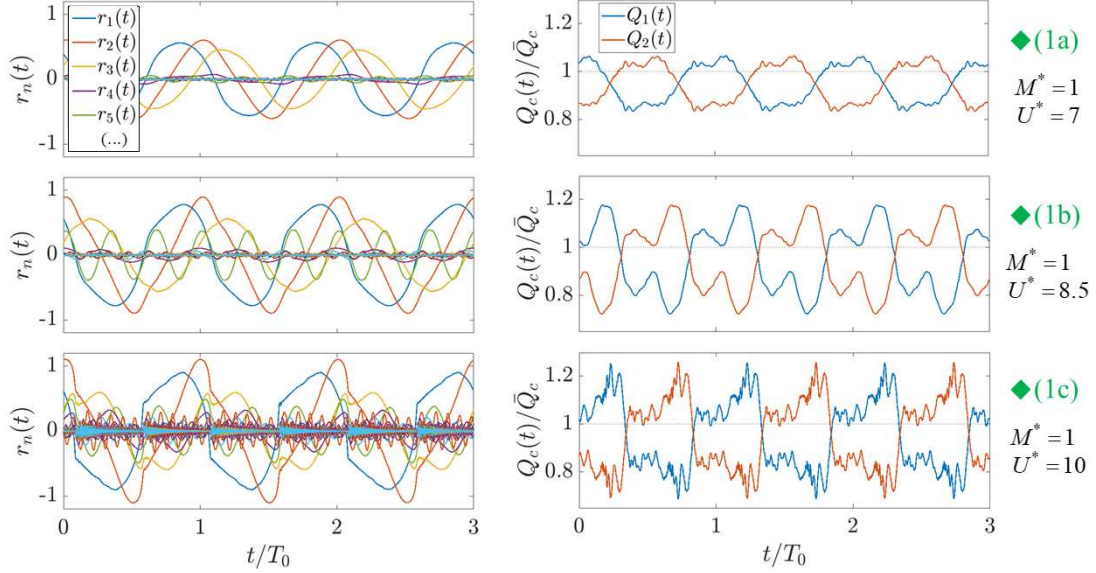

Figure 7 - Temporal evolution of the modal velocities $r_n(t)$ (left) and unsteady flow rates $Q_c(t)$ (right) in the limit cycles associated with configurations (1a), (1b) and (1c). For clarity, time scales are normalized by the fundamental period of the corresponding limit-cycle T_0 .

In Figure 6 we notice that, in all cases, intermittent contact occurs solely at the tip of the beam. As the velocity U^* increases (1b-c), impacts become more violent and the beam motion becomes increasingly perturbed, as higher order beam modes are intermittently excited and start playing a more prominent role in the overall beam motion. These effects are also seen by the evolution of the modal velocities shown in Figure 7 and the RMS-values in Figure 8. When impacts are relatively weak (1a), the tip simply “grazes” the wall and the overall beam motion is not significantly altered compared to the mode shapes estimated by the linear stability analysis.

Similarly, the oscillations of the flow rates become increasingly abrupt in the presence of violent impacts. However, it is interesting to note that sharp changes in the unsteady flow-rate (e.g. bottom-right plot in Figure 7) do not occur at the moments of contact but rather at the moments when the beam motion rapidly shifts from one side of the channel to the other. This effect can be illustrated, for example, by the beam-tip motion shown in Figure 8. Here we notice that as impacts become stronger, the overall contact time also becomes larger, meaning as well that the beam-tip will shift sides more abruptly, hence generating sharp fluctuations in the flow-rates. As expected, flow rates also oscillate around a value slightly lower than their steady component \bar{Q}_c . This means that the overall mass transport is reduced by the fluttering beam, compared to a static scenario. This seems physically plausible as, during flutter, some of the energy carried by the flow is transferred to the beam and lost through either structural dissipation or increased flow-dissipation effects.

In Figure 8 we note that the motions become increasingly nonlinear in the presence of stronger impacts. The phase-portrait shows more perturbed motions with larger gradients. Naturally, the spectra of the beam tip show a large number of high order harmonic components, increasing in amplitude as impacts become more violent. It is worth noting that, in limit cycles with very strong impacts (1c), the oscillations are not strictly periodic. Although the low frequency motions are stable, we notice small high frequency perturbations, related to the unsynchronized motion of the intermittently excited higher order beam modes. This behavior is clearly illustrated by the spectra of (1c), where we notice not only an increase in the amplitude of the harmonics, but also a visible presence of noise-like spectral behavior. Nevertheless, these motions might be tentatively classified as perturbed periodic oscillations, rather than aperiodic dynamics.

The impact forces represented in Figure 9 illustrate the fact that, during each beam-wall interaction, the beam tip impacts the wall multiple times. This chattering effect is a typical behavior of systems with impacts in multi-modal structures. In weaker impacts (1a) we notice only a few impacts of decreasing strength while in more violent regimes (1b-c) contact is composed of multiple impacts with stronger associated forces and an overall longer chattering time.

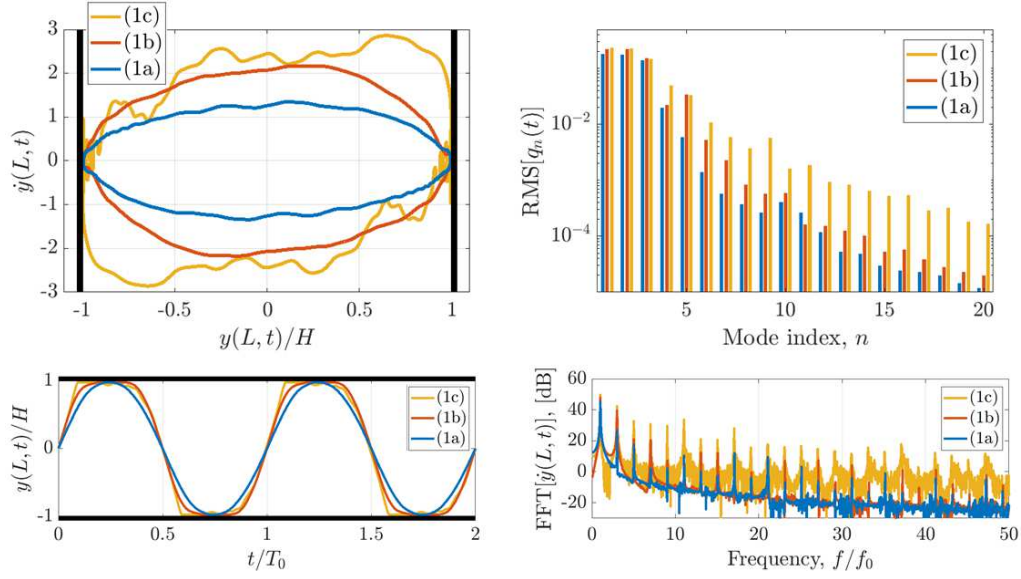

Figure 8 - Phase-portrait of beam tip (top-left); root-mean-square (RMS) value of the modal displacements (top-right); beam tip displacement (bottom-left) and spectra of the tip velocity (bottom-right, for the three configurations (1a), (1b) and (1c). For clarity, time/frequency scales are normalized by the fundamental period/frequency of the corresponding limit-cycle T_0 and f_0 .

Figure 9 – The evolution of the non-dimensional impact force through the limit-cycles associated with configurations (1a), (1b) and (1c). For clarity, time scales are normalized by the fundamental period of the corresponding limit cycle T_0 .

Conclusions

In this paper we have presented a framework for the comprehensive study of the nonlinear dynamics of a flexible beam subject to axial flow in a confined passage. Previous studies have been constrained by either large computational costs associated with 2D CFD models, the lack of a nonlinear flow formulation, and/or by the occurrence of contact between the beam and the side-walls. Here, a 1D model was formulated where the beam is described by its in-vacuo modes and incompressible bulk-flow equations, including distributed and localized head-losses, are used for the flow in both channels. An analytical resolution, based on the formal solutions for the velocity and pressure fields, is developed and leads to a fully nonlinear formulation of the fluid-structure interaction. Moreover, the possibility of contact between the beam and the walls is accounted for by a regularized impact model.

As a preliminary assessment of the potential of the proposed approach, results of linear stability analysis were compared to reference results using more realistic 2D CFD model. Overall, results were positively validated with only minor quantitative differences, at least for relatively narrow passages. Although not shown here, for brevity, it is worth noting that for larger confinement ratios $H/L > \sim 1/5$, we notice larger errors, as expected from the simplifying assumptions made in the bulk-flow approach.

Subsequently, nonlinear time-domain integrations were performed in order to illustrate the dynamical behavior occurring in such systems. Firstly, several simulations were performed to characterize the nonlinear dynamics for different configurations in the (M^*, U^*) -space. This led to a mapping of the nonlinear dynamics, separating the regions where limit cycles with and without impacts occur. Results suggest that, for low mass ratios (heavy beams/light fluids), the initial flutter instability always leads to contact, likely due to the contrast of the inertia of a heavy beam to that of a

light fluid. For moderate-to-large mass ratios, there are regions in the (M^*, U^*) -space where limit cycles without impacts occur, although these are relatively narrow. Secondly, several LCO with intermittent impacts were shown to elucidate the nature of the resulting nonlinear regimes. The lack of experimental data on the ensuing limit-cycles prevents us from a meaningful validation of our results, nevertheless, they seem physically plausible and consistent with experimental observations, at least qualitatively.

To the authors best knowledge, the presented framework allowed, for the first time, the calculations of the post-instability behavior of fluttering beams in confined flow, including vibro-impact dynamics. Future work might deal with the refinement of the impact model, to treat flow contact conditions and include damping. Moreover, bifurcation analysis using methods for the calculation and continuation of periodic solutions can contribute to a more comprehensive understanding of the associated nonlinear dynamics.

EXPLOITING NONLINEAR DYNAMICS FOR MANIPULATION OF ACOUSTICALLY LEVITATED PARTICLES

Izhak Bucher and Amit Dolev

Mechanical Engineering, Technion, Haifa, Israel

Summary. This paper describes an experimentally verified local and spatial model of a standing waves acoustic levitation system. By tailoring the waveforms fed to an array of ultrasonic transducers, arranged in a dome formation, individual potential-wells' can be created and altered periodically. The waveforms contain a fast part, geared to produce the nonlinear acoustic field and a slow part, tuned to create slow modulation of the local stiffness and principle parametric excitation. The latter can bring about large controlled oscillations of the levitated objects. Presented is a local, nonlinear model describing the dynamics of an individual acoustically levitated particle in a single potential well. And, for the first time, the dynamics of coupled floating particles tied through the weak nonlinear acoustic field, is shown. Nonlinearity of the acoustic field serves several purposes here: (i) It creates the nonlinear field with potential-wells and hence acoustic levitation (ii) It creates large motions and that produce hopping out of potential wells, given a suitably modulated slow excitation.

Introduction

This paper describes a method to perform fast dynamic manipulation of acoustically levitated particles. The results extend high frequency and high intensity acoustic excitation methods to dynamically manipulate standing and traveling wave patterns affecting particles' motion in 3D space in a controlled manner. Sound pressure levels that are generated in standing waves patterns at around 40 kHz can exceed 140db within a restricted area, giving rise to nonlinear acoustic phenomena. Such nonlinear phenomena can hold and mobilize particles of several millimeter in size at 10-80Hz frequencies. State-of-the-art research enables quasi-static motions of levitated particles by affecting the acoustic field and to slowly move their stable locations. The present work shows experiments where parametric excitation is created by modulating the acoustic field such that particles can be made to oscillate within acoustic potential wells. To achieve these goals, high order nonlinear models are generated, and embedded in a fast (1MHz sampling rate) excitation signals. The main uses of acoustic manipulation are in containerless and micro-gravity processing where contamination is a concern, when mild holding forces are sought and when particles and drops are to be mixed or moved in unison.

Described is the model of slow particle motion and its link to the fast (ultrasonic) acoustic excitation. In addition, some fast videos of a working experimental system are analyzed to produce qualitative and quantitative parameters shading light on the physical phenomenon. If viscosity has a small effect compared with the higher order acoustic radiation forces, the analysis of acoustic levitation devices (ALD), usually considers higher terms beyond the linear approximation of the pressure and particle velocity, but viscosity is often neglected in the initial computations.

Acoustic radiation pressure and force – simplified form

To predict nonlinear acoustic phenomenon creating the levitation, the well-known linear acoustic wave equation (2), does not suffice, and higher order terms should be considered [1,2]. Neglecting dissipation and heat related loss [3,4] for simplicity, one can obtain the fundamental nonlinear effect that predicts the stable acoustic potential-wells in space. These field parameters are used, whereas it is assumed that there is no mean flow in the cavity:

$$p = p_0 + p_1 + p_2 + \dots, \quad \mathbf{u} = \mathbf{u}_0 + \mathbf{u}_1 + \mathbf{u}_2 + \dots = \mathbf{u}_1 + \mathbf{u}_2 + \dots, \quad \rho = \rho_0 + \rho_1 + \rho_2 + \dots \quad (1)$$

The pressure field comprising the ambient pressure p_0 and high order terms p_1 and p_2 , \mathbf{u} is the particle velocity field expended in a similar manner and ρ is the density field comprising the ambient density and higher order terms. In the linear case, the wave equation reduces to

$$\nabla^2 p_1 = \frac{1}{c_0^2} \frac{\partial^2 p_1}{\partial t^2}. \quad (2)$$

In the nonlinear case, the time-averaged acoustic radiation pressure can be calculated from these linear fields [1]:

$$\langle p_2 \rangle = \frac{1}{\rho_0 c_0^2} \langle p_1^2 \rangle - \frac{\rho_0}{2} \langle \mathbf{u}_1 \cdot \mathbf{u}_1 \rangle, \quad (3)$$

whereas c_0 is the sound speed in the medium. The radiation force acting on an object is calculated as:

$$\mathbf{F}_{\text{rad}} = - \int_{S_0} \langle p_2 \rangle \mathbf{n} dS - \int_{S_0} \rho_0 \langle (\mathbf{n} \cdot \mathbf{u}_1) \mathbf{u}_1 \rangle dS. \quad (4)$$

whereas S_0 is the object surface while \mathbf{n} represents the surface normal vector. Viscous effects that create oblique and tangent forces [5] are ignored here. For small (i.e., the radius is much smaller than the acoustic wavelength) rigid spheres, the acoustic radiation force is approximated by:

$$\mathbf{F}_{\text{rad}} = -\nabla U, \quad U = 2\pi R^3 \left(\frac{f_1}{3\rho_0 c_0^2} \langle (p_1^{\text{in}})^2 \rangle - \frac{f_2 \rho_0}{2} \langle \mathbf{u}_1^{\text{in}} \cdot \mathbf{u}_1^{\text{in}} \rangle \right), \quad f_1 = 1 - \frac{\rho_0 c_0^2}{\rho_p c_p^2}, \quad f_2 = 2 \left(\frac{\rho_p - \rho_0}{2\rho_p + \rho_0} \right). \quad (5)$$

Here, R , ρ_p and c_p are the sphere radius, density and sound speed in the sphere, \bullet^{in} are computed in the absence of the sphere in the field, and U is called Gor'kov potential [6]. It is now possible to define the total potential energy as $U_{\text{tot}} = U + U_{\text{gravity}}$, and levitate objects steadily in the minima of U_{tot} .

Analytical model of a levitated particle subjected to parametric excitation

The dynamics of an acoustically levitated particle is governed by several physical effects: acoustic radiation forces, acoustic streaming, drag force and inertia. To accommodate effects not considered by (5) the following dynamical model for an acoustically levitated particle subjected to PE was developed, where the parameters were estimated experimentally [7].

$$u'' + 2\varepsilon\zeta_1 u' + \varepsilon\zeta_2 u'^2 + \varepsilon^2\zeta_3 u'^3 + (1 + \varepsilon\gamma \cos(\Omega\tau))(u + \varepsilon\kappa_2 u^2 + \varepsilon^2\kappa_3 u^3) = \varepsilon\gamma F \cos(\Omega\tau). \quad (6)$$

Equation (6) is dimensionless, where u is the particle position relative to the equilibrium position, ζ_i are damping coefficients, γ is the parametric excitation (PE) magnitude generated by modulating the voltage provided to the transducer [7], κ_i are nonlinear stiffness coefficients, Ω is the scaled parametric excitation frequency and F is an external force amplitude. The damping coefficients related terms dissipates energy from the system and can be due to drag, viscosity and acoustic streaming. The paper will include some asymptotic analysis and experimental results.

Contactless particle manipulation via standing wave acoustic levitation - experiments

In standing wave-based levitation, a strong standing wave acoustic field is generated in a confined space, also known as the acoustic cavity. When an object is placed in the cavity it is subjected to an acoustic radiation pressure, the control of this pressure allows manipulation of the object. The ability to control the motion of a floating particles vertically and horizontally is demonstrated by the experimental system depicted in Fig.1.

Figure 1. Left: Fast video set-up. Showing single levitated particle and fast Video recording (40,000 fps). Right/top: Fast video particle tracking using (DIC), horizontal oscillations within the potential-well for $\Omega=16.5$ Hz. Right/bottom: vertical oscillation by inducing $\Omega=31$ Hz videos. Links: [horizontal](#) and [vertical](#).)

Another feature not predicted by the Gor'kov's theory is the coupling between levitated particles when the acoustic field is modulated at suitable frequencies as shown below (see also [7]). The frames shown in Figure 2 illustrates that the bottom particle is stationary while the top and 2nd from bottom move in unison. The latter is caused by higher order forces than described by Gor'kov's theory and is one of the proposed topics.

Figure 2. Showing 3 frames from a fast video, spaced about 5 milliseconds apart. Using the experimental system Fig.1. See seconds 7-8 in Link to [VIDEO#1](#). For modulating the excitation at 37.83 Hz.

Conclusions

Presented is the analysis and experiments of an acoustic levitation system capable of manipulating levitated particles by means of time varying nonlinear effects. It is shown that previously ignored effects are important for the dynamics of an array of levitated particles. Nonlinear effect are controlled by a model based fast signal processor, showing good agreement with the asymptotic model.

Cristal Baschet: minimal model to predict the emergence of self-sustained oscillations

Audrey Couineaux, François Gautier and Frédéric Ablitzer

Laboratoire d'Acoustique de l'Université du Mans, CNRS UMR 6613, Le Mans, France

Context

The Cristal Baschet (Fig. 1a) is a contemporary musical instrument composed of a large number of glass rods arranged in chromatic scale. The sound is produced by rubbing glass rods with wet fingers, which causes the occurrence of stick-slip phenomenon. Each rod is connected to an assembly of threaded shafts, whose mechanical properties determine the pitch of the note. The vibrations are then transmitted to large metal sheets or cones that act as radiating elements. The manufacturing and tuning of the instrument is essentially based on empirical know-how and involves many parameters. Their influence on the sound and playability of the instrument is not clearly understood. One of the problems encountered is the difficulty to produce sounds in the high register of the instrument. In this study, a minimal model of Cristal Baschet is developed to analyze the emergence of self-sustained oscillations by means of linear stability analysis, with the aim of proposing design rules to improve the playability of the instrument.

Model

The minimal model focuses on the interaction between the wet finger and an isolated resonator (Fig. 1b). The resonator consists of a glass rod connected to a threaded shaft. Its dynamic behavior is represented by a set of modes. The modal parameters, which depends on design parameters (geometry, material properties...), can be obtained from a finite element model or from experimental modal analysis of the instrument. To model the occurrence of self-sustained oscillations from the frictional interaction with the finger, the knowledge of mode shapes at the interaction point is sufficient. Two gesture parameters, i.e. parameters that are controlled by the musician, are considered: the velocity of the finger v_f along the rod and the normal force F_N exerted by the finger on the rod. To describe the interaction between the finger and the resonator, the friction law considered in this study assumes that the glass rod perfectly sticks to the finger during sticking phases ($\Delta v = 0$) and that the friction force during sliding phases depends on the relative velocity $\Delta v = \dot{u} - v_f$ between the finger and the glass rod [2]. The sliding friction force is therefore expressed as $F_T = \mu(\Delta v)F_N$ with

$$\mu(\Delta v) = \mu_d + \frac{\mu_s - \mu_d}{1 - \Delta v/v_0}, \quad (1)$$

where μ_s is the coefficient of static friction, μ_d the asymptotic coefficient of dynamic friction and v_0 a parameter controlling the shape of the friction curve (Fig. 1c).

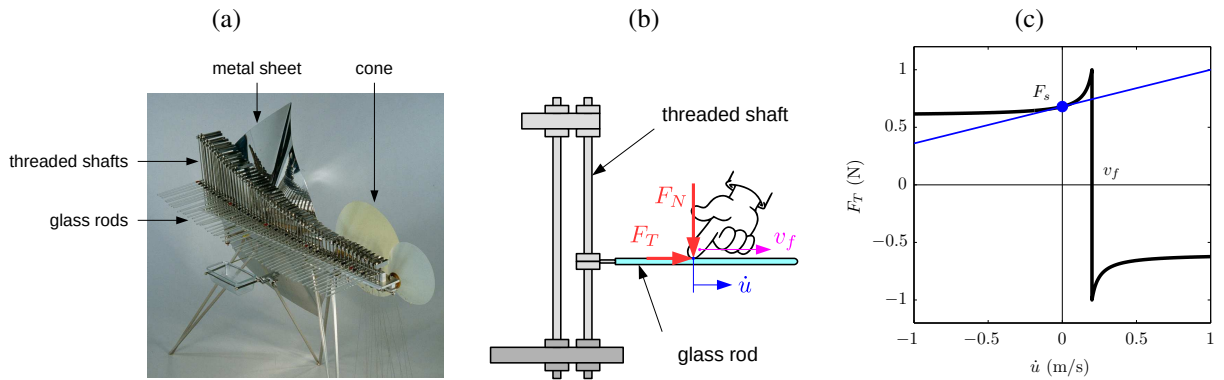

Figure 1: (a) Cristal Baschet (adapted from [1]). (b) Interaction between wet finger and resonator. (c) Friction curve and its linearization around static equilibrium in sliding situation.

Linear stability analysis

As a first step to determine the conditions at which the self-sustained oscillations can occur, the stability of the static solution in a sliding state is examined [3]. For this purpose, it is considered that the glass rod is in static equilibrium (i.e. $\dot{u} = 0$) under the action of a constant friction force F_s resulting from the motion of the finger at constant speed. Assuming small fluctuations of the glass rod velocity around its equilibrium position, a linearization of the friction curve around the static solution is performed to express the corresponding variations in friction force as $F_T \approx F_s + C\dot{u}$, where coefficient C represent the local slope of the friction curve (Fig. 1b). Inserting this linearized expression into the modal equations yields

$$\mathbf{M}\ddot{\mathbf{q}} + (\mathbf{C} - C\Phi_f\Phi_f^T)\dot{\mathbf{q}} + \mathbf{K}\mathbf{q} = \Phi_f F_s, \quad (2)$$

where $\mathbf{M} = \text{diag}(m_n)$, $\mathbf{C} = \text{diag}(2m_n\xi_n\omega_n)$, $\mathbf{K} = \text{diag}(m_n\omega_n^2)$ are the modal mass, damping and stiffness matrices, and Φ_f is a column vector containing the value of each mode shape at the location of the finger. Looking for a solution to the homogeneous equation in the form $\mathbf{Q}e^{\lambda t}$, one obtains an eigenvalue problem

$$(\lambda^2\mathbf{M} + \lambda(\mathbf{C} - \mathbf{C}\Phi_f\Phi_f^T) + \mathbf{K})\mathbf{Q} = \mathbf{0}, \quad (3)$$

where each eigenvalue λ characterizes an oscillating component whose amplitude either decreases (if $\text{Re}(\lambda) < 0$) or increases (if $\text{Re}(\lambda) > 0$) over time, corresponding respectively to stability or instability of the static equilibrium. Self-sustained oscillations occurs when the smallest modal damping ratio $\xi_{\text{eff}} = -\text{Re}(\lambda)|\lambda|^{-1}$ is negative (Fig. 2). The threshold depends on gesture parameters and friction law (both included in coefficient C) and design parameters (through the value of mode shapes Φ_f at the interaction point).

Time-domain simulations

In order to verify the criterion calculated from linear stability analysis, time-domain simulations are performed using an explicit numerical scheme of the form

$$\mathbf{x}(t_{i+1}) = \mathbf{A}\mathbf{x}(t_i) + \mathbf{B}\mathbf{f}(t_i), \quad (4)$$

where \mathbf{x} is a vector containing all modal coordinates and their time derivatives and \mathbf{f} is a vector containing the modal forces. The coefficients in \mathbf{A} and \mathbf{B} are obtained using a piecewise constant approximation of the right-hand side of modal equations. At each time step, the unknown friction force F_T exerted by the finger on the glass rod is obtained by enforcing a sticking or sliding condition. The results of time-domain simulations (Fig. 3) are in agreement with the predictions of linear stability analysis. The amplitude grow rate at various levels of normal force follows the same trend as the evolution of effective modal damping ratio shown in Fig. 2.

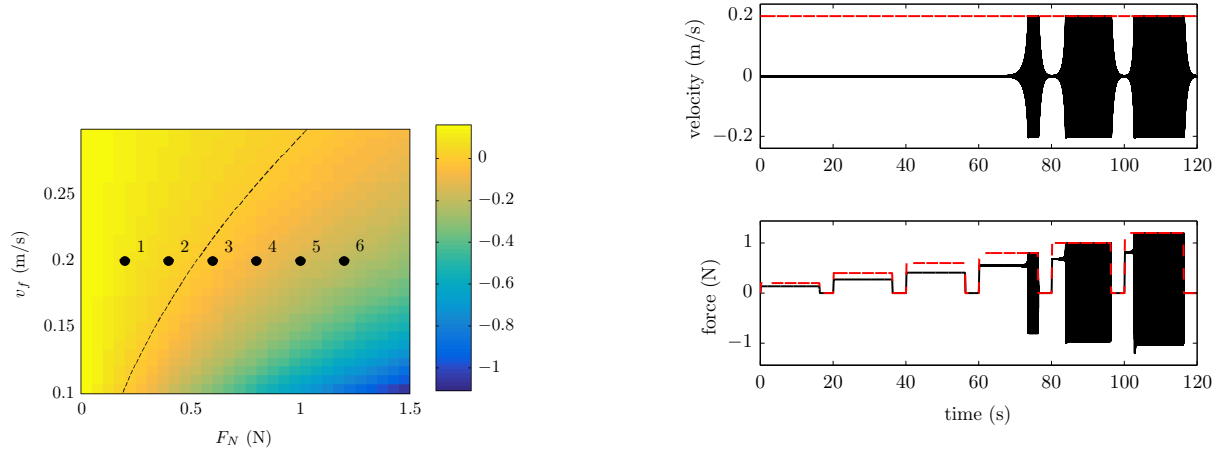

Figure 2: Smallest effective damping ratio ξ_{eff} as a function of the normal force F_N exerted by the finger and its velocity v_f . The dashed line indicates the limit between positive and negative values of the damping ratio, corresponding to stability or instability of the static equilibrium in sliding situation.

Figure 3: Velocity of the glass rod \dot{u} and friction force F_T obtained from time-domain simulation. The red dashed lines are respectively the finger velocity v_f and the normal force F_N (which also corresponds here to the maximum static friction force since $\mu_s = 1$ in this simulation). The different levels of force correspond to points 1 to 6 in Fig. 2. Although masked by the scale fixed for the velocity, the third level of normal force leads to oscillations with increasing amplitude but low growing rate, not allowing to see the permanent periodic regime.

Conclusion

The minimal model of the Cristal Baschet describes the dependence of the amplitude grow rate of instabilities on the physical parameters: it is shown that the law of friction plays an essential role but its influence depends also on the mode shapes of the resonator at the connection point. These modal parameters are directly adjusted by the instrument maker when he tunes the mobility of these resonators. The model shows that a too low mobility can be responsible for the difficulties in obtaining the sound in the upper register.

Summary. The possibility of exploiting the parametric resonance phenomena to perform morphing of piezoelectric surfaces is here investigated analytically and numerically. The case study consists of a PVDF beam subject to an in-plane pulsating strain applied through voltage variation. The dynamical excitation induces an out-of-plane parametric resonance of the beam which can be driven to excite desired individual modes or combination of them through nonlinear coupling. A nonlinear reduced order model for a piezoelectric thin Euler-Bernoulli beam is developed considering the multi-physics piezo-elastic coupling. The conservation of the electric charge is enforced in 3D while the equations of motion are expressed in 1D using the arclength parametrization along the beam centerline. The analytical treatment is based on the method of multiple scales and allows to obtain the region of the forcing parameters for which the parametric resonance is achieved. The analytical solutions are validated against numerical results provided by the finite element code ABAQUS through which a full 3D nonlinear model is addressed. The analytically obtained transition curves (representing the boundary between resonant and non resonant behavior in the space of forcing parameters) and the frequency response curves are compared to those obtained numerically achieving a good agreement. The voltage thresholds for which the parametric resonances are induced, and the robustness of the responses suggest that the investigated phenomenon is a promising strategy for surface dynamic morphing.

Introduction

A piezoelectric formulation valid rigorously only for parallelepiped-shaped beams is proposed. The model is focused on the parametric resonances induced by a pulsating voltage whose gradient is defined along the thickness [1]. The transition curves defining the forcing parameters for which the beam exhibits a parametric resonance are obtained using the method of multiple scales [2, 3]. The nonlinear equations of motion of the continuous piezoelectric beam are reduced employing a full-basis Galerkin-discretization of the continuous piezoelectric beam [4, 5].

Finally, the closed form asymptotic results are compared with those obtained by the direct integration of the nonlinear dynamic problem performed with the nonlinear finite element software ABAQUS [6]. The results show a good agreement and the simplified hypotheses adopted for the piezoelectric beam model are confirmed. The implemented assumptions could be also used for developing a simplified piezoelectric shell model.

Equations of motion

Consider the 3D Euclidean space with a Cartesian fixed frame (s, y, z) where the position of each point can be defined by a vector $\mathbf{x} = se_1 + ye_2 + ze_3$. The straight beam exhibits a rectangular cross-section of edges b and h and the position of each section along the beam span l , in the reference configuration, is described the vector $\mathbf{r}^0 = se_3$ with $s \in [0, l]$. The local frame in the reference configuration is denoted by $(\mathbf{b}_1^0, \mathbf{b}_2^0, \mathbf{b}_3^0)$. Unit vectors \mathbf{b}_1^0 is collinear with \mathbf{e}_1 while the pair $(\mathbf{b}_2^0, \mathbf{b}_3^0)$ represents a centered and principal frame for the beams cross-section.

The mechanical problem is formulated in the plane $\mathbf{e}_1 - \mathbf{e}_3$, and the displacement of the central line is denoted by $\mathbf{u}(s) = u(s)\mathbf{b}_1^0 + v(s)\mathbf{b}_3^0$. The rotation of the beam cross sections is $\boldsymbol{\theta}(s) = \theta(s)\mathbf{b}_2^0$ where \mathbf{b}_2^0 coincides with \mathbf{e}_2 . According to Saint-Venant ansatz, stresses and strain states are simplified: $\sigma_{22} = \sigma_{33} = \sigma_{23} = \sigma_{12} = 0$, $\varepsilon_{22} = \varepsilon_{33} = \gamma_{12} = \gamma_{23} = \gamma_{13} = 0$.

On the other hand, it is assumed that the voltage V varies only in the z direction according to the electric boundary conditions to which it is subject. We are interested in the problem in which the top beam surface at $z = h/2$ is connected to ground and presents $V(h/2) = 0$. On the bottom surface a voltage different from zero is assigned, $V(-h/2) = \bar{\Phi}$. Moreover, it is assumed that the potential varies with a quadratic law across the relatively small beam thickness according to

$$V(z, t) = \Phi_0(t) + \Phi_1(t)z + \Phi_2(t)\frac{z^2}{2}. \quad (1)$$

. Imposing the potential boundary conditions given above yields

$$\Phi_1(t) = -\frac{\bar{\Phi}(t)}{h}. \quad (2)$$

The beam axial force and the bending moment can be obtained by integration over the cross-section of the elastic axial tension.

The equations of motion for the nonlinear beam in the current local frame can be written as

$$N' + \frac{\mu}{\nu}M' = \rho A \ddot{u} \cos \theta + \ddot{v} \sin \theta, \quad (3)$$

$$\mu N + \left(\frac{M'}{\nu}\right)' = -\rho A \ddot{u} \sin \theta + \ddot{v} \cos \theta. \quad (4)$$

where the shear force has been condensed using equation for the balance of the angular momentum, the prime indicates differentiation with respect to s and the overdot with respect to time t . Equation (4) can be condensed considering that the axial force is constant along the beam.

Figure 1: Parametric resonance regions for the PVDF sample where the black solid lines are obtained according to the fifth order solutions for the lowest three beam modes assuming $\zeta = 3\%$ and $V_0 = 5$ V; the black and red circles denote nonresonant and resonant responses provided by ABAQUS while the blue circles indicate resonant responses for the plates modes; the gray and blue vertical thin lines are placed at twice the frequencies of the beam-like modes and twice the plate-like frequencies, respectively; the black dashed horizontal lines denote the amplitudes of the AC voltage V_1 for which the ABAQUS simulations were run, namely, (1.5, 2.5, 5) V.

The Method of Multiple Scales

The unknown displacement is expressed as follows

$$v(s, t) = \epsilon v_1(s, t_0, t_2, t_4) + \epsilon^3 v_3(s, t_0, t_2, t_4) + \epsilon^5 v_5(s, t_0, t_2, t_4). \quad (5)$$

and $\Phi_1 = V_0 + \epsilon^2 V_1 \cos \Omega t$ where the forcing frequency is $\Omega = 2\omega + \epsilon^2 \sigma$. The parameter σ represents the detuning of the forcing frequency with respect to twice of the frequency of the excited mode. Moreover, the damping ratio is assumed as $\epsilon^2 \zeta$. Collecting the terms with the same order of ϵ , the nonlinear equation of motion can be written up to the 5th order and solved asymptotically.

Results

The transition zones identified by ABAQUS are in accordance with the transition curves evaluated with the closed form expression. In fact, the threshold points provided by ABAQUS are very close to the asymptotically obtained curves (see Fig. 1). In particular, the correction obtained with the 5th order frequency response curves (black solid lines) show that the fully numerical and reduced model are in close agreement.

Conclusions

The present paper investigates the parametric resonance conditions induced by a pulsating voltage in a PVDF copolymer beam/plate. The piezoelectric properties of the PVDF film are exploited to induce an initial tensile stress that makes the structure stiffer and increases the natural frequencies. A nonlinear piezoelectric beam model is developed and the transition curves for the lowest three modes are computed using the method of multiple scales. The obtained results are validated via ABAQUS through which the piezoelectric system is addressed within geometrically nonlinear problem formulation.

Summary. Expanding the deployment of oscillating surge wave energy converters to deep waters requires mounting them on submerged platforms close to the water surface. One issue is that large amplitude waves, required for better energy generation, induce large platform motions, particularly in the surge direction. These motions could adversely impact the flap's hydrodynamic performance. We investigate, through an explanatory experimental study, the use of particle damping to control the surge motion of the platform under different wave excitations. The results point to complex nonlinear effects of particle damping and couplings among the different degrees of freedom, which yield differing responses under different excitation parameters.

Introduction

Oscillating surge wave energy converters (OSWEC) are one of the most efficient means for capturing and converting wave energy into a more useful form of energy, e.g., electricity. Because the surge component of ocean wave energy is most prevalent near the water surface, OSWEC wave capture components must be positioned near that surface to realize maximum efficiency. This placement, however, constrains their deployment to shallow water sites. In contrast, mounting the OSWEC onto a submerged platform close to the water surface, as schematically shown in Figure 1, expands the deployment range to deep water locations where there is need to power observation stations, autonomous underwater robots, offshore islands, ships and submarines, among many other blue economy systems and devices.

Figure 1: Schematic of oscillating surge wave energy converter mounted on a platform

Although resonance is always desired to achieve large amplitude motions for efficient energy generation, optimal wave energy conversion from a pitching flap-type device may not take place at resonance. Designing the flap to be resonant requires a relatively small added mass, which results in a small wave force. In contrast, designing the flap to attract a large wave force requires a large added mass, which results in a non-resonant device [1]. Clearly, larger wave forces induced by larger wave amplitudes, could be more effective in increasing the power capture than operating at resonance conditions for OSWEC. In the case of a floating oscillating surge wave energy converters (FOSWEC), large wave forces, intended to increase the flap's rotational displacement, could also induce significant platform motions, which may adversely impact the response of the flap oscillator and reduce the level of generated power. Consequently, it is important to control the platform's motion.

One control approach is to introduce passive damping by attaching a set of cylinders or boxes containing particle dampers to the platform, as schematically shown in Figure 1. This robust approach is particularly effective and practical under random excitation [2] and when considering the harsh operational conditions of FOSWEC in high sea states, over a broad range of frequencies defined by irregular wave spectra. Here, we perform experiments in a wave tank to investigate the effectiveness of particle damping in reducing the motion of the platform while increasing the flap's response as desired to enhance the energy generation. The results are used to characterize complex nonlinear effects and nonlinear couplings among the different degrees of freedom.

Experimental Setup

The experiments were performed in the wave tank of the Davidson Laboratory. The tank is 100 m long, 5.4 m wide and 2.1 m deep. The waves are generated by a dry-back, six-paddle, electrically driven, flap type wave-maker capable of generating regular and spectral waves with periods between 2 and 5 seconds and heights up to 0.65 m. Each paddle has

an individual servo-drive with purpose-built digital controller. The tests were performed on a scaled floating oscillating flap mounted on a platform positioned 0.79 m below the water surface. The 1.2 m wide, 0.95 m high and 0.127 m thick oscillating flap (Figure 1) was composed of an aluminum frame filled with foam. Its total mass and mass moment of inertia were respectively 21.5 kg and 5.5 kg.m². The flap was hinged to the (1.5 m x 1.17 m) platform, which was built using T-slotted framing rails attached by corner brackets. The platform was held by four strings at the corners that extended underwater and connected to extension springs with loop ends that were firmly held in position by heavy weights on the bottom of the tank. The particle damping system consisted of four 5-cm PVC tubes that were 0.53 m long. These tubes were partially filled with low carbon steel spheres having a diameter of 1.9 cm to yield 18% mass ratio. A displacement sensor was placed on top of the flap frame to measure the relative linear displacement between the flap and the platform. A 3-phase accelerometer and a 3-phase gyroscope IMU were mounted on the platform to measure all rotational and translational accelerations. One wave wire, placed at 5 m upstream of the flap, was used to measure the incident wave height. All data were acquired at the rate of 100 Hz. Tests were conducted for different wave heights and periods.

Particle damping

Figure 2 shows that particle damping yielded a 73% reduction in the platform's surge displacement when the period of the excitation 4.5 cm-wave was set to 4 seconds. This reduction percentage was not, however, consistent. Damping particles did not cause any reduction in the surge displacement when the wave period was set to 4.5 seconds. Furthermore, the platform surge displacement increased by 150% at the lower wave period of 2.85 seconds. Analysis of the pitch and yaw motions showed similar responses, pointing to the complex nonlinear dynamics of particle damping and the coupling between the different degrees of freedom. The impact of reducing the surge motion on the rotational displacement of the flap is deduced from figure 3, which shows that particle damping of the platform's surge motion increased the angular rotation of the flap by about 40%.

In the full paper, we will evaluate and discuss all mechanisms contributing to particle damping of the surge response of the platform. These include collisions between the particles and the container, inelastic particle-to-particle collisions, and frictional losses. These depend on different factors including mass ratio defined as the ratio of the mass of the damping particles to the total mass of the platform and flap; void ratio defined as the ratio of volume not occupied by particles to volume occupied by particles; porosity defined as the ratio of volume not occupied by particles to bulk volume of the particles; clearance defined as the distance particles can travel before impacting the wall, rolling friction; and coefficients of restitution among the particles and with the enclosure. We will also elaborate on the coupling between the different degrees of freedom and energy transfer between the flap and platform motions.

Figure 2: Reduction in surge amplitude induced by particle damping for a wave period of 4 seconds and amplitude of 4.5 cm.

Figure 3: Increase in angular displacement of the flap under particle damping of the platform's surge motion. Wave period 4 seconds.

Conclusions

We tested in a wave tank the use of particle damping to control the surge motion of a near-surface platform supporting an oscillating surge wave energy converter. The data showed effective damping and enhanced flap oscillations under specific excitation conditions, but less effective or even increased motions under other conditions. These observations point to the complex nonlinear features of particle damping.

A Design Methods for Particle Dampers in Low Frequency Horizontal Free Vibrations

Niklas Joachim Meyer* and Robert Seifried*

**Institute of Mechanics and Ocean Engineering, Hamburg University of Technology, Hamburg, Germany, www.tuhh.de/mum, n.meyer@tuhh.de, robert.seifried@tuhh.de*

Summary. Particle dampers show a huge potential to efficiently damp lightweight structures. However, they suffer from their nonlinear characteristics and the multitude of influence parameters. For horizontal vibrations of low frequency, recently, the rolling attribute of spheres has been used to obtain high energy dissipation rates in driven particle containers. As long as the particle container's acceleration amplitude stays below the gravitational acceleration, this rolling effect of spheres can be used. Hereby, the estimation of the damper's energy dissipation is accurately possible using analytical formulas.

In this paper, a design guideline for a systematic damper design for an underlying structure of low first eigenfrequency under free vibration is presented. To develop this guideline, the analytical expression of the rolling effect of spheres is analyzed in detail. The particle damper is separated into multiple layers with different lengths. Hence, a high damping ratio over a large vibration amplitude range can be obtained. For experimental validation purposes, a simple beam-like structure is utilized. A good agreement between expected and experimental obtained vibration response is achieved for the designed particle dampers.

Introduction

To reduce large vibrations amplitudes of lightweight structures, passive damping techniques are often used. Classical liquid dampers are commonly utilized for these applications. Those dampers are well studied and mathematically easy to describe. However, liquid dampers fail under harsh environmental conditions and do need an anchor point. Thus, for applications where liquid dampers are not suitable, alternative damping technologies are necessary. Hence, *particle dampers* are an alternative, due to their simple and robust design.

Particle damping technology uses containers that are attached to the vibrating structure and are filled with granular material. By structural vibrations, momentum is transferred to the granular material which start to interact with each other. Due to these interactions, energy is dissipated by impacts and frictional phenomena between the particles. Particle dampers show great advantages compared to other damping technologies, as these add only little mass to the primary system [4], are cost-efficient devices, and might be applied to a wide frequency range [2]. Particle dampers can also be applied in harsh environmental conditions [14, 18]. One popular example are spacecraft applications [13]. Despite particle damper's huge potential, their design is still a non-trivial and challenging task. This is because particle motion, also called *motion mode*, and the damper's energy dissipation correlate in a non-trivial way, which is often poorly understood. Identifying these correlations is still part of ongoing research, see e. g. [3, 6, 7, 16, 19, 20, 21].

Especially, for low frequency vibrations, the use of particle dampers is rarely seen so far. For these vibrations, the particle container's acceleration amplitude is mostly below the gravitational acceleration. Hence, particles begin to stick and no relative motion between particles and container is obtained. Thus, only a little amount of energy is dissipated [5]. To face this problem, recently, in [12] the rolling attribute of spheres is studied for horizontal vibrations. It is shown that for low filling ratios, particles begin to slide and roll over the container base instead of sticking. For vibration amplitudes below a certain threshold stroke, which only depends on the filling ratio of the damper, no synchronous particle motion is obtained. This motion is named *scattered state*. The scattered state results in a comparatively low energy dissipation. Increasing the amplitude of the vibration above the threshold stroke, a synchronous particle motion with the container is obtained. The particles start to move as one particle block and collide inelastically with the container walls. This results in high energy dissipation rates and is called *rolling collect-and-collide* motion mode. For both observed motion modes, in [12] analytical equations are derived describing the damper's energy dissipation. These analytical equations are validated by comparison to experimental measurements of a driven particle container.

In this paper, the damper design of [12] is adopted to damp a structure of low first eigenfrequency under free vibration. Therefore, the analytical equations are studied in detail and a simple design guideline is derived. The idea of the design guideline is to separate the particle damper into multiple layers with different lengths. Hence, different vibration amplitudes can be damped efficiently, leading to high damping ratios on a large amplitude range. For validation purposes, a simple beam-like structure is utilized. The base point of the beam is fixed. The particle damper is mounted at the tip of the beam and the damper's velocity is measured using a laser scanning vibrometer. Thus, the system's free response is measured.

This paper is organized as follows: First, in Sect. **Motion Modes** the occurring motion modes for low-intensity horizontal vibrations are introduced. In the following Sect. **Design Guideline**, the particle damper's design guideline is developed. Then, in Sect. **Experimental Validation** the design guideline is applied to design a particle damper for the free vibration attenuation of a simple beam-like structure. Finally, a conclusion is given.

Motion Modes

A motion mode describes the motion of a particle bed inside a harmonic vibrating container of the form $x_c = X \sin(\Omega t)$, with container amplitude X and angular frequency $\Omega = 2\pi f$. For such a container movement, the corresponding container velocity and acceleration follow to $\dot{x}_c = V \cos(\Omega t)$ and $\ddot{x}_c = -A \sin(\Omega t)$ with $V = X \Omega$ and $A = X \Omega^2$. For such a container movement, different motion modes of the particle bed can be observed. Various influence parameters affect the occurring motion mode, like excitation intensity and frequency but also gravity, excitation direction, or particle size. The most common motion modes are solid-like, local fluidization, global fluidization, convection, Leidenfrost effect, bouncing collect-and-collide, and buoyancy convection [3, 6, 7, 16, 19, 20, 21].

For horizontal vibrations of low acceleration amplitude, i.e. $A < g$ with g being the gravitational acceleration, two different motion modes can be observed if spherical particles on flat container bases with low filling ratio are used, see [12] for a detailed discussion. An example of such a container is shown in Fig. 4 in form of the later utilized particle damper. The observed motion modes inside this container are called scattered and rolling collect-and-collide and are depicted schematically in Fig. 1. Particle trajectories of these two motion modes, obtained by discrete element simulations, are shown in Fig. 2 [12]. Interestingly, both motion modes only depend on the so-called optimal stroke X_{opt} , which only depends on the clearance h , i.e. the distance of the particle bed to the opposite container wall as indicated in Fig. 1. Following [12], the optimal stroke is obtained to

$$X_{\text{opt}} \approx 0.4 h. \quad (1)$$

To judge about the particle damper's efficiency the effective loss factor $\bar{\eta}$ [6, 11] is used. It is calculated by a scaling of the dissipated energy of the particle damper per radian E_{diss} with the kinetic energy of the particle system using the mass of the particle bed m_{bed} , i.e. the mass of all particles, to

$$\bar{\eta} = \frac{E_{\text{diss}}}{E_{\text{kin}}} = \frac{E_{\text{diss}}}{\frac{1}{2} m_{\text{bed}} V^2}. \quad (2)$$

Scattered state: The scattered state occurs for container amplitude $X < X_{\text{opt}}$. This motion mode is similar to the gaslike state observed by Sack [15] under the condition of weightlessness. The particle movement is randomly and chaotic. Hence, in Fig. 1 just a schematic representation of the movement of the particles is shown. Particles are hitting each other and the container walls at random phases. In [12] it is observed that a higher vibration amplitude X leads to more particle collisions while a higher clearance h leads to fewer particle collisions.

The analytical solution of the effective loss factor of the scattered state is shown in Fig. 3 for $X < X_{\text{opt}}$ being a good approximation to experimental measurements [12]. The effective loss factor starts close to zero for very low container amplitudes, i.e. $X \ll X_{\text{opt}}$, and increases linearly. At the transition to the rolling collect-and-collide motion mode, i.e. at $X = X_{\text{opt}}$, the highest value of 0.4 is reached.

Rolling collect-and-collide: The second motion mode observed for low frequency horizontal vibrations is the rolling collect-and-collide one, see also Fig. 1 and Fig. 2. Within this motion mode, i.e. for $X > X_{\text{opt}}$, the particle bed rolls and slides as one single particle block over the container's base. Thus, the translational and rotational velocities of every single particle are assumed to be identical. First, the particle bed is pushed by the container until the container reaches its maximum velocity, i.e. at $\Omega t = n\pi$ with $n \in \mathbb{N}$. At this time point the container is positioned at $x_c = 0$ and its velocity is maximal, i.e. $\dot{x}_c = \pm V$. As the particle bed is pushed by the container, almost no rotational movement of the particles is seen during this pushing phase, i.e. $\dot{\varphi}_p = 0$. When the particle container has reached its maximum velocity and starts to decelerate, the particle block leaves the

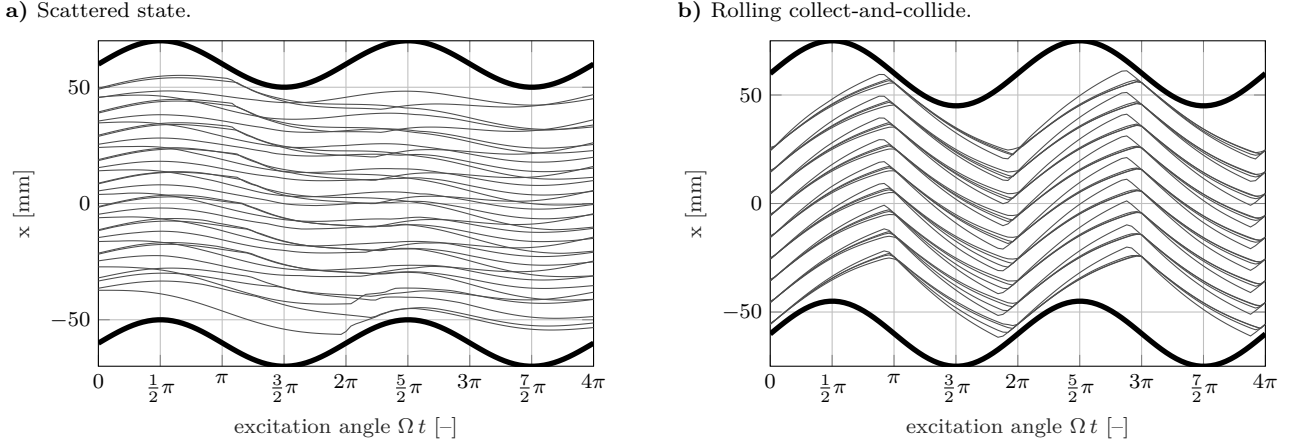

Figure 2: Particles trajectories obtained from DEM simulations for different container strokes [12].

Figure 3: Effective loss factor for scattered and rolling collect-and-collide motion mode [12].

container wall and the single particles start rolling due to friction with the container base. The particle block collides inelastically with the opposite container wall at the impact time point t_i . During this impact multiple inter-particle and particle-wall impacts occur. Although, by every single impact, only a small amount of energy is dissipated, in sum a perfectly inelastic collision of the particle bed with the container wall is achieved, i.e. the particle block adopts the velocity of the container [1, 17]. During this inelastic collision, the rotational movement of the particles stops. This sequence is repeated when the particle container moves in the other direction. Hence, in sum, two particle impacts with the container walls occur during one vibration cycle.

The effective loss factor for this motion mode is shown in Fig. 3 for $X > X_{\text{opt}}$. The effective loss factor starts at $X = X_{\text{opt}}$ with its maximum value $\bar{\eta}_{\text{max}} \approx 0.91$ and decreases slowly to higher container amplitudes. This progression of the effective loss factor can be explained by taking the relative velocity between particle bed and container at the impact time point with the container wall into consideration. For very high container amplitudes, i.e. $X \gg X_{\text{opt}}$, the particle bed leaves the container wall with a high velocity. Thus, the particle bed collides after a short period with the opposite container wall, i.e. $\Omega t_i \rightarrow 0$. Consequently, the relative velocity between particle bed and container at impact is comparatively low, resulting in a low efficiency. When the container amplitude decreases, i.e. is getting closer to X_{opt} , the impact time point increases, and thus the relative velocity at impact increases as well. This leads to a higher damper efficiency. The threshold for this motion mode is at an impact time point of $\Omega t_i = \pi$. For this time point, the container is located at $x_c = 0$ but moves in the other direction as the particle block, i.e. $\dot{x}_c = \mp V$. This is the impact time point of maximum relative velocity between particle bed and container and thus of the highest efficiency. For this time point, $X \approx 0.4h$ holds. For even lower container strokes, the system switches to the scattered state. This switch happens as for the rolling collect-and-collide motion mode less than two impacts with the container wall per vibration cycle would occur. However, this is a necessary condition of this motion mode.

One should note that the experimental results in [12] are in good agreement with the analytical solutions of the effective loss factor shown in Fig. 3. However, in [12] the testbed to subject the particle container to a sinusoidally motion is set up very precisely. It is obtained that especially a container tilt or a high friction coefficient, significantly lower the effective loss factor.

Design Guideline

To design an appropriate particle damper, at first some general points have to be discussed. At first, it is assumed that the system that should be damped is described by

$$M\ddot{x} + D\dot{x} + Kx = 0, \quad (3)$$

with mass M , structural damping D , stiffness K and particle damper position x . In [8] a detailed description is given, of how to derive this equation of motion for arbitrary structures.

For the damper design, the effective loss factor, see Fig. 3, has to be considered. As the particle damper exhibits much higher effective loss factors during the rolling collect-and-collide motion mode, this motion mode should be realized during the operation of the damper. Likewise, any free vibration of a structure with initial amplitude X_0 will decrease in amplitude over time. Hence, the particle layers should be designed such that $X_0 > X_{\text{opt}}$ holds to ensure an operation within the rolling collect-and-collide motion mode. However, the question arises of how to design the particle layers, i. e. particle mass and clearance h , appropriately.

In the first step, the necessary particle mass needs to be determined. It can be calculated by the desired damping ratio of the structure ζ_d and the effective loss factor, see [9]. However, the effective loss factor is not known and changes over time. Experimental measurements, as discussed later, have shown that an appropriate designed particle damper exhibits an effective loss factor of about $\bar{\eta} = 0.5$ on a large amplitude range. So this is a good starting value for design. The particle mass is obtained to

$$m_{\text{bed}} \approx 2 M \frac{\zeta_d}{\bar{\eta}}. \quad (4)$$

Many experimental measurements, see [8], have shown that a separation of the particle container into at least three layers leads to good damping properties. To ensure a high damping over a large vibration amplitude range, the damper layers should be designed such that

$$\frac{X_0}{X_{\text{opt}}} = \{2, 4, 6\}, \quad (5)$$

see also Fig. 3. Inserting Eq. (5) into Eq. (1) the clearances of the three damper layers are obtained to

$$h = \left\{ \frac{5}{4}, \frac{5}{8}, \frac{5}{12} \right\} \cdot X_0. \quad (6)$$

Hence, starting from an initial vibration amplitude X_0 , the effective loss factors are $\bar{\eta}_0 = \{0.69, 0.38, 0.25\}$ and are increasing as the vibration amplitude decreases until the optimal strokes of the individual damper layers are reached. When the optimal stroke of a layer is reached, the particle bed within this layer switches to the scattered state, and the energy dissipation of this layer reduces dramatically. The three optimal strokes are obtained by Eq. (5) to

$$X_{\text{opt}} = \left\{ \frac{1}{2}, \frac{1}{4}, \frac{1}{6} \right\} \cdot X_0. \quad (7)$$

Hence, the minimum vibration amplitude of the system will be about $X_{\text{min}} \approx \frac{1}{6} X_0$ as for lower vibration amplitudes all three particle layers will be in the scattered state. Hence, only a little amplitude reduction is achieved from that moment. To ensure uniform damping, the particle mass should be distributed evenly over the damper layers. It should be noted that lower vibration amplitudes could be reached if additional damper layers are used with a higher ratio of $X_0/X_{\text{opt}} = 6$. However, for very low vibration amplitudes, the effects of friction or little container tilts are becoming more and more dominant. Hence, additional damping might be hard to realize for very low container amplitudes. See [12] for further details.

To enable the inelastic collision property of the rolling collect-and-collide motion mode, see also Sect. **Motion Modes**, in each particle layer at least three by three particles should be used. To decrease the influence of friction a high particle radius is beneficial. As particle material, steel has been proven to be very durable [9, 12].

Experimental Validation

In the following, the presented design guideline shall be validated experimentally. The used experimental setup is shown in Fig. 4. It consists of a simple beam-like structure with the particle damper mounted at its tip. The elastic length of the steel beam is 512 mm with a rectangular profile of 80 mm \times 2 mm and a Young's modulus of $E = 200$ GPa. The base point of the beam-like structure is fixed and the tip consists of an additional mass and the particle container with a total weight of 1270 g. The particle container is made of polyvinyl chloride (PVC) and has a quadratic cross section with an inner edge width and height of 40 mm and a length L of 120 mm in

excitation direction. The container is separated into three horizontal layers with a height of 11 mm each, as shown in Fig. 4-right. Additionally, the length of each layer can be adjusted by separation walls. The container's velocity is measured using a laser scanning vibrometer, the *PSV-500* from POLYTEC, with a sampling frequency of 250 kHz and integrated internally to obtain the output position. The measurement starts at the first zero crossing of the particle container.

For this system, the mass and stiffness for Eq. (3), follow to $M = 1.058 \text{ kg}$ and $K = 143 \text{ N/m}$. The eigenfrequency of the undamped system is $f_0 = \omega_0/(2\pi) = 1.85 \text{ Hz}$. This numerical obtained eigenfrequency is very close to the experimental measured one with only a difference of 0.02 Hz. The structural damping parameter D is obtained from measurements and is with a value of 0.032 kg/s rather small [8, 10]. All three particle layers are filled with 16 steel spheres of 5 mm radius. Hence, a total particle weight of 196 g is used. To verify Eq. (4) for the necessary particle mass, a damping ratio $\zeta = 0.046$ should be measured with this particle setting. An initial amplitude of $X_0 = -63 \text{ mm}$ with clearances according to Eq. (6) are used, i. e. $h \approx \{80, 40, 25\} \text{ mm}$. The initial acceleration is $A_0 = 8.5 \text{ m/s}^2 < g$. Consequently, the particle bed is in the rolling collect-and-collide motion mode from the very beginning. The three resulting optimal strokes are $X_{\text{opt}} = \{32, 16, 10\} \text{ mm}$. Figure 5 shows the trajectory of the system's tip, i. e. the particle damper, and the hull curve of the undamped system. Additionally, the obtained damping ratios are depicted.

During the first vibration cycle, a damping ratio of $\zeta = 0.035$ is achieved, which increases as the container amplitude decreases. The damping ratio stays high with values around $\zeta \approx 0.046$, i. e. the desired damping ratio. Around the three optimal strokes, i. e. at container amplitudes of $X_c = \{32, 16, 10\} \text{ mm}$, a kink towards lower damping ratios is seen. This happens as here the corresponding particle layer switches into the scattered state, leading to a reduced energy dissipation. For container amplitudes below 11 mm, only very small damping ratios of about $\zeta \approx 0.02$ are achieved. This container amplitude is close to the theoretical minimum value X_{min} with 10 mm. The low damping ratios are achieved for strokes below 11 mm because all three particle layers are in the scattered state from that moment. In summary, for this system, the design guideline has been proven to be very efficient.

Sensitivity analyses: To prove that the design guideline also works efficiently for other systems, the beam-like structure is modified. The same initial amplitude, the same particle mass and the same clearances are used. For the first modification, an additional mass of 942 g is mounted at the tip. Its total mass is hence $M = 2.0 \text{ kg}$. The new eigenfrequency of this system results in $f_0 = 1.35 \text{ Hz}$. Due to the higher system mass, the achievable damping ratio according to Eq. (4) reduces to $\zeta = 0.025$. The experimental results of the container stroke and damping ratios are shown in Fig. 6. The results show the same qualitative behavior as for Fig. 5, but on a larger time scale, due to the higher system mass. The measured damping ratios are around $\zeta \approx 0.025$. Hence, the design guideline works still efficiently for this system.

For a second modification, a different beam is used. This steel beam has the same length but with a rectangular profile of $80 \text{ mm} \times 3 \text{ mm}$ instead of $80 \text{ mm} \times 2 \text{ mm}$. This significantly changes the stiffness to $K = 484 \text{ N/m}$. The system's mass is only a little affected, i. e. $M = 1.108 \text{ kg}$. The system's eigenfrequency follows to $f_0 = 3.33 \text{ Hz}$. Due to the increases eigenfrequency of the system, the acceleration at the initial stroke X_0 increases to $A_0 = 28 \text{ m/s}^2 > g$. This causes the system to be in the bouncing collect-and-collide motion mode first [8]. Here, the particles are flying thru the container instead of rolling. Indeed, the optimal stroke is only little affected as it is achieved to $X_{\text{opt}} \approx 0.32 h$ compared to $X_{\text{opt}} \approx 0.4 h$. The maximum effective loss factor value is $\bar{\eta}_{\text{max}} \approx 1.27$ compared to $\bar{\eta}_{\text{max}} \approx 0.91$. In Fig. 7 the trajectory of the system's tip and the damping ratios are depicted. Again, the results show similar qualitative behavior as for Fig. 5. Although the theoretical maximum effective loss factor is higher, the damping ratios are very similar compared to Fig. 5. Probably, the container layers hinder the deployment of a purely flying particle state. Indeed, this requires further investigations. Still, the design guideline even works well for container accelerations above the gravitational constant.

Conclusion

In this paper, a systematic design guideline for the development of layered particle dampers for low frequency horizontal free vibrations is presented. Hereby, the rolling collect-and-collide motion mode of the particle bed is employed. The particle damper is separated into multiple particle layers and filled with steel spheres. Via the design guideline, the necessary particle mass for the desired damping ratio is determined only based on the structure's mass. A simple analytical equation is given to design the clearances of the different particle layers, i. e. the distances between the particle bed and the opposite container wall.

The efficiency of the design guideline is verified experimentally. A simple beam-like structure is used for this task. The structure is subjected to an initial deflection and the damping ratio of the free vibration is measured. The damping ratios are close to the designed values. Finally, sensitivity analyses are performed by changing either the stiffness of the beam or by adding mass. Either way, the good damping performance is conserved.

Tracing periodic solutions in noise-contaminated experiments

Sandor Beregi, David A. W. Barton, Djamel Rezgui and Simon A. Neild

Faculty of Engineering, University of Bristol, United Kingdom

Summary. In our study, we trace the steady-state solutions of a periodically forced nonlinear oscillator experimentally using control-based continuation. Our investigation is motivated by nonlinear aeroelastic oscillations where the noise load of experiments is often significant due to the unsteady flow in the wake of the vortex-shedding, oscillating bodies. Polluting our experiment with different amount of noise, we evaluate the resilience of the control-based continuation method against random perturbations and assess its capability to retain the response of the underlying deterministic system.

Introduction

Tracing a family of periodic solutions is a long-established area of studying nonlinear systems. For numerical dynamical models, the techniques of bifurcation analysis have become standardised and are available nowadays in several software packages. In experiments however, the steady-state periodic solutions are often traced by performing parameter-sweeps. Although this approach is usually easy to implement it provides limited information from the system as it can capture stable solutions only. Control-based continuation is a technique which implements the ideas of bifurcation analysis in experiments [1]. By applying feedback-control on the system, this method is capable to trace both stable and unstable steady-state periodic oscillations in an experimental setting. To achieve this, a control process is introduced which has to be stabilising and non-invasive, i.e. the steady-state solution of the controlled system is also solution of the open-loop system.

Our study is motivated by examples of aeroelastic oscillations originated in the interaction between inertial, structural and aerodynamic forces. The related vibrations, such as stall flutter of an aerofoil, caused by the periodic detachment and re-attachment of the flow, or the galloping oscillation of blunt elastic structures (e.g. cables) in airflow due to vortex-generation around the body, are substantially nonlinear phenomena. In the literature, several semi-empirical, low-degrees-of-freedom models were developed to investigate these oscillations [2]. Since these models use empirical coefficients there is a great demand for reliable parameter identification methods in this area.

Tracing steady-state solutions in noise-polluted experiments

In experiments, it may be challenging to obtain data which represent the dynamics of the investigated system accurately if the measurements subject to significant noise, as it is often the case with aeroelastic oscillations.

A nonlinear analysis of aeroelastic dynamical models can reveal a rich structure of different steady-state solutions and bifurcations [3, 4]. Nevertheless, in a physical experiment, these oscillations can result in a highly unsteady flow in the wake of the vortex-shedding objects. Thus, one may observe that the magnitude of measurement noise is comparable to the vibration amplitudes. In such conditions, the standard, open-loop parameter-sweeps may not be satisfactory for the characterisation of the system. For instance, in parameter regions with two co-existing stable steady-state solutions, the system may jump repeatedly between the two domains of attraction leading to an incomplete coverage of even the stable solutions [5]. The aim of our study is to demonstrate that tracing the solutions with a control-based method is more resilient against random perturbations than open-loop parameter-sweeps.

Case-study: parameter identification of a forced nonlinear oscillator under noise-load

Figure 1: Left panel: The forced nonlinear oscillator. Right panel: The analogous model of vortex-induced vibrations.

To assess the capability of control-based continuation to deal with measurement noise we traced the steady-state solutions of a periodically forced nonlinear oscillator (see Fig. 1). In the experimental rig, the nonlinearity is primarily provided by the magnets mounted to the end of the elastic plate. As the plate vibrates the magnets are passing before the electromagnetic coil resulting in a nonlinear restoring force. The experiment can also be polluted with additional noise by driving current through the coil; thus, measurements can be conducted at different noise-levels.

This experimental setup may be seen as analogous to vortex-induced aeroelastic vibrations. These vibrations are similar to the galloping phenomenon in a sense that they can be originated in the vortex-shedding behind a blunt object as in the case of bridge cables. However, unlike in case of galloping where the frequency of vortex-shedding is equal to the

Figure 2: Steady-state response of the periodically forced nonlinear oscillator for different forcing amplitude. The blue markers correspond to amplitude-sweeps, the red ones to control-based continuation, respectively. The blue and red curves indicate the response of the fitted model while the dashed orange curve indicates the low-noise response in the panels corresponding to medium and high noise-levels.

vibration frequency, in case of vortex-induced vibrations, the frequency belonging to vortex-generation depends on the Strouhal number of the flow around the aerofoil [3]. Thus, while galloping is essentially considered as a self-excited vibration, vortex-induced vibrations are often modelled as forced nonlinear systems. One example is the semi-empirical model of Goswami et al. [6] given in the form

$$m(\ddot{x} + 2\zeta\omega_n\dot{x} + \omega_n^2x) = F(x, \dot{x}, \ddot{x}, \omega t) \quad (1)$$

where m is the mass of the vibrating object, ω_n is the structural natural angular frequency, ζ is Lehr's damping coefficient whereas the aerodynamic force F contains both the nonlinear and the periodic forcing terms.

Robustness against noise

We traced the S-shaped branch of periodic solutions of the experimental rig at different noise levels by performing both open-loop parameter-sweeps and control-based continuation. The acquired data was then used to identify the parameters of a one-degree-of-freedom Duffing-like oscillator with seventh-order nonlinearity. The results of parameter-sweeps and control-based continuation are compared in Fig. 2. At low noise level, the system can be characterised equally well by both methods. If a medium level of noise (around 25 % of the maximum vibration amplitude) parameter-sweeps begin to lose a part of the stable solutions as the jumps from low to high vibration amplitudes occur earlier than the folds in the low-noise solution branch. In the meantime, control-based continuation is still able to retain the original response reasonably well. However, at high noise levels (about 50 % of the maximum vibration amplitude) even the response curve fitted to the data obtained by control-based continuation visibly deviates from the branch corresponding to low noise. Nevertheless, control-based continuation still performs better as parameter-sweeps scarcely capture the bistable parameter region at this level of noise.

Conclusions

Comparing the response curves, acquired at different noise-levels, indicates that control-based continuation is more resilient against noise than open-loop parameter sweeps. Furthermore, having information about the unstable steady-state solutions of the system is clearly advantageous at nonlinear parameter fitting to noisy measurements. Therefore control-based continuation could be effectively used to investigate nonlinear aeroelastic systems experimentally.

Of course, our experimental rig has a relatively simple bifurcation diagram with only one bistable parameter domain and we also have access to the low-noise system. Consequently, if a more complicated structure of bifurcations is expected, based on deterministic theoretical models, the relationship between the measured and theoretical results may be less straightforward. Therefore, it is interesting to investigate what kind of response one can expect to find in a noise-contaminated measurement and how are the results obtained from the experiment related to the underlying deterministic system [7].

Abstract

In this study, active vibration control of bladed drum (BLUM), which has a high modal density, with piezoelectric patches utilizing decentralized controller evaluated experimentally. BLUM has 76 protruding blades, which create 76 modes in a short interval of frequency named as high modal density. High number of modes in a very short frequency range makes mitigating them quite challenging. In this article, 76 collocated pairs of piezoelectric patches are used to damp the vibration of these modes. These modes relate to the displacement of the blades. Therefore, piezoelectric patches are used as sensor to measure the displacement of each blade. Then the collocated actuator piezoelectric patch applies a force in a reverse direction to reduce displacement of the blade, actively. In order to avoid to cause any disturbance for air flow around the blades, the piezoelectric patches are glued in the bottom groove of BLUM where there is no air flow. The blades of BLUM are inclined and in order to increase the performance of the system, the piezoelectric patches are produced in a trapezoidal shape which will increase the control authority of system. 76 Open loops are extracted and an IFF controller is designed to implement in a decentralized manner. 76 pairs of piezoelectric patches are glued on the structure and connected to the connector board. Also, a circuit is designed and produced based on the controller's transfer function to apply on the setup in a decentralized way. The 76 controller boards are connected to the connector board to control the structure's vibration. The structure is excited by the acoustic speakers in the frequency band which the first family mode exists. The structure displacement is measured by a laser vibrometer. The performance index of system shows that in the controlled condition all of 76 modes in the first family mode are damped remarkably.

Summary. The aim of this contribution is to review and compare three different methods that have been proposed in order to derive reduced-order models for geometrically nonlinear structures, and relying on a nonlinear technique to better take into account the nonlinearities of the initial problem. The three methods are: implicit condensation, quadratic manifold derived with modal derivatives, and projection onto an invariant manifold, tangent at the origin to the linear eigenspace of the master modes. The methods are briefly reviewed theoretically and then compared with dedicated examples.

Nonlinear techniques for model-order reduction

In the realm of reduction methods for geometrically nonlinear structures, numerous methods have already been proposed in the past, and one can roughly divide the methods according to the fact that they use either a linear or a nonlinear change of coordinates. Among the linear methods, the POD is well-established and has been used for a long time. For the nonlinear techniques, the review paper [1] proposes an overview with applications to finite element (FE) problems.

When referring to vibrating structures discretized by the FE method, mainly three different nonlinear techniques have been proposed in the last years: implicit condensation (IC), quadratic manifold derived with modal derivatives (QM), and the direct parametrisation method for invariant manifolds, giving rise to either graph style or normal style solutions.

The implicit condensation is a non-intrusive method that can be used with any FE code. It relies on applying a series of static loads, having the shape of the selected master modes, to the structure; and retrieving the associated nonlinear displacements [2]. From this set that creates a stress manifold [3], a fitting procedure is derived in order to get the nonlinear restoring force of the master coordinates, which takes implicitly into account the non-resonant coupled modes in a static manner [2, 4].

The quadratic manifold method with modal derivatives have been introduced with the aim of proposing a nonlinear change of coordinates, directly applicable from the FE nodes of a mesh [5]. The main idea is to embed the modal derivatives, earlier defined in order to take into account the amplitude dependence of a mode when the nonlinearities are taken into account, as the quadratic component of the nonlinear mapping. The Galerkin projection is then used to compute the reduced dynamics from the nonlinear mapping.

The invariant manifold approach relies on firm theoretical results from dynamical systems theory. The main idea is to use an invariant manifold that is tangent to the master modes of interest at the origin, in order to obtain a rigorous computation of the amplitude dependence. Whereas the idea has been first introduced by Shaw and Pierre in the 90s [6], later embedded in the normal form theory in order to define nonlinear mappings [7], recent contributions tackled the problem of uniqueness by introducing spectral submanifolds (SSM) [8], as well as using the parametrisation method for invariant manifolds [9] in order to unify the previous derivations in the same settings, allowing one to select either a graph style solution or a normal form approach. However, until recently, the direct application of these methods to FE problems still remained difficult since the derivations assumed the problem expressed in the modal basis as a starting point. Recent contributions overcame this issue, by proposing a direct computation of the reduced dynamics, from the FE nodes to the invariant-based span of the phase space, thanks to dedicated nonlinear mappings, see *e.g.* [10, 11, 12].

Comparisons

Theoretical results

The three reduction methods have been compared in details in the following references [13, 4, 14]. In particular, it has been clearly demonstrated that both IC and QM methods needs a slow/fast assumption in order to propose accurate predictions. By slow/fast separation, it is meant that the eigenfrequencies of the slave modes needs to be larger than those of the master modes. This frequency gap has been estimated in [4, 14] to be around 4, based on the hardening/softening prediction of a single mode reduction. As a matter of fact, this limitation of these two methods comes from their derivation, which is static in nature and neglects important dynamical couplings. In particular, both IC and QM methods are neglecting the velocity dependence in the proposed nonlinear mappings, which then creates important limitations and the need to have this slow/fast separation [4, 14, 1]. As underlined for example in [1], when taking back the velocity dependence in the nonlinear mapping proposed in the QM method, then one recovers the more complete change of coordinates proposed with a direct normal form approach as proposed in [10].

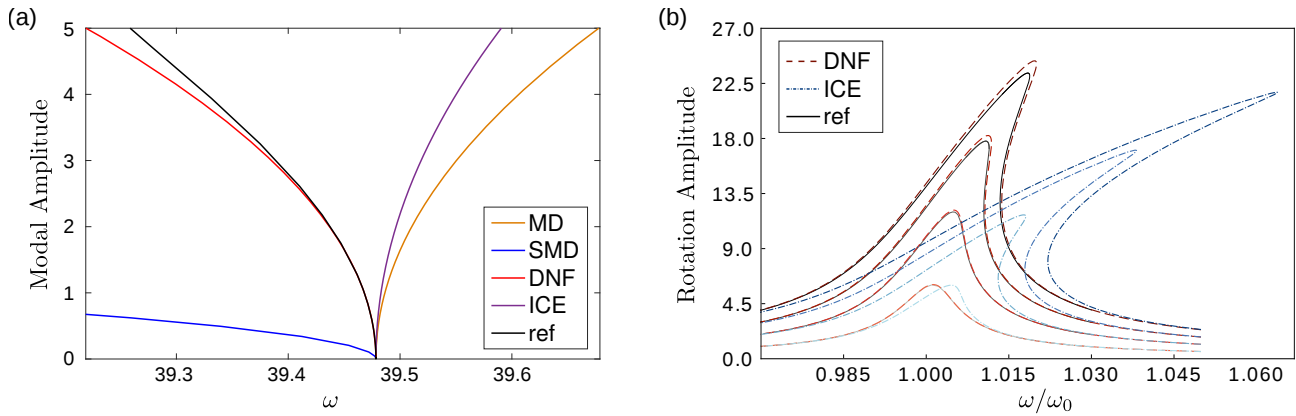

Figure 1: (a) Backbone curves for a linear beam resting on an elastic foundation, comparison between QM methods with either full modal derivatives (MD) or static modal derivatives (SMD), Implicit condensation (ICE), and direct normal form (DNF). Reference solution in black. (b) Comparison between Implicit condensation (IC), direct normal form (DNF) and full-order solution for a MEMS micromirror.

Numerical results

Two different numerical results are reported for the sake of illustration. The first case consists in computing the backbone curve of a linear beam resting on a nonlinear elastic foundation with reduction to a single master mode. The results are shown in Fig. 1(a), highlighting that in such a case, only the solution based on invariant manifold theory is able to correctly reproduce the softening behaviour [15]. The second example is that of a MEMS (Micro Electro Mechanical System) micromirror, discretized with 3D block elements. The mesh has 15 341 nodes. Fig. 1(b) highlights that the IC method overpredicts the hardening behaviour of this structure [16].

Summary. This paper presents a general methodology to obtain a reduced order model (ROM) of geometrically nonlinear electro-mechanical structures with piezoelectric transducers. A standard modal reduction is used and the ROM is built using a finite-elements software thanks to a non-intrusive strategy. In this context, this article focuses first on the validation of the proposed reduced order modelling strategy, especially for the piezoelectric part of the ROM, and second to the use of three-dimensional finite elements and associated convergence issues.

Figure 1: (left) Photograph of two examples of piezoelectric thin structures: a circular plate with eight piezoelectric patches and a micro-plate with two annular piezoelectric patches. (right) cutaway view of the microplate, showing its laminated structure

Geometrical nonlinearities, due to large transverse displacements of thin structures, are encountered in a large range of applications, as long as the thickness of the structure is small corresponding to the other dimensions. On the other hand, the use of piezoelectric materials to actuate or/and sense the vibrations is also widely spread. Applications, among others, range from vibration control [3, 11] to Micro/Nano-Electro Mechanical Systems (M/NEMS) developments, whose purpose can be to master and use the geometrically nonlinear behaviour [12, 14, 10]. This paper focuses on the numerical computation of the frequency response, in the frequency domain, of structures with geometrical nonlinearities and equipped with piezoelectric patches. Recent advances in non-intrusive reduced-order finite element modeling of nonlinear geometric structures offer new perspectives for massive nonlinear prediction in structural computation [7]. An application on piezoelectric nanobridges of such a method has been proposed in [6, 15]. Apart those two references, to the knowledge of the authors, the case of both geometrical nonlinearities and piezoelectric electromechanical coupling has been scarcely considered in the past literature. The purpose of this paper is to fill this gap and to propose a non intrusive method able to efficiently compute the coefficients of a modal reduced order model, taking into account both the geometrical nonlinearities and the direct and converse piezoelectric couplings.

Common architectures of thin structures with piezoelectric layers (see examples on Fig. 1) are often laminated, such as beams with complex cross section [13] and laminated beams/plate structures [2, 4, 1]. When modelling such a structure in a finite-element context, one can consider equivalent single layer theories [9, 6] or simply use three-dimensional finite elements (3DFE). Because in our case some layers of the structure are piezoelectric, in most of the cases, only 3DFE are available in commercial codes. In this article, we will consider both approaches.

We consider an elastic structures with P piezoelectric patches discretized by the finite-elements method. The vector containing the mechanical degrees of freedom is denoted by $U(t)$ and $V^{(p)}$ denotes the voltage across the terminals of the p -th. piezoelectric patch. As shown in [6], considering a modal expansion of $U(t)$ on K modes (Φ_k, ω_k) of the structure with all piezoelectric patches short circuited, $U(t) = \sum_{k=1}^K \Phi_k q_k(t)$, one obtains the following system of equations for the modal coordinates $q_k(t)$ and the voltages $V^{(p)}$, $\forall k = 1, \dots, K, p = 1, \dots, P$:

$$\begin{cases} \ddot{q}_k + 2\xi_k \omega_k \dot{q}_k + \omega_k^2 q_k + \sum_{i,j=1}^K \beta_{ij}^k q_i q_j + \sum_{i,j,l=1}^K \gamma_{ijl}^k q_i q_j q_l + \sum_{p=1}^P \chi_k^{(p)} V^{(p)} + \sum_{p=1}^P \sum_{i=1}^N \Theta_{ik}^{(p)} q_i V^{(p)} = F_k, & (1a) \\ C^{(p)} V^{(p)} - \sum_{k=1}^K \chi_k^{(p)} q_k - \sum_{i,j=1}^K \frac{1}{2} \Theta_{ij}^{(p)} q_i q_j = Q^{(p)}. & (1b) \end{cases}$$

In the above equations, three independent groups of term can be identified. First, the geometrical nonlinearities create quadratic and cubic terms in q_k with coefficients β_{ij}^k and γ_{ijkl}^k . Secondly, the piezoelectric linear coupling creates two terms of coefficients $\chi_k^{(p)}$, which correspond to the exchange of energy between the k -th. vibration mode and the p -th. piezoelectric patch. Then, both geometrical nonlinearities and piezoelectric coupling are responsible of additional coupling terms, of coefficient $\Theta_{ij}^{(p)}$, not symmetric because of the $1/2$ factor in the second equation. In addition, $C^{(p)}$ is the electric capacitance of the p -th. patch, F_k is the mechanical forcing and $Q^{(p)}$ is the electric charge contained in one of the electrodes of the p -th. patch.

In this context, this article has several purposes. First, it will be shown that it is possible to extend a particular non intrusive method, the so-called stiffness evaluation procedure (STEP), relying on the static application of prescribed displacements and introduced in [8], to compute the piezoelectric coefficients $\chi_k^{(p)}$ and $\Theta_{ij}^{(p)}$ using a commercial code in a non intrusive way. Then, even if the STEP has been validated in many articles in the past (see [5] and reference therein) to compute the geometrically nonlinear part of the ROM (the quadratic and cubic terms with coefficients β_{ij}^k and γ_{ijkl}^k), it will be shown that using 3DEF is not as straightforward as it could appear at first and that it conducts to strange behaviours of slow convergence as a function of the number K of modes retained in the expansion basis, much slower than in the case of the use of plate or shell two-dimensional finite-elements. Finally, the computation of the coupling coefficients $\chi_k^{(p)}$ and $\Theta_{ij}^{(p)}$ will be validated with comparison to an analytical reference model of a three layers hinged hinged beam with two collocated piezoelectric patches.

Summary. In this contribution we present a method to directly compute asymptotic expansion of invariant manifolds of large finite element models from physical coordinates and their reduced order dynamics on the manifold. We show the accuracy of the reduction method on selected models, exhibiting large rotations and internal resonances. The results obtained with the reduction compared to full-order harmonic balance simulations show that the proposed methodology can reproduce extremely accurately the dynamics of the original systems with a very low computational cost.

Introduction

Slender structures in large amplitude vibration exhibit geometric nonlinear effects that modify their dynamics. To accurately model structures with complex geometries, large finite element models with a high number of degrees of freedom are often required. Numerically, the geometric nonlinear forces affect all the elements in the structure thus making the simulation of such problems very demanding in terms of computational cost. Reduced order models of geometrically nonlinear structures are then an attractive solution to drastically reduce the size of the problem whilst maintaining the accuracy.

In damped systems, slow invariant manifolds are low-dimensional attractors for the dynamics of high-dimensional nonlinear systems, and therefore represents the ideal candidate for model order reduction. However, their computation was until very recently limited to small system written in modal coordinates [?]. Recent developments by the authors [2-4] have proposed the Direct Parametrisation of Invariant Manifolds method (DPIM) to compute invariant manifolds directly in physical coordinates, thus extending the applicability of said model order reduction strategy to large FE structures. A similar work is done in [5].

Direct parametrization of Invariant Manifolds (DPIM)

Mechanical structures in large deformations display geometric nonlinearities in the form of quadratic and cubic restoring forces. When discretised with the finite elements method, the dynamics of such structures can be written as a system of N ordinary differential equations in time, with N the number of degrees of freedom:

$$M\ddot{\mathbf{U}} + C\dot{\mathbf{U}} + \mathbf{KU} + \mathbf{G}(\mathbf{U}, \mathbf{U}) + \mathbf{H}(\mathbf{U}, \mathbf{U}, \mathbf{U}) = \mathbf{0} \quad (1)$$

Invariant manifolds tangent to a given linear *master* subspace of the system are computed as an arbitrary order (o) asymptotic expansion of the physical coordinates \mathbf{U} in terms of the so-called *normal* coordinates \mathbf{z} , which are tangent to the linear modal coordinates of the selected *master* mode:

$$\mathbf{U} = \sum_{p=1}^o \Psi^{(p)}(\mathbf{z}) \quad (2)$$

The reduced dynamical model, which represents the dynamics on the computed manifold, is also built as a polynomial function of the normal coordinates in first-order form:

$$\dot{\mathbf{z}} = \sum_{p=1}^o \mathbf{f}^{(p)}(\mathbf{z}) \quad (3)$$

The coefficients of the change of coordinates Ψ and reduced dynamics \mathbf{f} are then found iteratively order by order by assembling a so-called homological equation for each monomial in \mathbf{z} , which results in the solution of a series of $N \times N$ linear system of equations.

Numerical Results

Since each homological equation is underdetermined, different styles of parametrisation can be chosen by selecting appropriate resonance conditions, namely the Real Normal Form style (RNF), the Complex Normal Form style (CNF), and the Graph style [3]. The main difference between Normal Form styles and the Graph style is that in the former the manifold is parametrised as an embedding, whereas in the latter it is parametrised as a graph. In most cases, the results provided by each style are very similar but in case the computed manifold presents a folding, the graph style would diverge in

the vicinity of the folding point [6]. Physically, the folding of an invariant manifold can be seen as the point where the nonlinear mode becomes less and less represented by its linear counterpart, at a level such that as the nonlinear modal amplitude continues increasing, then the linear one starts to decrease.

The first nonlinear mode of a cantilever beam is studied here, and it is shown in Fig. 1 that the graph style fails at representing the full system dynamics when the amplitude of oscillations has order of magnitude comparable to the beam length. This failure can be observed both in the non-physical softening effect in the backbone curve and in the divergence of the invariant manifold. On the other hand, both normal form styles can perfectly reproduce the folding in the manifold and the backbone curves obtained with these styles are perfectly overlapped with that obtained from continuation of the full order model, up to very large amplitude oscillations. This exemplifies how powerful the method is in perfectly reproducing the dynamics of a large finite element system with a single oscillator reduced order model.

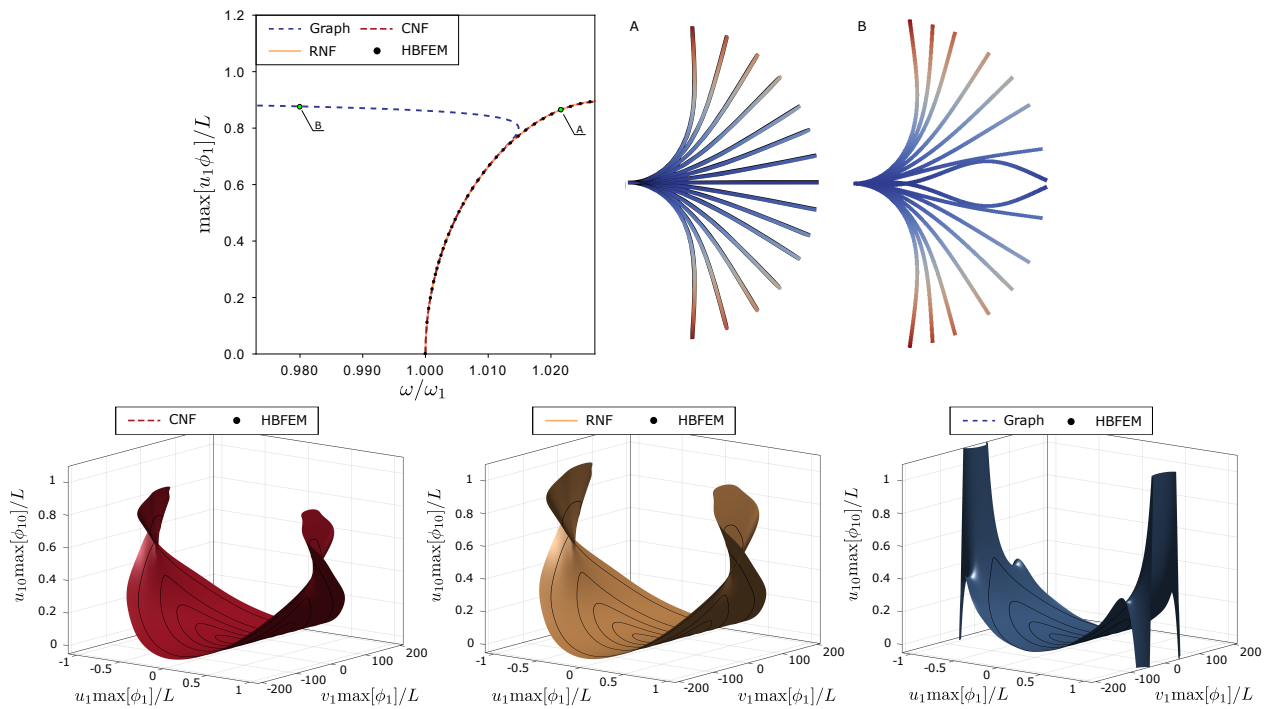

Figure 1: Model reduction of the first nonlinear mode of a cantilever beam up to large amplitude vibration. Backbone curves (top left), reconstruction of reduction at point A and B along the backbone curves (top right), and invariant manifolds (bottom). Three different parametrization styles are used, and the full order model solution is obtained with harmonic balance method (HBFEM)

Conclusions

Nonlinear modes have become an essential tool for engineers in that they provide crucial insights on the dynamics of structures. The computation of nonlinear modes and their associated invariant manifolds for model order reduction is of utmost importance for modern industry. In this respect, the extension of nonlinear modes calculations to large scale finite element models is a critical issue that will allow the use of this tool in industrial scale problems. The method proposed here is based on a classical asymptotic expansion of invariant manifolds, but its computation is adapted to the case of FE models with a high number of degrees of freedom. The rigorous mathematical foundation of the method coupled with a thoughtful implementation make it extremely accurate and fast, thus making it the ideal candidate for reduced order modelling of geometrically nonlinear structures in an industrial framework.

Data-driven aerodynamic models for reduced-order aeroelastic simulations

Dávid András Horváth, János Lelkes

Budapest University of Technology and Economics, Faculty of Mechanical Engineering, Department of Fluid Dynamics, Budapest, Hungary

Summary. Time-dependent aerodynamic loads of thin elastic structures subjected to airflow can be calculated by numerous methods. Analytical, semi-empirical, reduced-order, and CFD-based models can be utilized to calculate the aerodynamic loads. Calculations of the aerodynamic loads are influenced by nonlinear aerodynamic effects for large deformations of the elastic structure, such as dynamic stall, hysteresis, and vortex formation. In this work, the applicability and accuracy of a data-based identification method for calculating the aerodynamic loads in the time domain are investigated. To create the data-based model, high precision validated CFD simulations were used. The model was constructed using the SINDy (Sparse Identification of Nonlinear Dynamics) algorithm. After the initial data fitting process, the reduced-order aeroelastic simulations with the identified aerodynamic models run up to five magnitudes faster than classical high precision FSI simulations. The most significant advantage of this method is that it can be applied to a large variety of different geometries, and it is also accurate for large deformations and large angles of attack in the nonlinear aerodynamic regime.

Introduction

Obtaining accurate and efficient aerodynamic models has been a fundamental goal of research efforts in aeronautics over the past century [1]. Aerodynamic models are essential for designing aircrafts [2], building large span elastic bridges [3]. Accurate aerodynamic models are used to evaluate static and dynamic aeroelastic stability and develop feedback control laws for aircraft. Closed-form solutions for the attached incompressible unsteady flow problem around a two-dimensional (2D) airfoil exist in both the frequency and time domains [4]. However, these models do not provide acceptable results in the case of rapid oscillations and high angles of attack.

Semi-empirical models such as ONERA and Leishman-Beddoes can be used to approximate the aerodynamic nonlinearity caused by the dynamic stall and flow separation. Lelkes and Kalmár-Nagy modeled the aerodynamic forces for large angles of attack as a piecewise linear function, which was able to capture the phenomenon of dynamic stall [5].

Considering machine learning advancements, developing reduced-order models based on data obtained from measurements or numerical simulations began to gain popularity recently [6]. An overview of data-driven methods in aerospace engineering is given by Brunton et al. [7]. In the work of Pohl et al. [8] the SINDy method is used to derive polynomial models for the lift of an airfoil.

In this paper, the Sparse Identification of Nonlinear Dynamics (SINDy) method [9] is applied to create accurate aerodynamic models of a simple flat plate subjected to airflow using data obtained from CFD (Computational Fluid Dynamics) simulations.

Sparse Identification of Nonlinear Dynamics (SINDy)

In this paper, we use the Sparse Identification of Nonlinear Dynamical systems (SINDy) method, introduced by Brunton et al. [9, 10], and later refined in the work of Champion et al. [11]. An overview of the method and the description of the Python package that is used in our paper is given by Silva et al. [12]. Sparse Identification of Nonlinear Dynamics is a method based on representing the model as a system of possible nonlinear ordinary differential equations, whose right side can be written as a linear combination of some elementary functions [9]. Then a sparsity promoting regression is applied to determine the coefficients, resulting in easily interpretable models with only a few active terms. Physical constraints can be easily incorporated by constraining the regression procedure.

The LASSO and the STLSQ optimization method have been used for the regression. These methods have l_1 and l_2 regularized objective functions, respectively. The STLSQ procedure incorporates an adjustable threshold, any coefficient below this threshold is neglected. Then the regularization is repeated again for some iterations. The norms are defined as

$$l_1(\mathbf{x}) = \sum_{i=1}^n |x_i|, \quad (1)$$

$$l_2(\mathbf{x}) = \sqrt{\sum_{i=1}^n (x_i)^2}. \quad (2)$$

Using the formulas (1) and (2), the objective functions for the LASSO and STLSQ optimization procedure are respectively:

$$\frac{1}{2n} \|\mathbf{y} - \mathbf{X} \mathbf{w}\|_2^2 + \lambda \|\mathbf{w}\|_1, \quad (3)$$

$$\frac{1}{2n} \|\mathbf{y} - \mathbf{X} \mathbf{w}\|_2^2 + \lambda \|\mathbf{w}\|_2^2. \quad (4)$$

To determine the hyperparameters, the Optuna [13] package was used. Using this package, a multiobjective optimization was performed with the objectives defined as the error of the integrated model and the number of terms. So-called Pareto-optimal hyperparameter groups were determined. This means that for a given group, there are no other groups, which would result in an improvement over both objectives. This way, multiple models can be chosen, depending on the needs of the given task.

Identified models

The CFD simulations that the models have been trained on were obtained by prescribing a sinusoidal oscillation for the pitch (α) or the plunge (h) motion of the flat plate wing, with a 1m chord length. During the simulations we prescribed the motion in the following form

$$\alpha(t) = \alpha_{amp} \cos(\omega t), \quad h(t) = h_{amp} \cos(\omega t), \quad (5)$$

where α_{amp} and h_{amp} are the oscillation amplitudes, and ω is the angular frequency of the oscillation.

Data were obtained for three oscillation amplitudes and frequencies of the pitching and plunging motion, resulting in 18 different time series of the aerodynamic lift coefficient. The details of the CFD simulations are described in [14, 15].

Three models were identified, one for each frequency. The frequency was nondimensionalized; the resulting reduced frequency is defined as $k = \frac{\omega b}{U}$, where b is the half chord length, U is the wind velocity, and ω is the angular frequency of the oscillation.

The aerodynamic model equations were created by using the state variables $\alpha, \dot{\alpha}, C_{L\alpha}, h, \dot{h}, C_{Lh}$. The Reduced-Order Models (ROMs) of the pitch $C_{L\alpha}$ and the plunge C_{Lh} induced lift coefficients are

$$\dot{C}_{L\alpha}(\alpha, \dot{\alpha}, C_{L\alpha}; k) = a_1(k)\alpha + a_2(k)\dot{\alpha} + a_3(k)C_{L\alpha} + a_4(k)\alpha^2 + a_5(k)\alpha\dot{\alpha} \dots, \quad (6)$$

$$\dot{C}_{Lh}(h, \dot{h}, C_{Lh}; k) = b_1(k)h + b_2(k)\dot{h} + b_3(k)C_{Lh} + b_4(k)h^2 + b_5(k)h\dot{h} \dots, \quad (7)$$

where a lexicographic ordering was used for the coefficients $a_i(k)$ and $b_i(k)$, which are listed in Table 1 and 2. We assume that the total lift coefficient C_L is the sum of the pitch and the plunge induced lift coefficients, i.e.,

$$C_L = C_{L\alpha} + C_{Lh}. \quad (8)$$

Reduced frequency	a_1	a_2	a_3	a_{11}	a_{16}	a_{19}	a_{35}	a_{50}
$k = 0.1$	0.213	5.42	0	249	0	0	-665.76	$-1.52 \cdot 10^6$
$k = 0.2$	12.2	0	-2.70	0	0	0.799	0	0
$k = 0.5$	4.01	6.32	-1.34	0	-56.5	0.463	0	0

Table 1: The coefficients of the pitch reduced-order model (Eq. (6)).

Reduced frequency	b_1	b_2	b_3	b_9	b_{35}	b_{50}
$k = 0.1$	-0.172	2.874	-0.398	0	0	0
$k = 0.2$	-0.715	2.33	-0.34	0	0	0
$k = 0.5$	-6.47	6.43	-1.6	-0.033	14113	23599

Table 2: The coefficients of the plunge reduced-order model (Eq. (7)).

We determined the Normed Root Mean Squared Error (NRMS) of the aerodynamic models using the formula

$$\text{NRMS}_{C_L} = \frac{1}{C_{Lmax} - C_{Lmin}} \sqrt{\frac{\sum_{i=1}^N (C_L - \hat{C}_L)^2}{N}}, \quad (9)$$

where N is the number of data points, C_L is the CFD simulation data, \hat{C}_L is the predicted value by the ROM simulation, C_{Lmax} is the maximum, while C_{Lmin} is the minimum value of the CFD simulation data. The NRMS for the three pitch and three plunge models can be found in Table 3 and 4, respectively.

For the reduced frequency $k = 0.1$, the lift coefficients from the CFD simulation and the fitted model as the a function of the angle of attack for oscillation amplitudes $\alpha_{amp} \in \{2^\circ, 5^\circ, 10^\circ\}$ are shown in Figure 1.

Figure 1: Comparison of the identified ROM with the CFD simulation for $k = 0.1$ and $\alpha_{amp} \in \{2^\circ, 5^\circ, 10^\circ\}$.

Figure 2 illustrates the comparison of the identified ROM with the CFD simulation for $k \in \{0.1, 0.2, 0.5\}$ and $\alpha_{amp} = 10^\circ$. It can be observed that the models provide a very good fit overall, can reproduce the nonlinear behavior associated with the high angle of attack and high-frequency oscillations.

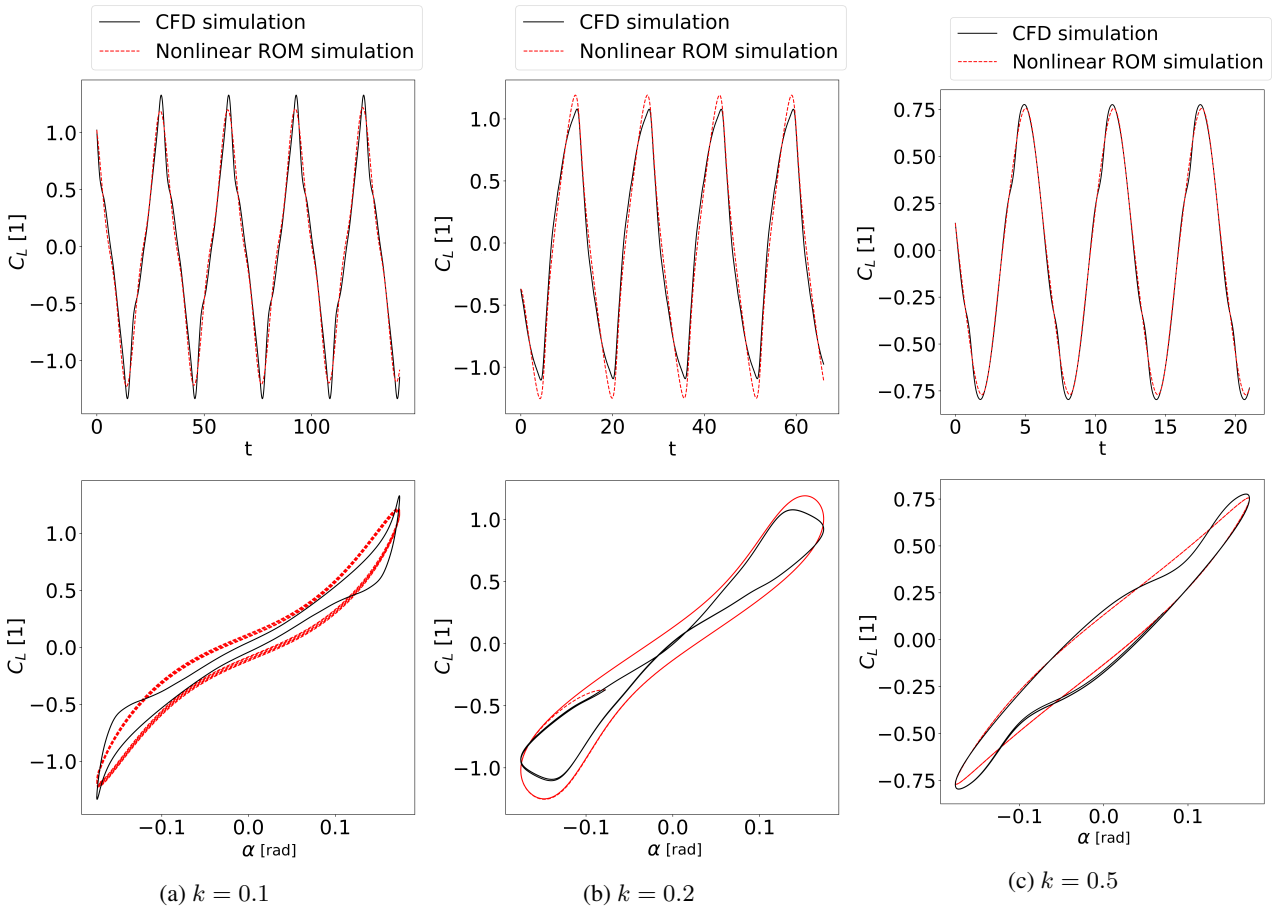

Figure 2: Comparison of the identified ROM with the CFD simulation for $k \in \{0.1, 0.2, 0.5\}$ and $\alpha_{amp} = 10^\circ$.

For the reduced frequency $k = 0.1$, the lift coefficients from the CFD simulation and the fitted model as a function of the plunge displacement for oscillation amplitudes $h_{amp} \in \{0.02\text{m}, 0.05\text{m}, 0.10\text{m}\}$ are shown in Figure 3. For the low reduced frequency $k = 0.1$, the reduced-order model gives an almost perfect fit.

Figure 3: Comparison of the identified ROM with the CFD simulation for $k = 0.1$ and $h_{amp} \in \{0.02\text{m}, 0.05\text{m}, 0.10\text{m}\}$.

Figure 4 illustrates the comparison of the identified ROM with the CFD simulation for $k \in \{0.1, 0.2, 0.5\}$ and plunge amplitudes $h_{amp} = 0.1\text{m}$. It can be observed that the models provide a very good fit overall, can reproduce the nonlinear behavior associated with the high plunge amplitudes and high-frequency oscillations.

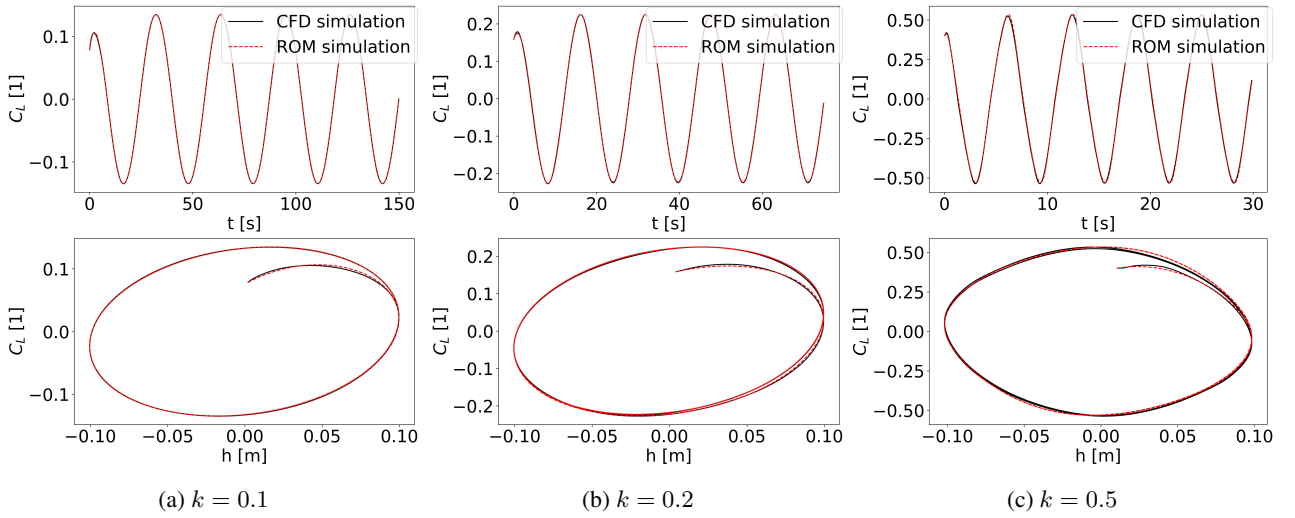

Figure 4: Comparison of the identified ROM with the CFD simulation for $k \in \{0.1, 0.2, 0.5\}$ and $h_{amp} = 0.10\text{m}$.

Oscillation amplitude	Model for $k = 0.1$	Model for $k = 0.2$	Model for $k = 0.5$
2°	2.53%	1.88%	1.66%
5°	2.45%	2.25%	0.94%
10°	3.44%	4.62%	1.61%

Table 3: The NRMS values of the identified aerodynamic models for the pitching motion.

Oscillation amplitude	Model for $k = 0.1$	Model for $k = 0.2$	Model for $k = 0.5$
0.02m	0.46%	0.67%	4.73%
0.05m	0.4%	0.65%	4.13%
0.10m	0.36%	0.65%	0.89%

Table 4: The NRMS values of the identified plunge aerodynamic models.

Performance of the models for coupled pitch and plunge motions

To check the accuracy of the identified models, we have run coupled pitch and plunge motion simulations. We defined the following coupled motion

$$\alpha(t) = \alpha_{amp} \cos(\omega t), \quad h(t) = h_{amp} \cos(\omega t + \phi), \quad (10)$$

where ϕ is the phase between the motions of the pitch and plunge.

In Figure 5 the comparison is shown between the CFD simulation, and the identified ROM model for $k = 0.1$, $\alpha_{amp} = 10^\circ$, and $h_{amp} = 0.1\text{m}$ for three different phase shift values. Both the combined pitch-plunge model and also the pitch-only model is shown. It can be observed that the combined model can capture the nonlinear aerodynamic forces for the coupled pitch and plunge motion. Using the combined model, the error in the maximum value of the lift is reduced by up to 87%. The NRMS values of the combined model for the three test cases were under 5%.

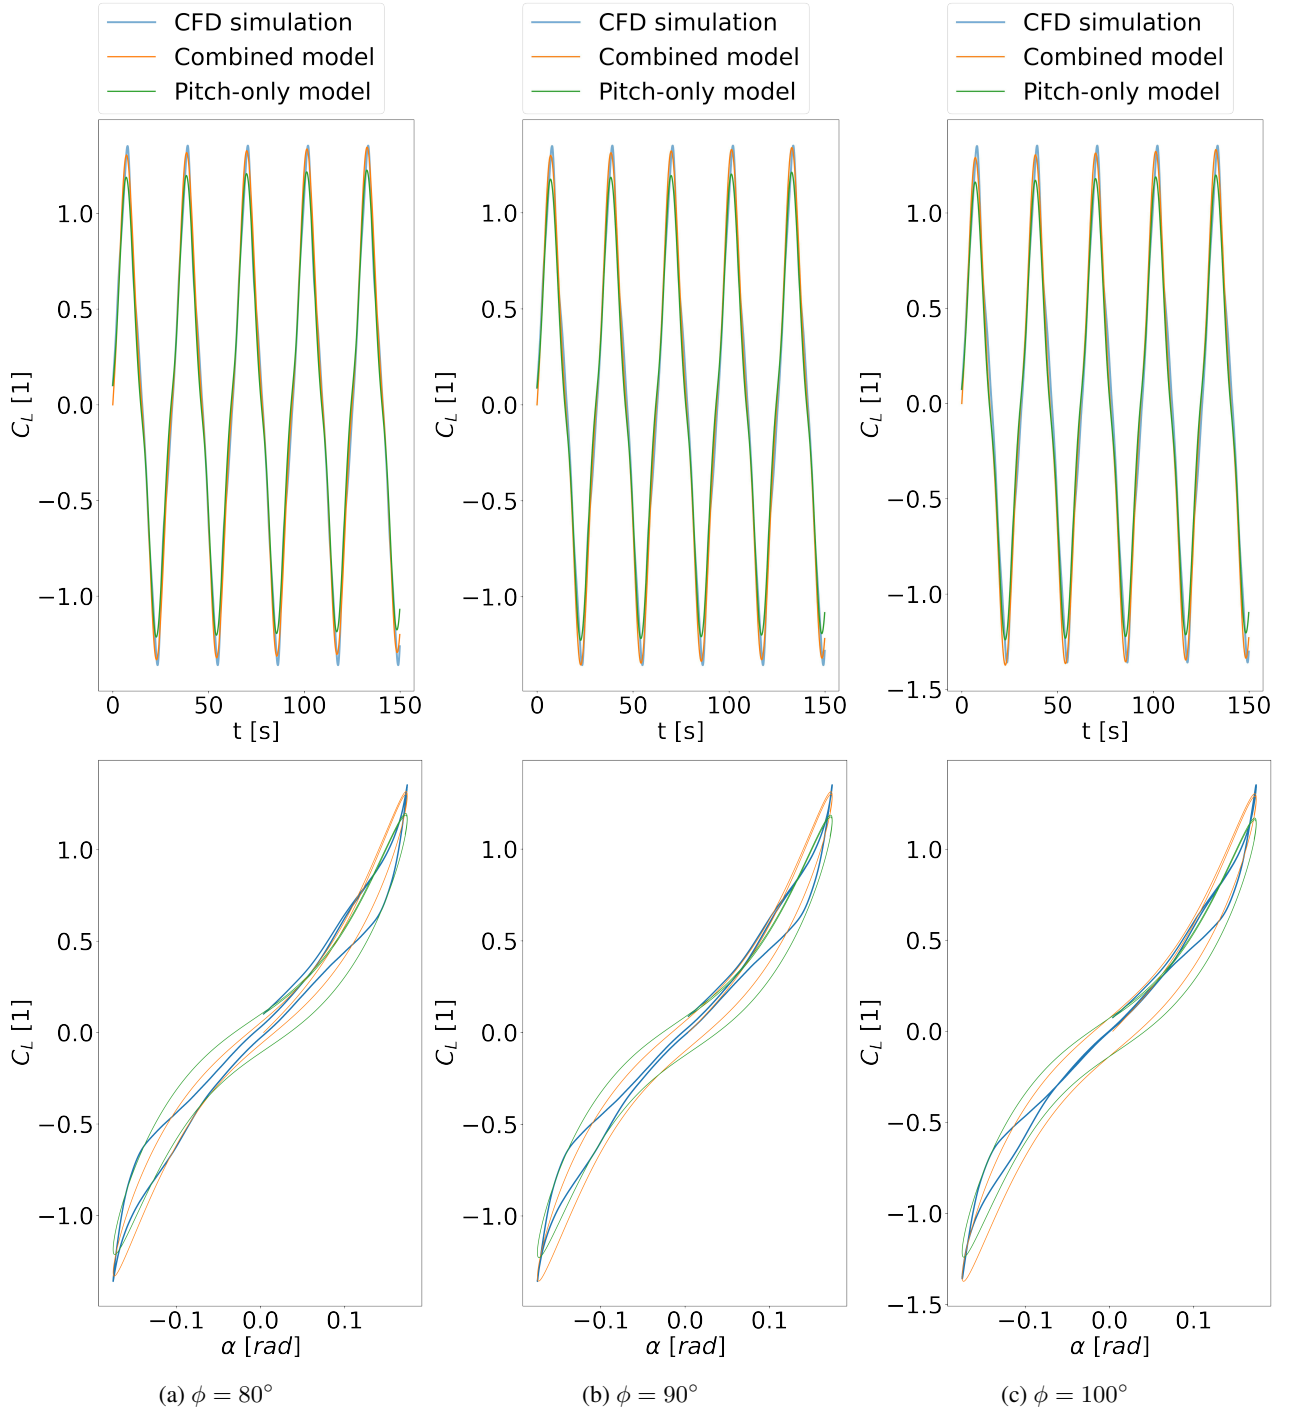

Figure 5: Comparison of the identified ROM with the CFD simulation for $k = 0.1$, $\alpha_{amp} = 10^\circ$, and $h_{amp} = 0.1\text{m}$.

Conclusions

The significant problem of creating reduced-order models for aerodynamic loads, valid for large amplitude, and frequency oscillations, was studied. The SINDy method was utilized to extract the governing differential equation of the aerodynamic lift coefficient from CFD data of a flat plate with pitching and plunging motion. This method resulted in easily interpretable, simple models. It was shown that the identified models for one particular frequency show excellent agreement with the CFD simulation data for varying amplitude oscillations. The future goal of this research is to couple the created aerodynamic model to the structural dynamical model of a flexible plate subjected to airflow.

Development and Parameter Estimation of a Low Order Model of a Hyperelastic Plate Exhibiting 2:1 Resonant Response

Nizar Jaber¹, Nasir Bilal², and Anil Bajaj²

¹Department of Mechanical Engineering and the Center for Communication Systems and Sensing, King Fahd University of Petroleum and Minerals, Dhahran, 31261, Saudi Arabia

²School of Mechanical Engineering, Purdue University, West Lafayette, IN 47907, USA

Summary. This work presents results of experimental investigation and a low-order model development for resonant complex dynamics of a cantilever macro-plate. The plate is fabricated from a ‘hyperelastic’ material using 3D printing technology. The geometry of the plate with cut-outs is optimized such that the second linear bending mode frequency ω_{02} is nearly twice the linear first twisting mode frequency ω_{11} . Based on the observed 2:1 resonant response under harmonic excitation near ω_{02} , a low-order 2 DOF dynamic model is developed to simulate the plate response. The unknown model parameters are extracted using Harmonic Balance solutions and curve fitting techniques. A good agreement is observed between the analytical and the experimental results for different excitation levels.

Introduction

Modal coupling and their influence on system response continues to attract much interest and has been the subject of several review papers that study the influence of mode interactions on different structures from the macro to the micro scale and their potential applications [1]. Internal resonance is among the primary nonlinear coupling mechanisms between the different modes of vibration which can be triggered when the ratio between the frequencies of coupled modes is commensurate and the directly excited response amplitude exceeds a certain threshold [1]. Parameter estimation techniques have received significant attention for developing models that can predict the complex dynamics of a structure under loading conditions that are difficult to test experimentally [2]. Most of the prediction techniques rely on error minimizing algorithms that minimize the difference between predictions of the analytical model and the experimental results. Conventionally, one system state is experimentally measured, and the other states are derived using numerical integration or differentiation techniques which amplify noise at low or high frequency. Processing the signal to reduce the high frequency noise might remove the response at higher harmonics and also introduce aliasing in the data [2]. Frequency response approach based on curve fitting eliminates the issues associated with signal processing but requires more theoretical effort and a comprehensive understanding of the system model and the effects of different coefficients on the response [2]. In this work, the plate geometry, Fig. 1a, is designed following the topology optimization procedure described in [3] such that for the cantilever plate, the second bending mode ω_{02} (71 Hz) and the first twisting mode ω_{11} (35.5 Hz) are in 2:1 ratio. The plate is fabricated using 3D printing technology from a hyperelastic material thus incorporating material nonlinearity. To study the plate dynamics, a TIRA shaker is used to actuate the plate at different acceleration levels and a laser Doppler vibrometer is used to record the response.

Figure 1: (a) The dimensions of the optimized plate are in millimeters showing the laser measurements point. Plate thickness = 1.27 mm. (b) The FFT of the impulse response showing the first three modes of vibration (insets: Corresponding mode shapes).

Results and discussion

To capture the modal interaction of the two modes in the cantilever plate response, two coupled oscillators described by generalized coordinates $u(t)$ and $v(t)$ are considered. The directly driven mode $u(t)$ is modeled as nonlinear oscillator with linear natural frequency ω_{02} along with cubic $\alpha_c u^3(t)$ and quadratic $\alpha_q u^2(t)$ nonlinear stiffness forces. The experimental data for the directly excited mode shows a nonlinear dependence of the damping on the amplitude of vibration implying that a nonlinear dissipation mechanism needs to be incorporated. Here, a nonlinear damping model compromising of quadratic displacement multiplied by the velocity $u^2(t)\dot{u}(t)$ is assumed. The secondary mode amplitude $v(t)$, the mode only excited due to its coupling with the primary mode, is modeled with a linear oscillator of frequency ω_{11} which equals to half the driven mode frequency ω_{02} , and a nonlinear interaction term. The interaction between the two oscillators is assumed to be nonlinear in the form of $(v(t))^2$ acting on the driven oscillator and $u(t)v(t)$ acting on the secondary oscillator. The equations of motion normalized by the modal masses $m_{1,2}$ are then:

$$\ddot{u}(t) + 2\xi_2\omega_{02}\dot{u}(t) + (\omega_{02})^2u(t) + \alpha_q u^2(t) + \alpha_c u^3(t) + 2\xi_{non}\omega_{02}u^2(t)\dot{u}(t) = \gamma_2(v(t))^2 + rA \cos(\Omega t) \quad (1)$$

$$\ddot{v}(t) + 2\xi_1\omega_{11}\dot{v}(t) + (\omega_{11})^2v(t) = \gamma_1 u(t)v(t) \quad (2)$$

where ξ_2, ξ_1 are the modal damping ratios acting on the driven and the secondary oscillators, respectively. ξ_{non} is the nonlinear damping coefficient. γ_2, γ_1 are the coupling coefficients between the two modal amplitudes, A is the amplitude

of the base excitation acceleration, and r is the projected modal force acting on the driven oscillator. To extract the unknown parameters, the system of equations are initially numerically integrated for different values of the parameters and the numerical results are compared with experimentally recorded data. Also, the effect of each parameter on the final response is studied which helps in understanding its influence on the system response. Subsequently, the harmonic balance method is used to solve for steady state solutions of Eq. (1) and Eq. (2) in which the response is assumed to have the form of a truncated Fourier series. In the current analysis, two harmonics plus the constant term are utilized. To find the unknown parameters, the parameter extraction procedure is divided into multiple steps. The resonant frequencies values ω_{02} and ω_{11} can be inferred from the impulse response results given in Fig. 1b and are found to be $\omega_{11} = 35.5$ Hz and $\omega_{02} = 71$ Hz. Then, the response in which only the directly excited mode has non-zero response and the internal resonance has not yet activated is considered, see Fig. 2 for the case of 1.65g base excitation. The system of equations assuming zero coupling coefficients, that is, γ_1 and γ_2 are set equal to zero, are solved for different values of the unknown parameters ξ_2 , α_q , α_c , ξ_{non} , and r until the simulation results match the experimentally recorded frequency response, as shown in Fig. 2. To extract the coupling coefficients γ_1 and γ_2 , the experimental response at 1.75 g, Fig. 3, is considered, and the 2 DOF model in Eq. (1) and Eq. (2) is solved for different sets of coupling coefficients until error is minimized between the harmonic balance results and the experimental response curve. Summary of the all the extracted parameters is given in Table 1. To verify the 2DOF model with the extracted parameter values, Eq. (1) and Eq. (2) are used for higher excitation levels and the simulation results are compared with the corresponding experimental data. As shown in Fig. 4, the harmonic balance results at various excitation levels are in reasonable agreements with the experimental measurements.

Figure 2: Experimental and harmonic balance frequency response results (HB) for the 1.65 g excitation case.

Table 1: Summary of the extracted parameters.

Parameter	ω_{11}	ω_{02}	ξ_2	α_q	α_c	ξ_{non}	r	γ_1	γ_2	ξ_1
Value	35.5	71	2.5×10^{-3}	6×10^7	1.54×10^{10}	1.5×10^4	0.525	1.45×10^7	2.3×10^6	0.1

Summary and Conclusions

A two-mode nonlinear model to predict the resonant response of a 3D printed cantilever macroplate to a base excitation is developed. The system is modeled with two nonlinearly coupled oscillators. The plate is designed such that the linear natural frequencies ω_{02} and ω_{11} are in 2:1 frequency ratio. A harmonic balance analysis is used to approximate the response of the coupled oscillators using curve fitting techniques to extract the unknown parameters. The parameter estimation procedure is divided into three steps. In each step, the experimentally recorded results are used to find a subset of the unknown parameters. The final estimated parameters are used to predict the response at higher excitation levels. The analytical model predictions are seen in good agreement with experimental data.

Acknowledgments

This work was support in part by the Alpha P. Jamison Professorship endowment at Purdue University. The authors would like to thank Dr. Astitva Tripathi for his help in designing and fabricating the plate.

Summary. The theoretical study of the change of steady state regime of an unstable dynamic system coupled to a nonlinear energy sink with the respect of a set of parameters is developed in this paper. This study is carried out by the use of asymptotic methods (multiple scale method mixed with harmonic balance method), it leads to singular perturbed system that is studied with geometric singular perturbation theory. The steady state regime of the dynamic system is linked to the information extracted from the singular perturbed system : the slow flow fixed points and their stability. From this information, analytical conditions are established. These conditions lead to parametric analysis and bifurcation diagrams which are describing the mechanism of steady state regime change. This study will allow to test huge and important set of parameters for a NES rapidly in comparison of numerical or experimental studies.

Introduction

The use of Nonlinear Energy Sink (NES) based on Targeted Energy Transfer is very efficient solutions for passive control. A NES is a device composed of a light mass or inertia compared to the main system, a nonlinear stiffness and a viscous linear damper. NES have been developed for the past ten years and many different technologies are used in order to realize them experimentally. A state of the art is presented in [1] about these technologies such as piece-wise linear, non-smooth, vibro-impact, bistable and magnetic NES.

Among several applications, NES are used to control dynamic instabilities or resonances, e.g.: helicopter ground resonance, friction system (Hult  n's model), airfoil system and systems under periodic excitation.

In order to control unstable or resonant system through nonlinear vibration absorber, a design approach needs to be carried out. The method used for designing a NES consists in predicting the response of the nonlinear system through asymptotic analytical approach. Among different approaches, the complex-averaging method (CX) [2] and the method of the multiple scale combined with the harmonic balance method (MMS-HBM) [3] have been extensively applied. These approaches lead into a singular perturbed set of differential equations of the modulation response amplitude.

This system of equation is later treated by applying the Geometric Singular Perturbation Theory (GSPT) [4] which decompose the complex motion of the system into a fast and a slow dynamic. Such methodology has been recently used to survey the response regimes reached with a NES coupled to a primary system [5]. Based on the best authors knowledge, the GSPT has only been used on the modulation equation obtained with CX-method and this approach has not been further developed for parametric study of the NES's parameters applied on the mitigation of unstable systems.

In this work, the design of NES used to mitigate divergent oscillations of unstable system is carried out. The fast and slow dynamics of the singular perturbed system obtained with the combined MMS-HBM is treated with GSPT. The relation between the critical manifold of the fast dynamics, the nature and position of the fixed points of the slow dynamics and the NES response is evaluated. Finally, an extensive parametric study maps the different regimes of the dynamic system for a large set of NES's parameters and instability severity of the primary system.

Development and Results

The dynamic system considered is a single degree of freedom composed of a mass M , a linear stiffness K and a linear negative damping coefficient C (SDOF in black line) coupled to a NES, composed of a mass m , a nonlinear stiffness k and a linear damping factor c (red line) attached (see Figure 1).

Figure 1: Mechanical model : in black an unstable SDOF, in red a Nonlinear Energy Sink (NES) attached.

By introducing a relative displacement $v = x - y$ between the main system and the NES and the usual parameters such as $\omega^2 = \frac{K}{M}$, $\zeta = \frac{C}{2\omega M}$, $\lambda = \frac{k}{M}$, $r_c = \frac{c}{M}$ and $r_m = \frac{m}{M}$ the equations of motion are obtained :

$$\begin{cases} \ddot{x} + 2\zeta\omega\dot{x} + \omega^2x + r_c\dot{v} + \lambda v^3 = 0 \\ r_m\ddot{v} - r_m\ddot{x} - r_c\dot{v} - \lambda v^3 = 0 \end{cases} \quad (1)$$

After applying the whole method (MMS-HBM and GSPT) and getting the information from the slow flow (SIM, fixed points, singular folded points, slow flow dynamics and stability) and the fast flow (modulation equation and dynamic fixed point) it is possible to obtain the dynamic of the system represented in Figure 2.

The slow-flow fixed points in red are governing the response of the phase portrait (in black) Figure 2. The cycle is governed mainly by the SIM (in blue), after reaching the first fold point, the system has enough energy to jump on the

Figure 2: Nonlinear manifold, Slow flow information and Dynamic information with physical parameters $r_m = 4\%$, $\alpha = 2\%$, $\zeta = -1\%$, $\Lambda = 50$.

other stable branch of the Slow Invariant Manifold (SIM). The highest fixed point which is unstable is forcing the system's amplitude to decrease to the second folded point in order to jump back on the first stable branch of the SIM.

From a parametric study, it is possible to understand that the stability (highly linked to the position) of the slow flow fixed points governs the change of steady state response. It is also possible to highlight it by producing a bifurcation diagram (Figure 3a).

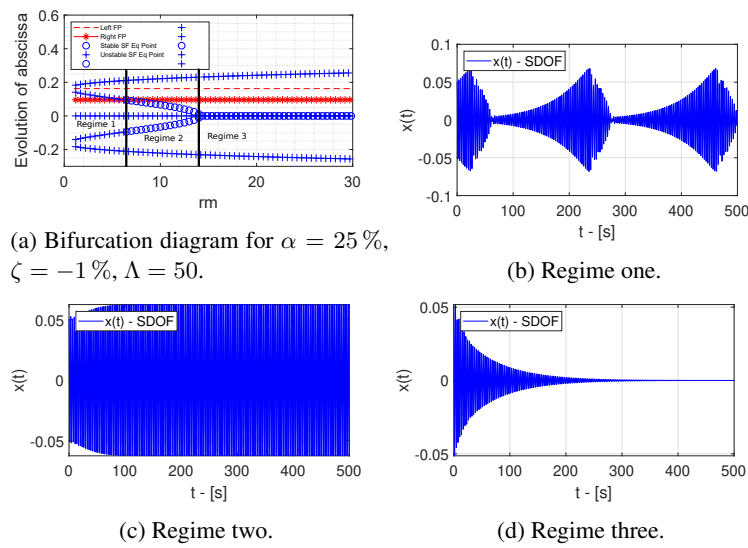

Figure 3: Bifurcation mechanism.

Figure 3a shows the mechanism responsible for the steady state regime change. There are three specific areas that will lead to three different regime. The regime one corresponds to a Limit Cycle Oscillations (LCO) with strong or low modulated response (Figure 3b). This regime appears when the intermediate slow flow fixed point is between the two folded singular point of the SIM and unstable. When this fixed point is moving toward the first folded singular point, it becomes stable and then leads to the regime two (Figure 3c). Finally, this point move to the static fixed point (0,0) and leads to the regime three (Figure 3d).

Conclusion

The analytical study of a complex dynamic system composed of an unstable single degree of freedom and a NES through asymptotic methods and singular perturbation method have been addressed. The theoretical result obtained allowed to improve the influence of the NES parameter on the steady state regime of the dynamic system by conducting extensive parametric study and computing bifurcation diagrams. All these results will now be used to design a NES theoretically and reduce the numbers of iterations needed to design a NES that will mitigate the response of an unstable dynamic system.

^{**}Department of Civil, Construction-Architectural and Environmental Engineering, University of L'Aquila, 67100 L'Aquila, Italy

Summary. In this paper, the analysis of a self-excited suspension bridge under turbulent wind flow is carried out. The stationary wind is responsible for self-excitation, while the turbulent part is responsible for parametric excitations. The simultaneous presence of those excitations is taken into account in a specific resonance condition. The periodic solutions are studied by means of a perturbation method and the effects of the turbulence on the dynamics of the structure are analyzed.

Introduction

Suspension bridges are long, slender flexible structures which are very sensitive to dynamic actions induced by wind, which causes a variety of instability phenomena, related to different kind of excitation. In particular, the aeroelastic instability dealing self-excited vibrations, such as galloping and flutter, is of particular interest, since these phenomena may cause devastating effects, leading to structural collapse like in the famous Tacoma Narrows bridge. The aeroelastic behavior of long-span bridges, and especially the aeroelastic instability, has drawn remarkable attention in the fields of structural engineering and physics. The modern era of bridge aeroelasticity was launched by [1]-[4]. More recently, many linear and nonlinear aeroelastic analysis frameworks for cable-supported bridges were developed, e.g. [5]-[9], to predict the aeroelastic response of bridges under steady and turbulent winds (the most by solving the motion equations by numerical tools).

In this paper, the aeroelastic behavior of a suspension bridge is investigated by a continuous model. A simple analytical model of suspension bridge, subjected to turbulent wind flow, is proposed to analyze the aeroelastic in-plane instability (galloping). The objective is to take into account the possible occurrence of Hopf bifurcations, due to the steady part of the wind, and to analyze modifications on the solutions due to the turbulent part. The main innovative aspect relies in directly attacking the continuous problem by perturbation methods, leading to approximate formulae suitable for preliminary designs.

Model

A standard single-span suspension bridge, made of a main cable, a stiffening girder, uniformly distributed hangers (or suspenders) and two supported towers or pylons, is considered. The main cable is rigidly connected to the support towers, assumed to be rigid. The main cable is assumed to be uniform and elastic, and its bending stiffness is ignored. The structure is subjected to a turbulent wind flow of velocity $U(t)$, blowing orthogonally to the plane of the bridge. A scheme of the model is shown in Fig. 1.

Figure 1: Single-span suspension bridge model.

Linear visco-elastic continuous models of beam and cable are formulated, coupled by vertical suspenders, modeled as uniformly distributed axially rigid links. Both external and internal damping are accounted, this latter according to the Kelvin-Voigt rheological model. The aeroelastic effects of the wind are evaluated via the classical quasi-static theory.

Aerodynamic forces

The aerodynamic load is caused by the wind, which blows orthogonally to the plane of the bridge, with time-dependent velocity $U(t)$. This, triggers in-plane forces, which depend on the structural velocity, as result of the aeroelastic interaction. Only forces on beam are accounted, while force on the cable are neglected. Nonlinear aerodynamic forces are formulated in the framework of the quasi-steady theory (see [10]); by truncating them to the third-order, they read:

$$p^a = -\left(b_1 U(t) \dot{v} + b_3 \frac{1}{U(t)} \dot{v}^3\right) \quad (1)$$

where the coefficients b_i are aerodynamic coefficients depending on the shape of the cylinder cross-section. The wind velocity is decomposed as $U(t) = \bar{u} + u(t)$, where \bar{u} is a constant (average) part, representing the steady component, and $u(t)$ is a periodically time-dependent part, representing the turbulence. By assuming that the turbulent part is small compared to the steady one, the aerodynamic force is expanded in Taylor series.

Equation of motion

The dimensionless motion equations read:

$$\begin{aligned} \rho^2(1 + \eta_b \partial_t)v'''' - (1 + \eta_c \partial_t)v'' + \Lambda^2(1 + \eta_c \partial_t) \int_{-\frac{1}{2}}^{\frac{1}{2}} v ds + \dot{v} + \left(c_e + b_1(\bar{u} + u(t))\right)\dot{v} + b_3\left(\frac{1}{\bar{u}} - \frac{u(t)}{\bar{u}^2}\right)\dot{v}^3 &= 0 \\ v\left(-\frac{1}{2}, t\right) = 0 \quad \rho^2(1 + \eta_b \partial_t)v''\left(-\frac{1}{2}, t\right) &= 0 \\ v\left(\frac{1}{2}, t\right) = 0, \quad \rho^2(1 + \eta_b \partial_t)v''\left(\frac{1}{2}, t\right) &= 0 \end{aligned} \quad (2)$$

The dimensionless parameters Λ^2 and ρ^2 account: the first, for the elastic and geometric properties of the cable (known as the Irvine-Caughey cable parameter [11]); the second, for the beam-cable stiffness ratio. The dimensionless terms η_b, η_c and c_e are internal and external damping parameters. The Eqs. (2) are a generalization of the motion equations provided for the first time by Bleich et al. in [12], and recently re-examined by [13], accounting for additional damping and aerodynamic loads. They describe an infinite-dimensional system, parametrically excited by the turbulence. Here the turbulent part is considered harmonic, i.e., $u(t) = \hat{u} \cos(\Omega t)$, where \hat{u} is the amplitude and $\Omega = 2\omega + \sigma$ is the frequency of the parametric excitation, chosen close to the double of the natural frequency ω , with σ a small detuning. Therefore, the condition of principal parametric excitation occurs.

To investigate the behavior of the structure in the nonlinear field, close to the dynamic bifurcation, a nonlinear asymptotic analysis is carried out. The Multiple Scale Method (MSM) is used, by directly attacking the partial differential equations of motion. A bifurcation equation in the amplitude of motion $a(t)$ is obtained, from which periodic oscillations and their stability are analyzed.

Main results

The main results consist in the stability domains (Fig. 2a) and bifurcation diagrams (Fig. 2b).

Figure 2: (a) Stability domains; (b) Bifurcation diagrams in presence of turbulent wind.

Shape Optimization of Curved Mechanical Beams for Zero-Dispersion Point

Sahar Rosenberg* and Oriel Shoshani*

*Ben-Gurion University of the Negev, Be'er-Sheva 84105, Israel

Summary. In this study, we develop an optimization procedure of zero-dispersion point in curved mechanical beams. The zero-dispersion point is associated with a zero-slope in the frequency-amplitude relation of a nonlinear resonator. As an outcome, local to this zero-dispersion point, the nonlinear effect of amplitude-to-frequency noise conversion is eliminated, albeit the large oscillation amplitude. This zero-dispersion point can be used for noise suppression and frequency stabilization of precision clocks and sensitive detectors. The overall goal is to obtain the zero-dispersion point at the highest possible amplitude (for signal-to-noise ratio enhancement) and frequency (for resolution enhancement). To this end, we found the optimal midpoint elevation of the curved beam and optimized its initial bell-shape function using a genetic algorithm to maximize the frequency and energy level of the zero-dispersion point.

Many technological applications use micromechanical beams as a frequency-selective element to attain high RF frequencies. The practical requirement to operate above the noise floor of the device necessitates the need for large-amplitude oscillation (relative to the small size of the micro-beam); these large amplitudes lie deep in the nonlinear range, where there is considerable amplitude-to-frequency (A-f) noise conversion. However, in a specific class of nonlinear resonators, the dependence of oscillation frequency on the energy (or amplitude) may be non-monotonic, generating energy levels where, locally, the frequency is independent of the energy. For example, the oscillation frequency $\omega(E_{\text{tot}})$ can exhibit a softening behaviour for low energy levels $E_{\text{tot}} < E_{\text{ZD}}$, and hardening behaviour for high energy levels $E_{\text{tot}} > E_{\text{ZD}}$, where in the transition between these two behaviours, there is an extremum of the frequency corresponding to a zero-dispersion (ZD) point $E_{\text{tot}} = E_{\text{ZD}}$ satisfying the condition $d\omega/dE_{\text{tot}}|_{E_{\text{ZD}}} = 0$ (Fig. 1, left panel). Hence, small amplitude fluctuations are not translated into frequency fluctuations near this ZD point. Consequently, the ZD point can be used for suppression of frequency noise in both open-loop [1] and closed-loop [2] systems at large vibration amplitudes, which guarantee operation above the noise floor of the device with a large signal-to-noise ratio (SNR).

In this study, we analyze the possibility to generate an optimal ZD point from the well-known and thoroughly explored curved micro-beam [3, 4] (Fig. 1, right panel). In the curved beam, there are inherently hardening and softening nonlinearities, and therefore, we can obtain the ZD point, where these opposing nonlinearities cancel one another and the fluctuations in the amplitude of vibrations do not locally affect the frequency [5].

Figure 1: Left panel: The frequency-energy backbone curve of a nonlinear resonator with a zero-dispersion point. At the point of zero-dispersion, $E_{\text{tot}} = E_{\text{ZD}}$, there is an extremum of the frequency with a zero slope, and hence, the frequency is locally constant. Right panel: Definition sketch of a curved micro-beam. The doubly clamped micro-beam of length ℓ and rectangular cross-section ($b \times d$) have an initial shape of an inverse bell, which is described by a function $w_0(x)$ and a maximal depth of $h = |w_0(\ell/2)|$.

We consider the conservative transverse vibration of a clamped-clamped shallow arch micro-mechanical beam of an initial shape described by $w_0(x)$ with a maximal height of h , width b , thickness d and length ℓ (Fig. 1, right panel). We wish to obtain a reduced-order nonlinear model for the beam and analyze its dynamics using the Euler-Bernoulli beam model. We assume that the flexural motion of the beam is dominated by its fundamental frequency, and use a single-mode approximation, $w(x, t) = q(t)\phi(x)$, where $\phi(x)$ is the eigenfunction of the fundamental mode that satisfies the doubly clamped beam boundary conditions. We perform a Galerkin projection onto $\phi(x)$ to obtain the following nonlinear ordinary differential equation for the modal coordinate $q(t)$

$$\ddot{q} + \omega_0^2 q + \beta q^2 + \gamma q^3 = 0. \quad (1)$$

For an initially bell-shaped beam with $w_0(x) = h\phi(x)$, the coefficients ω_0^2 , β and γ in Eq. (1) are a function of h (the normalized initial elevation of the midpoint of the beam). Moreover, Eq. (1) has an exact analytical solution that describes the strongly nonlinear dynamics of $q(t)$ in terms of elliptic functions [5]. Thus, we can find closed-form expressions for the ZD point $d\omega/dE_{\text{tot}}|_{E_{\text{ZD}}} = 0$ that yield the energy at the ZD point E_{ZD} , and the fundamental frequency at the ZD point $\omega(E_{\text{ZD}})$. We note that both E_{ZD} and $\omega(E_{\text{ZD}})$ are functions of the coefficients ω_0^2 , β and γ , which in turn are functions of h . Therefore, using the initial elevation h as the design parameter, we can optimize these two expressions $E_{\text{ZD}} = f(\omega_0^2, \beta, \gamma) = f(h)$ and $\omega_{\text{ZD}} = g(E_{\text{ZD}}) = g(\omega_0^2, \beta, \gamma) = g(h)$. Specifically, by setting $dE_{\text{ZD}}/dh = 0$, we can find the initial elevation h that maximize the energy level of the ZD point, $\max\{E_{\text{ZD}}(h)\}$, and by setting $d\omega_{\text{ZD}}/dh = 0$ we can find the initial elevation h that maximize the frequency of oscillation at the ZD point, $\max\{\omega_{\text{ZD}}(h)\}$. As can be seen from the left panel of Fig. 2, E_{ZD} is an increasing monotonic function of h , and thus, the maximal E_{ZD} is achieved at the maximal initial elevation that is possible h_{max} . In contrast, ω_{ZD} is not a monotonic function of h (Fig. 2, left panel). Therefore, for given dimensions and properties of the beam, there is a unique optimal frequency (Fig. 2, left panel). Using the bell-shaped beam $w_0(x) = h\phi(x)$ as an initial shape of the curved beam, we apply a genetic algorithm [6] to find the optimal shape of the curved beam that yields a ZD point at the highest frequency and energy level. The genetic algorithm uses the initial shape of the beam to create a population (group of shape functions) of other solutions in its vicinity. After calculating the objective function $d\omega/dE_{\text{tot}}|_{E_{\text{ZD}}} = 0$ for each individual (certain shape function) of the population, the algorithm creates the next generation of population using the fittest solutions of the last generation by: (i) selection, where the fittest solutions survive for the next generation, (ii) crossover, where each two solutions are being used to create a new solution, and (iii) mutation, where some of the solutions are changed randomly. For each shape function, we used spectral methods to calculate the coefficients of Eq. (1) and find its ZD point. After 500 generations of a population of 15 individuals, the algorithm converged to an optimal shape function. The ZD point of the new shape function is achieved at energy levels 3 times higher than the initial bell-shaped beam $w_0(x) = h\phi(x)$ and with a frequency of more than 3 times higher (see Fig. 2, right panel).

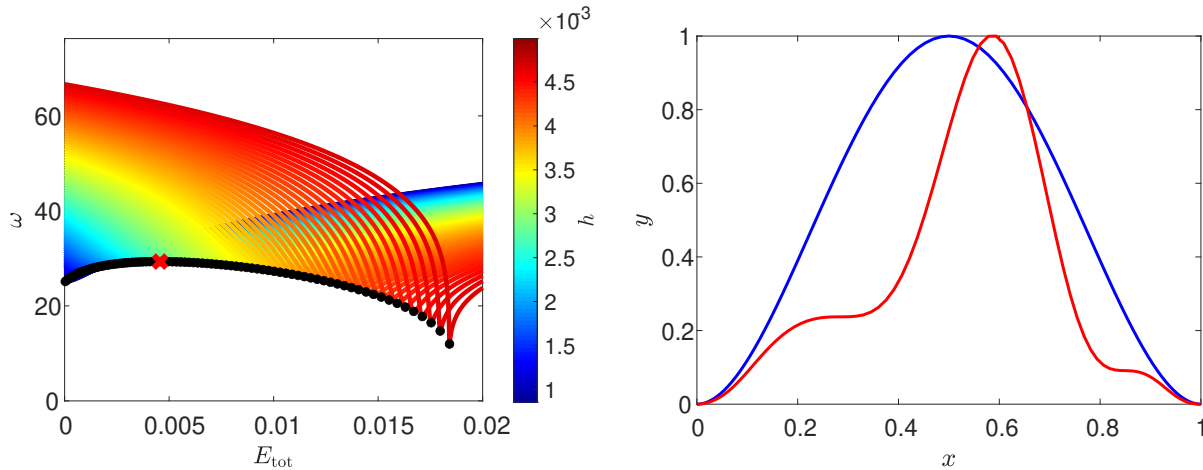

Figure 2: Left panel: The frequency-energy dependency of a bell-shaped beam. The fundamental frequency of oscillation ω is overlaid by the frequency of oscillation at the ZD point ω_{ZD} (black) as a function of the total energy of the system E_{tot} for different values of initial elevation h . The maximal oscillation frequency at the ZD point, $\max\{\omega_{\text{ZD}}(h)\}$, is denoted by the red crossmark on the curve of ω_{ZD} . Right panel: Comparison between the initial bell-shaped function of the beam (in blue) and the optimal shape function after 500 generations of a population of 15 individuals (in red). The frequency and energy of the zero-dispersion point in the optimal shape are threefold higher than in the bell-shaped beam.

Recent advances on spectral-submanifold-based model reduction: bifurcations and configuration constraints

Mingwu Li*, Shobhit Jain* and George Haller *

**Institute for Mechanical Systems, ETH Zürich, Switzerland*

Summary. We show how spectral submanifold theory can be used to construct reduced-order models for forced nonlinear systems possibly with internal resonances. We perform continuation of equilibria (or limit cycles) of the reduced-order models to obtain (quasi-) periodic response of the full system and predict their bifurcations. In addition, we show how to construct reduced-order models for constrained mechanical systems using spectral submanifolds. These reduced-order models enable bifurcation analysis and efficient extraction of backbone and forced response curves of high-dimensional mechanical systems with configuration constraints.

Introduction

The analysis of high-dimensional nonlinear mechanical systems has been a significant challenge. The construction of reduced-order models for original high-dimensional systems is then of great importance because they enable efficient nonlinear analysis. Among these constructions, the reduced-order models based on invariant manifolds are prominent for nonlinear systems as they are supported by rigorous theory. In particular, the theory of *spectral submanifolds* (SSM) has laid a solid foundation for constructing mathematically rigorous reduced-order models [1]. Recent developments [2] have enabled the computation of SSMs and their reduced dynamics in physical coordinates. The software implementation of the method has been available in an open-source package, SSMT00L [3]. In previous studies, the applications have been limited to two-dimensional SSMs. Here, we derive reduced-order models on higher-dimensional SSMs to analyze systems with internal resonances. We integrate continuation package COCO [4] with SSMT00L to obtain forced response curves and perform bifurcation analysis of internally resonant mechanical systems. We further demonstrate how SSMT00L can handle mechanical systems with configuration constraints.

Reduced-order model and bifurcation analysis

Reduced-order model

We consider a periodically forced nonlinear mechanical system

$$M\ddot{\mathbf{x}} + C\dot{\mathbf{x}} + K\mathbf{x} + \mathbf{f}(\mathbf{x}, \dot{\mathbf{x}}) = \epsilon \mathbf{f}^{\text{ext}}(\Omega t), \quad (1)$$

where $\mathbf{x} \in \mathbb{R}^n$ is displacement vector; $M, C, K \in \mathbb{R}^{n \times n}$ are the mass, damping and stiffness matrices; $\mathbf{f}(\mathbf{x}, \dot{\mathbf{x}})$ is a C^r smooth nonlinear function such that $\mathbf{f}(\mathbf{x}, \dot{\mathbf{x}}) \sim \mathcal{O}(|\mathbf{x}|^2, |\mathbf{x}||\dot{\mathbf{x}}|, |\dot{\mathbf{x}}|^2)$; and $\epsilon \mathbf{f}^{\text{ext}}(\Omega t)$ denotes external harmonic excitation. Let $\mathbf{z} = (\mathbf{x}, \dot{\mathbf{x}})$, the equation of motion (1) can be transformed into a first-order form

$$B\dot{\mathbf{z}} = A\mathbf{z} + \mathbf{F}(\mathbf{z}) + \epsilon \mathbf{F}^{\text{ext}}(\Omega t), \quad 0 \leq \epsilon \ll 1, \quad (2)$$

with appropriate definition of A, B, \mathbf{F} and \mathbf{F}^{ext} . We assume that $\mathbf{z} = \mathbf{0}$ is an asymptotically stable fixed point at $\epsilon = 0$. We construct SSM-based reduced-order model for (2) in following steps

1. We determine the master subspace for reduction based on external and internal resonances. Specifically, we first include the modes subject to (near) external resonance with excitation frequency Ω to the master subspace. We further add the modes having internal resonances with the externally resonant modes to the master subspace.
2. We compute the parametrization $W_\epsilon(\mathbf{p}, \Omega t)$ of the SSM associated with the master subspace along with its reduced dynamics $\dot{\mathbf{p}} = \mathbf{R}_\epsilon(\mathbf{p}, \Omega t)$, where the parameterization coordinates \mathbf{p} are of the same dimension as the that of the master subspace. We express the parametrizations $W_\epsilon(\mathbf{p}, \Omega t)$ and $\mathbf{R}_\epsilon(\mathbf{p}, \Omega t)$ as Taylor series expansion in \mathbf{p} and determine the unknown expansion coefficients by balancing polynomials in the invariance equation, as shown in [2].
3. We transform the reduced dynamics $\dot{\mathbf{p}} = \mathbf{R}_\epsilon(\mathbf{p}, \Omega t)$ to factor out the Ωt -dependent terms. In particular, using the transformation $\mathbf{p} = \mathbf{H}(\Omega t)\mathbf{q}$ with an explicit diagonal matrix \mathbf{H} , we obtain an autonomous reduced-order model

$$\dot{\mathbf{q}} = \mathbf{h}(\mathbf{q}, \Omega, \epsilon). \quad (3)$$

Further details about the above construction can be found in our preprint [5].

Bifurcation analysis

The bifurcation analysis of the full high-dimensional system (2) is simplified to the bifurcation analysis of the reduced-order model (3). This simplification enables the prediction of bifurcations of periodic/quasi-periodic orbits of the full system (2) via the bifurcations of the equilibria/limit cycles of the reduced-order model (3). For instance, we simply identify Hopf bifurcations of equilibria and limit cycles in the reduced system (3) to predict the existence of two-dimensional and three-dimensional quasi-periodic invariant tori in the full system (2) of arbitrary dimension.

We have integrated the continuation package COCO with SSMT00L to perform such bifurcation analysis. Specifically, we have developed the following three toolboxes within SSMT00L.

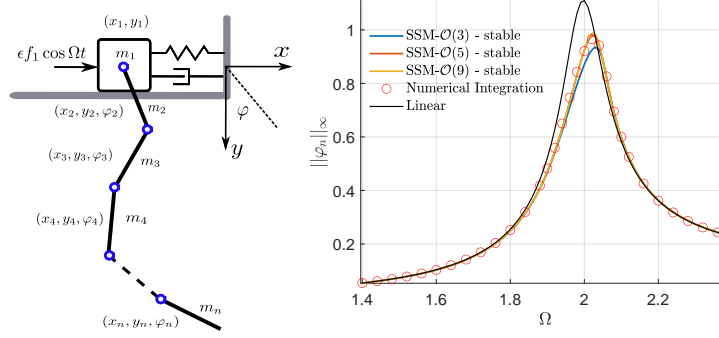

Figure 1: A chain of pendulums (left) with $n = 41$ and the forced response curve of rotation angle of the last pendulum (right).

- SSM-ep: continuation of (bifurcated) equilibria of the reduced-order model (3) and the construction of corresponding (bifurcated) periodic orbits of the full system (2);
- SSM-po: continuation of (bifurcated) limit cycles of the reduced-order model (3) and the construction of corresponding (bifurcated) two-dimensional quasi-periodic invariant tori of the full system (2);
- SSM-tor: continuation of two-dimensional quasi-periodic invariant tori of the reduced-order model (3) and the construction of corresponding three-dimensional quasi-periodic invariant tori of the full system (2).

More details about these toolboxes and their applications to finite-element examples can be found in our preprints [5, 6].

Extension to constrained mechanical systems

Now, we consider a periodically forced nonlinear mechanical system with configuration constraints of the form

$$M\ddot{x} + C\dot{x} + Kx + f(x, \dot{x}) + G^\top \lambda = \epsilon f^{\text{ext}}(\Omega t), \quad g(q) = 0 \quad (4)$$

where $x, M, C, K, f, \epsilon, f^{\text{ext}}$ carry the same definitions as in (1), $g : \mathbb{R}^n \rightarrow \mathbb{R}^m$ ($m < n$) represents configuration constraints, $G = \partial g / \partial q$, and λ denotes the Lagrange multipliers corresponding to the configuration constraints.

With $z = (x, \dot{x}, \lambda)$, we can again transform (4) into the first-order form (2) with appropriate definition of A, B, F and F^{ext} . We assume $g(0) = 0$ such that the origin $z = 0$ is still a fixed point of the full system (2). We further assume that $G(0)$ is of full rank, i.e., the constraints g are not redundant and the origin is not a singular configuration. As a result, the vector λ of the Lagrangian multipliers is well-defined. Under these assumptions, the matrix B is singular and the matrix pair (A, B) has $3m$ infinite eigenvalues corresponding to the m configuration constraints.

Indeed, the computation of SSM and its associated reduced-order model does not require the invertibility of B matrix [2]. This enables us to use SSMTOOL to construct SSM-based reduced-order model for the full system (4) following the same procedure as in the previous section. Hence, we can again perform bifurcation analysis and obtain backbone and forced response curves of the constrained system (4) directly from the SSM-based reduced-order (3).

As a demonstration, we consider a chain of planar pendulums attached to a harmonically excited oscillator, as shown in Fig. 1. The configuration constraints in this system come from the revolute joints. We extract the forced response curve of the system via a two-dimensional SSM-based reduced-order model. As shown in the right panel of Fig. 1, the forced response curve predicted by this reduced-order model agrees with the one obtained from the numerical time integration of the full system, thereby demonstrating the effectiveness of SSM reduction.

Conclusions

We derived SSM-based reduced-order models for nonlinear systems with internal resonances. Such reduced-order models enable efficient nonlinear analysis of the full systems with arbitrary dimensions. We further extended this analysis to constrained mechanical systems where the equations of motion are in the form of differential-algebraic equations.

Reduced-Order Modelling of Moore-Greitzer PDEs using Sparse Regression

Yusuf Aydogdu, Thambirajah Ravichandran, Alyssa Novelia and N. Sri Namachchivaya
Department of Applied Mathematics, University of Waterloo, Waterloo, Ontario N2L 3G1, Canada

Summary. This paper develops a data-driven reduced-order model of the viscous Moore-Greitzer (MG) partial differential equations (PDEs) by threading together ideas from dimensionality reduction to sparse regression and compressed sensing. Numerical simulation of the infinite dimensional viscous MG system is reduced into low dimensional data using principal component analysis (PCA) and autoencoder neural networks based dimensionality reduction methods. Based on the observation that MG equations close to bifurcations have a sparse representation (normal forms) with respect to high-dimensional polynomial spaces, we use the Sparse Identification of Nonlinear Dynamics (SINDy) algorithm which uses a collection of all monomials as a sampling matrix and a sparse regression technique to recover a system of two sparse ordinary differential equations (ODEs) with cubic nonlinearities.

Introduction

This paper develops data-driven theory and algorithms to detect and mitigate stall compressor instability. The motivation is to produce a high-fidelity simulation of a jet engine compressor called the digital twin, which has the ability to monitor and diagnose complex systems to improve performance efficiency and utilization. Jet engine compressor models typically integrate a hierarchy of multi-physics and multi-fidelity models which are continually updated with data streams from the sensors. The model used to describe airflow inside the jet engine compressor is the viscous MG equations [12, 22] which consist of a nonlinear partial differential equation (PDE) and two ODEs. There are three types of Hopf bifurcations that can exist in the viscous MG equations corresponding to physical oscillations dominated by the ODE (surge), PDE (rotating stall), or a mixture of both. The objective of this particular work is to use optimization and regression techniques from machine learning to arrive at a lower dimensional description of the PDE from datasets. The success of compressor reduced-order modelling is rooted on accurate representations of the multi-physics and multi-fidelity models.

First, we describe the viscous MG equations, provide an explicit expression for the system's equilibrium, and show that the steady operating axial flow and pressure drifts from the aforementioned equilibrium during PDE bifurcation. Then, we introduce reduced-order modeling (ROM) to significantly alleviate computational costs by projecting the high dimensional state variables onto a low-dimensional subspace. We perform ROM on simulated data from viscous MG equations to construct a set of "good" basis functions. Approximations of bases spanning this subspace are constructed using principal component analysis (PCA) [15, 28] and both linear and nonlinear autoencoder neural networks [26, 27].

It is impossible to effectively "learn" from high dimensional data unless there is some kind of implicit or explicit low dimensional structure. Over the past 10 years, researchers have focused on sparsity as one type of criteria for low-dimensional structure. The inherent sparsity of natural signals is central to the mathematical framework of compressed sensing [5, 6, 9]. The main aim of compressed sensing is to construct a sparse vector from linear measurements of the vector such that the number of observed measurements m is significantly smaller than the dimension n of the original vector and satisfies the "Restricted Isometry Property" (RIP). Intuitively, the existence of a RIP implies that the geometry of sparse vectors is preserved through the measurement matrix, as illustrated in a high dimensional application [23]. These techniques rely heavily on the fact that many dynamical systems can be represented by governing equations that are sparse in the space of all possible functions. The assumption for the low dimensional structure for the MG equations originates from the center manifold theory in dynamical systems [13, 31], where a high dimensional system undergoing Hopf bifurcation can be fully described by projecting the equations onto the subspace of a 2-dimensional center manifold.

Finally, we adapt a recently developed technique called Sparse Identification of Nonlinear Dynamics (SINDy) [4, 7, 8] which has demonstrated the ability to recover governing equations of complex dynamical systems. The methods presented in SINDy approach the problem of automating the discovery of dynamic equations that describe natural systems through the lens of sparsity-promoting regression techniques such as Least Absolute Shrinkage and Selection Operator (LASSO) [29]. To lend insight into this process, the SINDy algorithm was applied to simulated data from various ROM models to recover their respective sparse equations which is then used to reconstruct the original system's dynamics.

Viscous Moore-Greitzer Equations

Model and Analysis

Turbo-jet engine is comprised of 3 parts: axial flow compressor where air gets compressed, the plenum where the air undergoes combustion and rapidly expands, and the turbine where the air is let out (see for example, Figure 1 in [30]). The flow enters from atmospheric pressure at the inlet duct, proceeds through the compressor block where the static pressure is increased, enters the outlet duct, and then exits to atmospheric pressure through the downstream turbine's throttle. The compressor is made out of an entrance duct, an inlet guide vane (IGV), multiple stages of stator-rotor pairs, and an exit duct towards the plenum. A stator is a rotary system with static blades and a rotor comprises of revolving blades.

The following basic assumptions of the MG compressor model [12, 22] are made. The pressure rise across the compressor lags behind the pressure drop delivered by the throttle due to mass storage in the exit duct (or plenum). Across the compressor, the difference between the pressure delivered by the compressor and pressure rise that currently exists across the compressor acts to accelerate the flow rate through the compressor. The flow is assumed to be incompressible and irrotational everywhere except inside the plenum where combustion occurs and rapidly expands the air.

The viscous MG equations for a cylindrical axial flow compressor consist of Laplace's partial differential equation (PDE) for disturbance velocity potential $\tilde{\phi}'(t, \theta, \eta)$

$$\tilde{\phi}'_{\eta\eta} + \tilde{\phi}'_{\theta\theta} = 0. \quad (1)$$

with boundary conditions

$$\psi_c(\Phi(t) + (\tilde{\phi}'_{\eta})_0) - \frac{1}{2\pi} \int_0^{2\pi} \psi_c(\Phi(t) + (\tilde{\phi}'_{\eta})_0) d\theta - m(\tilde{\phi}'_t)_0 - \frac{1}{a}(\tilde{\phi}'_{t\eta})_0 - \frac{1}{2a}(\tilde{\phi}'_{\eta\theta})_0 - \frac{v}{2a}(\tilde{\phi}'_{\eta\theta\theta})_0 = 0 \quad (2)$$

at $\eta = 0$ and $\tilde{\phi}' = 0$ at $\eta = -\infty$ and a pair of ordinary differential equations (ODEs) for annulus average of axial momentum $\Phi(t)$

$$\Psi(t) + \ell_c \frac{d\Phi(t)}{dt} = \frac{1}{2\pi} \int_0^{2\pi} \psi_c(\Phi(t) + (\tilde{\phi}'_{\eta})_0) d\theta. \quad (3)$$

and pressure drop from across the compressor $\Psi(t)$

$$\frac{d\Psi(t)}{dt} = \frac{1}{4B^2\ell_c} (\Phi(t) - F_T^{-1}(\Psi(t))). \quad (4)$$

The subscripts of $\tilde{\phi}'$ indicate partial derivatives with respect to time t , angular θ and axial η coordinates of the cylindrical compressor. $(\cdot)_0$ means the quantity is evaluated at the compressor entrance $\eta = 0$. a is the internal compressor lag, $\ell_c = l_l + l_e + \frac{1}{a}$ is the characteristic compressor length (dimensionless quantity normalized with respect to compressor radius), and B is the plenum to compressor volume ratio [11]. Detailed derivation of the non-viscous model can be found in [11, 12, 22] while the viscous model was developed in [1, 21] and thoroughly derived in [3].

The compressor $\psi_c(\phi)$ and throttle $F_T(\phi)$ characteristic functions that are considered follow [12, 22]

$$\psi_c(\phi) = \psi_{c0} + H \left[1 + \frac{3}{2} \left(\frac{\phi}{W} - 1 \right) - \frac{1}{2} \left(\frac{\phi}{W} - 1 \right)^3 \right] \quad (5)$$

$$F_T(\phi) = \frac{\phi^2}{\gamma^2}. \quad (6)$$

H and W are the characteristic height and width of the compressor and ψ_{c0} is a value determined by experiments. Throttle coefficient γ describes the amount of opening - large γ implies a wide open throttle while small γ implies a closed throttle. Equations (1), (2), (3), and (4) can be combined into a compact state-space form $\frac{\partial \mathbf{y}}{\partial t} = \mathbf{A}\mathbf{y} + \mathbf{f}(\mathbf{y})$ following [2]

$$\frac{\partial}{\partial t} \begin{bmatrix} g \\ \Phi \\ \Psi \end{bmatrix} = \begin{bmatrix} K^{-1} \left(\frac{v}{2} \frac{\partial^2}{\partial \theta^2} - \frac{1}{2} \frac{\partial}{\partial \theta} \right) & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} g \\ \Phi \\ \Psi \end{bmatrix} + \begin{bmatrix} aK^{-1}(\psi_c(\Phi + g) - \bar{\psi}_c) \\ \frac{1}{\ell_c}(\bar{\psi}_c - \Psi) \\ \frac{1}{4B^2\ell_c}(\Phi - \gamma\sqrt{\Psi}) \end{bmatrix} \quad (7)$$

by introducing state variable g

$$g(t, \theta) = (\tilde{\phi}'_{\eta})_0 = \sum_{n \in \mathbb{Z}} |n| \tilde{\phi}'_n(t) e^{in\theta} = \sum_{n \in \mathbb{Z}} g_n e^{in\theta}. \quad (8)$$

where

$$\tilde{\phi}'(t, \theta, \eta) = \sum_{n \in \mathbb{Z}} \tilde{\phi}'_n(t) e^{|n|\eta + in\theta}, \quad (9)$$

is the solution to (1) and we define

$$\bar{\psi}_c = \frac{1}{2\pi} \int_0^{2\pi} \psi_c(\Phi + g) d\theta. \quad (10)$$

as well as an operator K that acts on $\phi = \sum_{n \in \mathbb{Z}} \tilde{\phi}_n e^{in\theta}$ such that

$$K(\phi) = \sum_{n \in \mathbb{Z}} \left(1 + \frac{ma}{|n|} \right) \tilde{\phi}_n e^{in\theta}. \quad (11)$$

To inspect the nonlinearities in $\mathbf{f}(\mathbf{y})$, we perform Taylor series' expansion on $\psi_c(\Phi + g)$ up to the third cubic term to expand the integrand of $\bar{\psi}_c$

$$\bar{\psi}_c = \psi_c(\Phi) + \frac{1}{2} \psi_c''(\Phi) \sum_{m,n \in \mathbb{Z}} g_m g_n + \frac{1}{6} \psi_c'''(\Phi) \sum_{k,m,n \in \mathbb{Z}} g_k g_m g_n. \quad (12)$$

Note that $g(t, \theta)$ has a vanishing average property due to assumptions made to the disturbance flow. Therefore, $\bar{\psi}_c$ is only a function of t and not θ and as a result, $K^{-1}(\bar{\psi}_c) = 0$. The nonlinearity vector $\mathbf{f}(\mathbf{y})$ becomes

$$\mathbf{f}(\mathbf{y}) = \begin{bmatrix} aK^{-1}(\psi'_c(\Phi)g + \frac{1}{2}\psi''_c(\Phi)g^2 + \frac{1}{6}\psi'''_c(\Phi)g^3) \\ \frac{1}{l_c}(\psi_c(\Phi) + \frac{1}{2}\psi''_c(\Phi)\sum_{m,n \in \mathbb{Z}}^{m+n=0} g_m g_n + \frac{1}{6}\psi'''_c(\Phi)\sum_{k,m,n \in \mathbb{Z}}^{k+m+n=0} g_k g_m g_n - \Psi) \\ \frac{1}{4B^2 l_c}(\Phi - \gamma\sqrt{\Psi}) \end{bmatrix}. \quad (13)$$

The system (7)'s equilibrium consist of $g_e(\theta) = 0$ and $\Psi_e = \psi_c(\Phi_e) = F_T(\Phi_e)$ which means (Φ_e, Ψ_e) lies on the intersection of curves (5) and (6). Φ_e can be solved by finding the root of the polynomial

$$-\frac{H}{2W^3}\Phi_e^3 + \left(\frac{3H}{2W^2} - \frac{1}{\gamma^2}\right)\Phi_e^2 + \psi_{c0} = 0. \quad (14)$$

(14) has one real root and a pair of imaginary roots, where the real root is

$$\Phi_e = \sqrt[3]{X - Y^3} + \sqrt{X(X - 2Y^3)} + \sqrt[3]{X - Y^3} - \sqrt{X(X - 2Y^3)} - Y \quad (15)$$

and

$$X = \frac{W^3}{H}\psi_{c0}, \quad Y = \frac{2W^3}{3H}\left(\frac{1}{\gamma^2} - \frac{3H}{2W^2}\right). \quad (16)$$

For our analysis, γ is the bifurcation parameter to be varied for different kinds of Hopf bifurcation.

The Jacobian of $\mathbf{f}(\mathbf{y})$ at equilibrium is

$$\nabla \mathbf{f}_{\mathbf{y}_e} = \begin{bmatrix} aK^{-1}(\psi'_c(\Phi_e)) & 0 & 0 \\ 0 & \frac{1}{l_c}\psi'_c(\Phi_e) & -\frac{1}{l_c} \\ 0 & \frac{1}{4B^2 l_c} & -\frac{1}{4B^2 l_c} \frac{\gamma^2}{2\Phi_e} \end{bmatrix}. \quad (17)$$

The eigenvalues of $(\mathbf{A} + \nabla \mathbf{f}_{\mathbf{y}_e})$ corresponding to the PDE are

$$\lambda_n = \left(\frac{a|n|}{|n| + am}\right) \left(\psi'_c(\Phi_e) - \frac{\nu}{2a}n^2 - \frac{1}{2a}(in)\right) \quad (18)$$

and the eigenvalues of $(\mathbf{A} + \nabla \mathbf{f}_{\mathbf{y}_e})$ corresponding to the ODEs are

$$\mu_{1,2} = \frac{1}{2l_c} \left[\left(\psi'_c(\Phi_e) - \frac{\gamma}{8B^2\sqrt{\Psi_e}} \right) \pm \sqrt{\left(\psi'_c(\Phi_e) + \frac{\gamma}{8B^2\sqrt{\Psi_e}} \right)^2 - \frac{1}{B^2}} \right]. \quad (19)$$

Hopf bifurcation occurs when a pair of $(\mathbf{A} + \nabla \mathbf{f}_{\mathbf{y}_e})$ eigenvalues' real parts cross the imaginary axis with the derivative of the real parts with respect to γ is not equal to zero. There are three possibilities: surge (ODE bifurcation), stall (PDE bifurcation), and combination (simultaneous ODE and PDE bifurcations).

The critical bifurcation point for surge is $\gamma_{c,surge}$ such that $Re(\mu_{1,2}) = 0$. When $\gamma < \gamma_{c,surge}$, surge occurs. It is difficult to obtain an explicit expression for $\gamma_{c,surge}$ but $\gamma_{c,surge}$ is the solution to

$$\Phi_e(\gamma_{c,surge}) \left(2 - \frac{\Phi_e(\gamma_{c,surge})}{W} \right) - \frac{\gamma_{c,surge}^2}{4B^2} \frac{W^2}{3H} = 0. \quad (20)$$

The condition for surge is $\left. \frac{\partial}{\partial \gamma}(Re(\mu_{1,2})) \right|_{\gamma_{c,surge}} > 0$.

The critical bifurcation point for stall is $\gamma_{c,stall}$ such that $Re(\lambda_1) = 0$. When $\gamma < \gamma_{c,stall}$, stall occurs. Again, it is difficult to obtain an explicit expression for $\gamma_{c,stall}$ but $\gamma_{c,stall}$ is the solution to

$$\Phi_e(\gamma_{c,stall}) \left(2 - \frac{\Phi_e(\gamma_{c,stall})}{W} \right) - \frac{\nu W^2}{3aH} = 0. \quad (21)$$

The condition for stall is $\left. \frac{\partial}{\partial \gamma}(Re(\lambda_1)) \right|_{\gamma_{c,stall}} > 0$.

It is possible for the largest PDE eigenvalue pairs and both ODE eigenvalues to simultaneously cross the imaginary axis. This is achieved when $\gamma = \gamma_{c,combo}$ where

$$\psi'_c(\Phi_e(\gamma_{c,combo})) = \frac{\gamma_{c,combo}^2}{8B^2} \frac{1}{\Phi_e(\gamma_{c,combo})} = \frac{\nu}{2a}. \quad (22)$$

For the combination case, it is possible to calculate the expression for the normal form which are the diagonal entries of $(\mathbf{A} + \nabla \mathbf{f}_{y_e})(\gamma_{c,combo})$

$$\mathbf{D}(\gamma_{c,combo}) = \mathbf{T}^{-1}(\mathbf{A} + \nabla \mathbf{f}_{y_e})\mathbf{T}(\gamma_{c,combo}) = \text{diag} \left(\begin{bmatrix} (K^{-1}(\frac{\nu}{2}(1-n^2) - \frac{1}{2}ni)) \\ \frac{1}{2l_c} \sqrt{\frac{\nu^2}{a^2} - \frac{1}{B^2}} \\ -\frac{1}{2l_c} \sqrt{\frac{\nu^2}{a^2} - \frac{1}{B^2}} \end{bmatrix} \right). \quad (23)$$

Rotating Stall Simulation Results

The system of equations (7) is integrated using the spectral method. $\theta \in [-\pi, \pi]$ is discretized into 512 equally spaced points, leading to a system of 514 ODEs (512 of which are Fourier coefficients of $g(t, \theta)$) to be numerically integrated using SciPy's `solve_ivp` with $dt = 0.1$. The following parameter values are used in all cases

$$l_c = 8, \quad m = 1.75, \quad a = 1/3.5, \quad \nu = 1, \quad \psi_{c0} = 1.67H, \quad H = 0.18, \quad W = 0.25. \quad (24)$$

The plenum to compressor volume ratio B and the throttle opening γ are chosen to produce different type of bifurcations, and for the stall case, the simulations results are given below in Figure 1.

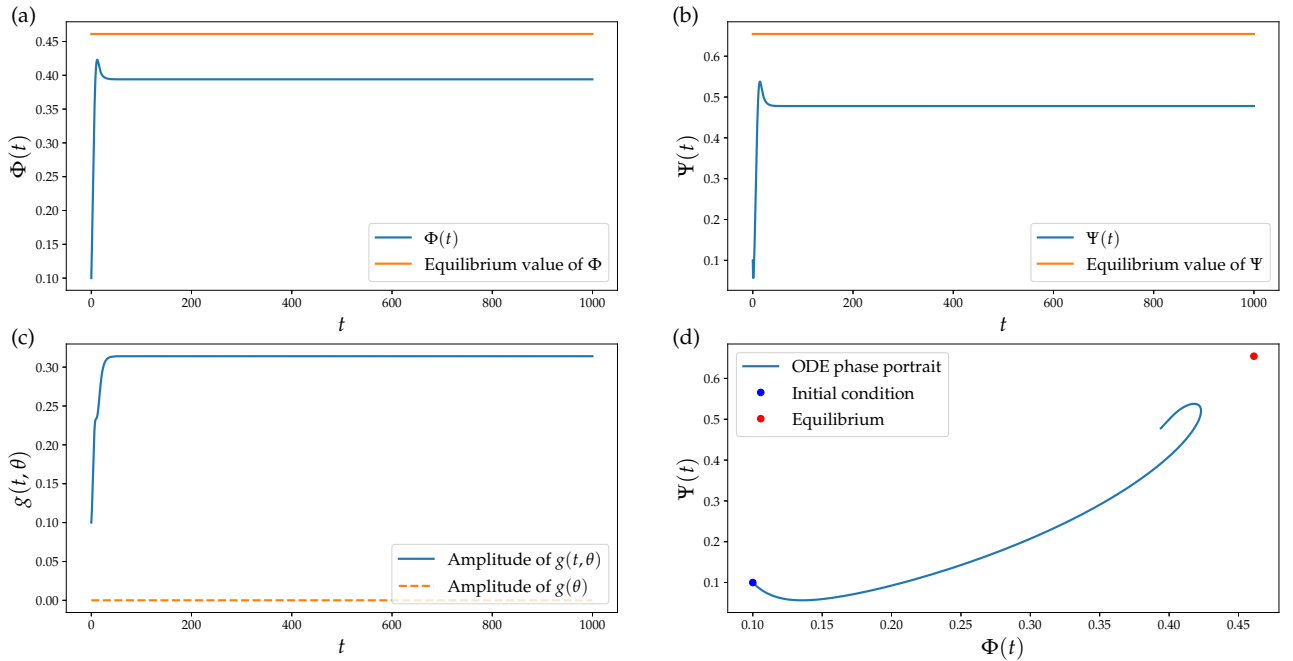

Figure 1: Stall dynamics of viscous Moore-Greitzer equations: (a) $\Phi(t)$ and (b) $\Psi(t)$ do not settle at their stable equilibrium values due to influence from PDE Hopf bifurcation. (c) Amplitude of $g(t, \theta)$ in t settles to a non-zero value during Hopf bifurcation. (d) Phase portrait of ODE states $\Phi(t)$ and $\Psi(t)$ which does not settle at the equilibrium point.

Dimensionality Reduction for Reduced-Order Modelling (ROM)

Principal Component Analysis (PCA)

PCA is also known as proper orthogonal decomposition (POD) in mechanical engineering [15] and discrete Karhunen-Loève expansion in signal processing and information theory [20]. PCA is a method to find principal axes in high dimensional data. These principal axes span the eigenvectors of the covariance matrix of the measurements which are orthonormal to each other such that the individual data along these directions are linearly uncorrelated. PCA can also be used as a dimensionality reduction tool by truncating a measurement's linear combination in its principal axes. Constructing basis functions from data using PCA can be formulated mathematically as a low-rank matrix approximation problem which can be easily computed by using the singular value decomposition (SVD) [10].

Suppose we have N observations of n -dimensional data

$$\mathbf{Y} = [\mathbf{y}_1 \dots \mathbf{y}_N] \quad (25)$$

where $\mathbf{Y} \in \mathbb{R}^{n \times N}$, $\mathbf{y}_i = \mathbf{y}(t_i) \in \mathbb{R}^n$. After centering the data about its empirical mean to get \mathbf{Y}_0 , define a transformation $\mathbf{W} \in \mathbb{R}^{n \times m}$ where $m < n$ in the context of dimensionality reduction. The lower dimensional data is calculated by

$$\mathbf{X}_0 = \mathbf{W}^T \mathbf{Y}_0. \quad (26)$$

If we use PCA, then the transformation is defined as

$$\mathbf{W} = \mathbf{P}_m = [\mathbf{p}_1 \dots \mathbf{p}_m] \quad (27)$$

where \mathbf{p}_m are the principal axes of \mathbf{Y}_0 or the first m eigenvectors of the covariance matrix $\mathbf{Y}_0 \mathbf{Y}_0^T$.

Neural Network Implementation of PCA

An autoencoder is a type of multilayer feedforward neural network that at its simplest form (see Figure 2 without 64-nodes hidden layers) has an input layer with n nodes, followed by a hidden layer with m nodes (where $m < n$), followed by an output layer with n nodes. When the activation functions are chosen to be linear, the input-output relationship is given by

$$\hat{\mathbf{y}} = \mathbf{W}_2(\mathbf{W}_1 \mathbf{y} + \mathbf{b}_1) + \mathbf{b}_2 \quad (28)$$

where $\mathbf{W}_1, \mathbf{W}_2^T \in \mathbb{R}^{m \times n}$ are the encoder and decoder weight matrices, and $\mathbf{b}_1 \in \mathbb{R}^m$, $\mathbf{b}_2 \in \mathbb{R}^n$ are the encoder and decoder bias vectors. Once the optimal $\{\mathbf{W}_1, \mathbf{W}_2, \mathbf{b}_1, \mathbf{b}_2\}$ are found, we can construct an encoder to reduce the input into a reduced-order data $\mathbf{x} \in \mathbb{R}^m$ using $\{\mathbf{W}_1, \mathbf{b}_1\}$ and a decoder to convert the encoded data back to its original dimension using $\{\mathbf{W}_2, \mathbf{b}_2\}$.

Under certain assumptions on the error function landscape, the minimization problem for the autoencoder reduces to

$$\min_{\{\mathbf{W}_2\}} \|\mathbf{Y}_0 - \mathbf{W}_2 \mathbf{W}_2^+ \mathbf{Y}_0\|_F^2. \quad (29)$$

where \mathbf{W}_2^+ is the Moore-Penrose inverse/pseudoinverse [25] of \mathbf{W}_2 . For the case when the columns of \mathbf{W}_2 are orthonormal like \mathbf{P}_m , then $\mathbf{W}_2^+ = \mathbf{W}_2^T$ will make (29) equal to the reconstruction error of PCA. Therefore, it is clear that \mathbf{P}_m is a solution to the autoencoder optimization problem. The problem is that the product of \mathbf{P}_m with any proper orthogonal matrix $\mathbf{Q} \in \mathbb{R}^{m \times m}$ will be a minimizer \mathbf{W}_2 , such that there are infinitely many solutions. Coupled with the fact that mini-batch stochastic gradient descent [19] is the go-to optimization algorithm in today's neural network frameworks, there is no guarantee that \mathbf{W}_2 converges to the same value when the training procedure is repeated, let alone align itself to \mathbf{P}_m . While any \mathbf{W}_2 in this space can be used to mimic the input data almost perfectly, this inconsistency is an issue in our problem as we would like to further uncover the underlying structure of the encoded measurements $\mathbf{X} = [\mathbf{x}_1 \dots \mathbf{x}_N]$.

Regularized Linear Autoencoder

An approach to recover the principal axes from autoencoder weights is based on the following hypothesis [26]: the first m left singular vectors of \mathbf{W} is also the first m principal axes of \mathbf{Y}_0 . This hypothesis can be framed as an autoencoder with a regularizer or penalty to the sum of the Frobenius norms of the encoder weight matrix \mathbf{W}_1 and decoder weight matrix \mathbf{W}_2

$$\min_{\{\mathbf{W}_1, \mathbf{W}_2\}} \|\mathbf{Y}_0 - \mathbf{W}_2 \mathbf{W}_1 \mathbf{Y}_0\|_F^2 + \lambda (\|\mathbf{W}_1\|_F^2 + \|\mathbf{W}_2\|_F^2). \quad (30)$$

For a large enough λ value, the error surface is guaranteed to be convex with a single global minima which will correspond to the principal axes [17]. Additionally, the minimum values of this loss function is $\mathbf{W}_1^* = \mathbf{W}_2^T$ unlike $\mathbf{W}_1^* = \mathbf{W}_2^+$ in the original approach.

Nonlinear Principal Component Analysis (NLPCA) and Autoencoder

NLPCA was developed to uncover the underlying nonlinear manifold in large dimensional datasets. The neural network architecture we are considering to train our NLPCA autoencoder is shown in Figure 2.

$$\begin{aligned} \mathbf{X} &= \mathbf{W}_2 \tanh(\mathbf{W}_1 \mathbf{Y} + \mathbf{b}_1) + \mathbf{b}_2 \\ \hat{\mathbf{Y}} &= \mathbf{W}_4 \tanh(\mathbf{W}_3 \mathbf{X} + \mathbf{b}_3) + \mathbf{b}_4. \end{aligned} \quad (31)$$

We choose the nonlinear activation function $\tanh()$ as in [27] under the justification that a trigonometric function would fit well with the solutions of the MG equations which are spanned by the Fourier basis (8). The NLPCA autoencoder is trained to minimize the loss function of

$$\min_{\{\mathbf{W}_{1,2,3,4}, \mathbf{b}_{1,2,3,4}\}} \|\mathbf{Y} - \hat{\mathbf{Y}}\|_F^2. \quad (32)$$

The resulting $\{\mathbf{W}_{1,2,3,4}\}$ and $\{\mathbf{b}_{1,2,3,4}\}$ are then used to construct an encoder and decoder as per (31).

 Figure 2: Autoencoder architecture for MG compressor data with $\tanh(\cdot)$ activation function

Sparsity in Reduced-Order Data

Over the past two decades, researchers have focused on sparsity as one type of low-dimensional structure. Given the recent advances in both compressed sensing [6, 9] and sparse regression [29], it has become computationally feasible to extract system dynamics from large multimodal datasets. The term sparse in signal processing context refers to the case where signals (or any type of data, in general) have few non-zero components with respect to the total number of components. It is well known in dynamical systems, the normal forms provide a way of finding a coordinate system in which the dynamical system takes the “simplest” or “minimal” form. The normal forms, which are sparse in the space of homogeneous vector polynomial of certain degree, is calculated by making judicious choices of the solutions to the homological equations [13]. Hence, in the context of our work, close to the bifurcation point, the sparse regression techniques rely heavily on the fact that many dynamical systems can be represented by governing equations that are sparse in the space of all possible functions of a given algebraic structure.

Compressed Sensing

Compressed sensing (CS) is a technique for sampling and reconstructing sparse signals that can be represented by $k \ll n$ significant coefficients over an n -dimensional basis. The central goal of CS is the recovery of sparse vectors from a small number of linear measurements, which distinguishes CS from other dimensionality reduction techniques. In [9] and [6], the original sparse (k -sparse) signal is projected onto a lower-dimensional subspace via a random projection scheme, called the sampling matrix. More precisely, this broader objective is exemplified by the important special case in which one is interested in finding a vector $S \in \mathbb{R}^n$ using the (noisy) observation or the measurement data

$$Y = \Theta S + \eta, \quad \text{where } \Theta \in \mathbb{R}^{m \times n} \text{ with } k < m < n, \quad (33)$$

is the known sensing or sampling matrix and η is the measurement noise.

In general, this problem cannot be solved uniquely. However, if S is k -sparse i.e., if it has up to k non-zero entries, the theory of CS shows that it is possible to reconstruct S , a k -sparse vector in \mathbb{R}^n uniquely from m linear measurements even when $m \ll n$, by exploiting the sparsity of S . This can be achieved by finding the sparsest signal consistent with the vector of measurements [9], i.e.

$$\arg \min_{S \in \mathbb{R}^n} \|S\|_0 \quad \text{subject to } \|Y - \Theta S\|_2 \leq \varepsilon \quad (34)$$

where $\|S\|_0$ denotes the l_0 norm for S (the number of non-zero entries of S), while ε denotes a parameter that depends on the level of measurement noise η . However, l_0 minimization problem (34) is a non-convex problem which is NP-hard.

Instead of problem (34) we consider its l_1 convex relaxation which may be stated as

$$\arg \min_{S \in \mathbb{R}^n} \|S\|_1 \quad \text{subject to } \|Y - \Theta S\|_2 \leq \varepsilon \quad (35)$$

where the l_1 norm (sum of the absolute values of the entries of S) is a convex function. Hence (35) is a convex optimization problem which can accurately approximate the solution to (34) in polynomial time with high probability if measurement matrix Θ is chosen to satisfy a necessary condition called “Restricted Isometry Property” (RIP) [5, 6]. One should note that the l_1 minimization in (35) is closely related to the LASSO problem [29]

$$\arg \min_{S \in \mathbb{R}^n} \|Y - \Theta S\|_2^2 + \alpha \|S\|_1 \quad (36)$$

where $\alpha \geq 0$ is a regularization parameter. If ε and α in (35) and (36) satisfy some special conditions, the two problems are equivalent; however, characterizing the relationships between ε and α is difficult except for the special case of orthogonal sensing matrices Θ . The practical success of the LASSO can be attributed to the fact that in many cases S is sparse.

Sparse Identification of Dynamical Systems (SINDy)

Sparse identification of nonlinear dynamics (SINDy) [4] is an algorithm for discovering the dynamical equations directly from the data. The problem of model discovery from data can be formulated as a feature selection problem in machine learning. The SINDy algorithm takes m -time measurements of $\mathbf{x} \in \mathbb{R}^n$, $\mathbf{X} = [\mathbf{x}(t_1), \dots, \mathbf{x}(t_m)]^T \in \mathbb{R}^{m \times n}$ and attempts to discover the structure of a nonlinear differential equation of the form

$$\dot{\mathbf{X}} = \mathbf{f}(\mathbf{X}(t)) \approx \Theta(\mathbf{X})\mathbf{S} \quad (37)$$

where $\Theta(\mathbf{X}) = [\theta_1(\mathbf{X}), \theta_2(\mathbf{X}), \dots, \theta_p(\mathbf{X})] \in \mathbb{R}^{m \times p}$ form the dictionary of basis functions, and $\mathbf{S} = [\mathbf{s}_1 \dots \mathbf{s}_k \dots \mathbf{s}_n] \in \mathbb{R}^{p \times n}$ is the matrix of coefficients, where each column \mathbf{s}_k corresponds to an equation with p terms. p is the maximal number of n -multivariate monomials of degree at most d . The majority of \mathbf{S} entries are zero while the remaining non-zero entries identify the active terms contributing to the sparse representation of the dynamics $\mathbf{f}(\mathbf{X})$. To guarantee sparsity, SINDy is reformulated as a LASSO problem

$$\arg \min_{\mathbf{s}_k} \frac{1}{m} \sum_{i=1}^m \|\dot{\mathbf{x}}(t_i) - \Theta(\mathbf{x}(t_i))\mathbf{s}_k\|_2^2 + \alpha \|\mathbf{s}_k\|_1 \quad (38)$$

where α is the l_1 regularization coefficient. LASSO is an optimization algorithm that finds a sparse solution for (38) by initializing $\mathbf{s}_k = \mathbf{0}$ and at each iteration, it tries to find an update for \mathbf{s}_k one entry at a time. The coefficient α acts as a threshold such that if the an optimal condition involving α is not satisfied for a particular \mathbf{s}_k entry, the entry is chosen to be equal to zero. Increasing the value of α leads to more zero entries in \mathbf{s}_k , resulting in a sparse model.

The dictionary of basis functions for monomial sampling of dynamical system is

$$\Theta(\mathbf{X}) = \begin{bmatrix} | & | & | & | & | \\ \mathbf{1} & \mathbf{X} & \mathbf{X}^{P_2} & \mathbf{X}^{P_3} & \dots \\ | & | & | & | & | \end{bmatrix}. \quad (39)$$

The dictionary $\Theta(\mathbf{X})$ is constructed by appending candidate nonlinear functions of \mathbf{X} column-wise. Here, higher order polynomials are denoted as \mathbf{X}^{P_d} where d is the order of the polynomial considered. For example, element $\mathbf{1}$ is a column-vector of ones, element \mathbf{X} is as defined above, element \mathbf{X}^{P_2} is the matrix containing the set of all quadratic polynomial functions of the state vector \mathbf{x} , and is constructed as follows:

$$\mathbf{X}^{P_2} = \begin{bmatrix} x_1^2(t_1) & x_1(t_1)x_2(t_1) & \dots & x_2^2(t_1) & \dots & x_n^2(t_1) \\ x_1^2(t_2) & x_1(t_2)x_2(t_2) & \dots & x_2^2(t_2) & \dots & x_n^2(t_2) \\ \vdots & \vdots & \ddots & \vdots & \ddots & \vdots \\ x_1^2(t_m) & x_1(t_m)x_2(t_m) & \dots & x_2^2(t_m) & \dots & x_n^2(t_m) \end{bmatrix}. \quad (40)$$

We interpolate the reduced MG simulation data as a dynamical systems with cubic nonlinearity which is up to \mathbf{X}^{P_3} .

ROM Results and Analysis

We run 10 simulations of the viscous MG equations' stall case for $t \in [0, 500]$ with $dt = 0.1$. The initial conditions for $g(t, \theta)$'s amplitude, Φ , and Ψ are drawn from the normal distribution with mean 0.1 and standard deviation 0.05. The first 2000 data points (up to $t = 200$) containing the transient dynamics are discarded. This gives us 10 $\mathbf{Y} \in \mathbb{R}^{3000 \times 514}$ datasets. We perform k -fold cross validation [14] on PCA, regularized autoencoder, and NLPCA autoencoder to find the best ROM parameters to bring down the data dimension to 2. Both autoencoders' training were performed using Adam optimizer [16] with learning rate of 10^{-4} for 10 epochs of 4 mini-batch size for the regularized linear autoencoder and 20 epochs of 4 mini-batch size for the NLPCA autoencoder.

We encode the 10 datasets using the 3 different encoders to obtain 3 versions of 10 $\mathbf{X} \in \mathbb{R}^{3000 \times 2}$. For each group of reduced-order/encoded data, we perform a cubic nonlinearity dynamical system identification using PySINDy [8] paired with LASSO optimizer from Python's `sklearn` package. We train the 3 groups of 10 \mathbf{X} datasets in order to find the best α which hits the sweet spot between sparsity and accuracy using grid search [18]. After finding the best α for each group, we perform another k -fold cross validation to decide on a model that best represent the 10 datasets of each ROM.

The discovered reduced governing equations satisfy the normal form if it is sufficiently described by 4 coefficients μ, ω, b_1, b_2 up to an acceptable numerical tolerance

$$\begin{aligned} \dot{x}_1 &= \mu x_1 - \omega x_2 + b_1(x_1^2 + x_2^2)x_1 - b_2(x_1^2 + x_2^2)x_2 \\ \dot{x}_2 &= \omega x_1 + \mu x_2 + b_2(x_1^2 + x_2^2)x_1 + b_1(x_1^2 + x_2^2)x_2. \end{aligned} \quad (41)$$

However, when the linear operator is semi-simple (as in Hopf bifurcations), the correct identification of a normal form depends critically on the null space of the homological operator [13]. The consequence of this fact is that the nonlinear terms in normal form (41) commutes with the linear term. As shown in [24], a consequence of this property is that, when the equation is normalized to any finite degree, say $k = 3$, and truncated, it will have symmetries that were not present in the original system. More precisely, rewriting the normal form equations (41) at the bifurcation point ($\mu = 0$) as

$$\dot{\mathbf{x}} = A\mathbf{x} + f^*(\mathbf{x}) \quad \mathbf{x} \in \mathbb{R}^2, \quad (42)$$

and letting $\mathbf{x} = \exp(At)\mathbf{y}$, the transformed equations are

$$\dot{\mathbf{y}} = \exp(-At)f^*(\exp(At)\mathbf{y}) \quad \mathbf{y} \in \mathbb{R}^2. \quad (43)$$

Using the commutation property [24] of the normal form f^* ,

$$\exp(-At)f^*(\exp(At)\mathbf{y}) = f^*(\mathbf{y}), \quad \forall t \in \mathbb{R}, \forall \mathbf{y} \in \mathbb{R}^2,$$

the normal form equations in the new variables \mathbf{y} reduce to

$$\dot{\mathbf{y}} = f^*(\mathbf{y}) \quad \mathbf{y} \in \mathbb{R}^2. \quad (44)$$

For post-bifurcation dynamics, the discovered reduced governing equations satisfy the normal form (44) if it is sufficiently described by 2 coefficients (b_1, b_2) up to an acceptable tolerance

$$\begin{aligned} \dot{y}_1 &= b_1(y_1^2 + y_2^2)y_1 - b_2(y_1^2 + y_2^2)y_2 \\ \dot{y}_2 &= b_2(y_1^2 + y_2^2)y_1 + b_1(y_1^2 + y_2^2)y_2. \end{aligned} \quad (45)$$

Hence, MG equations close to a Hopf bifurcation have a sparse representation (45) with respect to high-dimensional polynomial spaces. The practical success and importance of the LASSO can be attributed to correctly identifying the relevant variables when the underlying model is sparse. LASSO algorithm is used in the subsequent sections to recover a system of two sparse ordinary differential equations (ODEs) with cubic nonlinearities.

For the reconstruction, the obtained SINDy equations are integrated using the forward Euler method with a fixed integration time step $dt = 0.1$ to be consistent with the chosen smoothed forward difference differentiation scheme. The global truncation error is then subtracted from the raw numerical integration result to correct the estimate. Lastly, the integrated SINDy data are fed into the decoder of the respective reduction methods to reconstruct the high dimensional time series and compared with the original dataset.

PCA and SINDy

The best SINDy regression is obtained using a LASSO threshold of $\alpha = 0.11$, which outputs a system of two ODEs with 8 coefficients and a R^2 score of 0.9999 on the test data $\|\hat{\mathbf{X}}\|$ as

$$\begin{aligned} \dot{x}_1 &= -0.000144x_1^3 - 0.008137x_1^2x_2 - 0.000144x_1x_2^2 - 0.008136x_2^3 \\ \dot{x}_2 &= 0.008136x_1^3 - 0.000144x_1^2x_2 + 0.008136x_1x_2^2 - 0.000144x_2^3. \end{aligned} \quad (46)$$

The normal form coefficients $(-0.000144, 0.008136)$ are visibly detected. Reconstruction results for a chosen random dataset are shown on the left in Figure 3.

Regularized Linear Autoencoder and SINDy

The best SINDy regression is obtained using a LASSO threshold of $\alpha = 0.30$. The output is a system of two ODEs with 9 coefficients and a R^2 score of 0.9999 on the test data $\|\hat{\mathbf{X}}\|$ and is given as

$$\begin{aligned} \dot{x}_1 &= -0.000440x_2^2 - 0.000145x_1^3 + 0.008138x_1^2x_2 - 0.000143x_1x_2^2 + 0.008138x_2^3 \\ \dot{x}_2 &= -0.008136x_1^3 - 0.000144x_1^2x_2 - 0.008139x_1x_2^2 - 0.000144x_2^3. \end{aligned} \quad (47)$$

The normal form coefficients $(-0.000145, -0.008138)$ are also visibly detected, albeit with wider deviation in values compared to (46) and an additional quadratic term in the first equation. Reconstruction results for a chosen random dataset are shown on the right in Figure 3.

NLPCA Autoencoder and SINDy

The best SINDy regression is obtained using a LASSO threshold of $\alpha = 0.60$. The output is a system of two ODEs with 11 coefficients and a R^2 score of 0.9998 on the test data $\|\hat{\mathbf{X}}\|$ which does not satisfy the normal form. A representative equation (since the outcome is always random) is given as

$$\begin{aligned} \dot{x}_1 &= -0.001031x_2^2 - 0.000091x_1^3 + 0.007704x_1^2x_2 + 0.000429x_1x_2^2 + 0.006863x_2^3 \\ \dot{x}_2 &= -0.001664x_1^2 - 0.000580x_2^2 - 0.007607x_1^3 - 0.000473x_1^2x_2 - 0.007470x_1x_2^2 - 0.000237x_2^3. \end{aligned} \quad (48)$$

Reconstruction results for a chosen random dataset are shown in Figure 4.

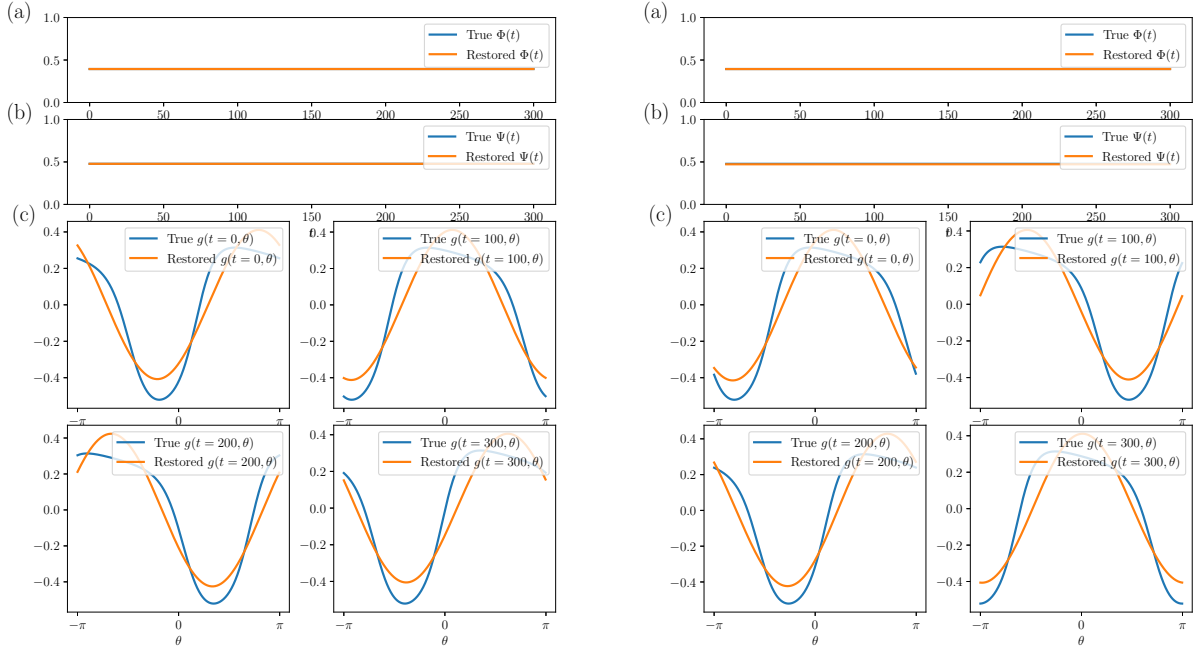

Figure 3: Reconstruction of viscous MG stall dynamics using PCA and SINDy (on the left) and regularized linear autoencoder and SINDy (on the right): (a) $\Phi(t)$, (b) $\Psi(t)$, and (c) $g(t, \theta)$ reconstruction results at $t = 0, 100, 200, 300$

Conclusions

We have showed that it is possible to fully reconstruct the solutions of the viscous MG equations from a system of 2 ODEs up to cubic nonlinearity, constructed from data sets by sparse regression. Additionally, it seems that the only requirement

to detect the normal form of the PDE Hopf bifurcation is to have reduced-order data that falls along the first two principle axes, and reconstruction quality is entirely independent of whether normal forms of the underlying PDE is detected or not. The NLPKA autoencoder has to be trained for twice as long (double the number of epochs) compared to the linear autoencoder in order to converge to the local minimum that produces great reconstruction result. Table 1 summarizes our findings for the three chosen dimensionality reduction methods. Our simple approach rooted in physics-based machine learning which involves a priori knowledge of sparsity and the center manifold theory allows us to bypass deep neural network performing synchronized dimensionality reduction and SINDy approach in [7]. It is shown in Table 1 that performing dimensionality reduction and SINDy independently does not result in any significant reconstruction loss. Additionally, it would be interesting to find out if nonlinear principal components would lead us to normal form discovery from a nonlinear autoencoder, and if those components can be found using a simple regularization based approach to ensure the convexity of loss landscape just like its linear counterpart [17].

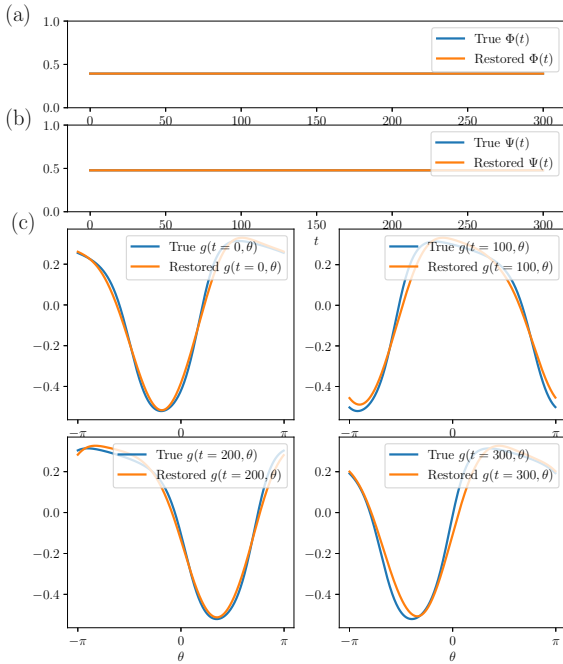

Figure 4: Reconstruction of viscous MG stall dynamics using NLPKA autoencoder and SINDy

	PCA	Linear Autoencoder	NLPCA Autoencoder
Training time	25 s	103 s	283 s
PDE reconstruction R^2 score from training data	0.8973	0.8973	0.9916
PDE reconstruction R^2 score from SINDy equations	0.8950	0.8948	0.9890
Number of RHS terms in reduced equations	8	9	11
Normal form detected	yes	yes	no

3D FEM Model of Intact Human Middle Ear Compared to Lumped Mass Model and Experimental Results

Robert Zablotni*, Rafal Rusinek*

**Department of Applied Mechanics, Lublin University of Technology, Poland*

Summary. The human body can be considered by micro biomechanical systems and human middle ear is one of the smallest of those systems. In this abstract, finite elements method model and three degrees of freedom lumped mass model of human middle ear is proposed. Moreover in introduction it contains description of intact human middle ear.

Keywords: middle ear; stapes vibration; relaxation; ligaments modelling

Introduction

The human body can be considered as a set of micro biomechanical systems where human middle ear is one of the smallest of those systems. Human ear can be divided into three basic parts sequentially: external ear, middle ear and internal ear. Through auditory canal sonic waves reaches tympanic membrane which sets in motion three bones of a middle ear – the malleus, the incus and the stapes. The stapes transfers waves to the internal ear. Nest in semicircular canals mechanical vibrations are converted into nerve impulses. Over the years, many attempts have been made to create models of the human ear. The first study in this field was published in 1961 by Möller [1] where the first scheme of middle ear mechanism was proposed. Next, a similar model was investigated by Zwislocki [2]. In both publications, authors used an electrical circuit to analyse middle ear system. Currently, the most popular models of human ear are created by means of finite elements method, rarely as lumped mass models. Due to microscopic structure of human middle ear, examinations are extremely difficult. Moreover experimental studies must be carried out on the human temporal bone, therefore the amount of research is limited. For the above reasons, it is necessary to create models of the middle ear and their validation, because the tests carried out on them are limited only by the computing power of computers. Research on human ear models could lead to breakthroughs in the field of laryngology and otolaryngology.

Results and Discussion

The intact human middle ear lumped mass model is presented on Figure 1(a). There are three masses in the model: m_m , m_i and m_s . Each mass corresponds to one of the bones of the human middle ear: m_m – the malleus, m_i – the incus and m_s – the stapes. All masses are connected to each other by springs and dampers that correspond to joints, ligaments and tendons in s human middle ear. In this case presented here, the human middle ear with the Kelvin–Voigt type of viscoelasticity is used for analysing. Parameters as stiffness and damping coefficients of the middle ear used in numerical simulations were taken both from experimental validation and literature. Figure 1 (b) shows meshed Finite Elements Method (FEM) model of the intact human middle ear to compare numerical results. This model was created by Micro CT scanning of the human middle ear. Three bones: the malleus, the incus and the stapes and the eardrum was separated and then they have undergone a scanning procedure. Parts that were obtained were connected in Computer Aided Design (CAD) software. Moreover simplified ligaments and tendons were created in CAD and were connected to the bones. At the end, a simplified cochlea and oval window was made in order to connect the stapedia annular ligament (SAL). Material data for the Finite Elements Model of intact human middle ear was taken from the literature [4].

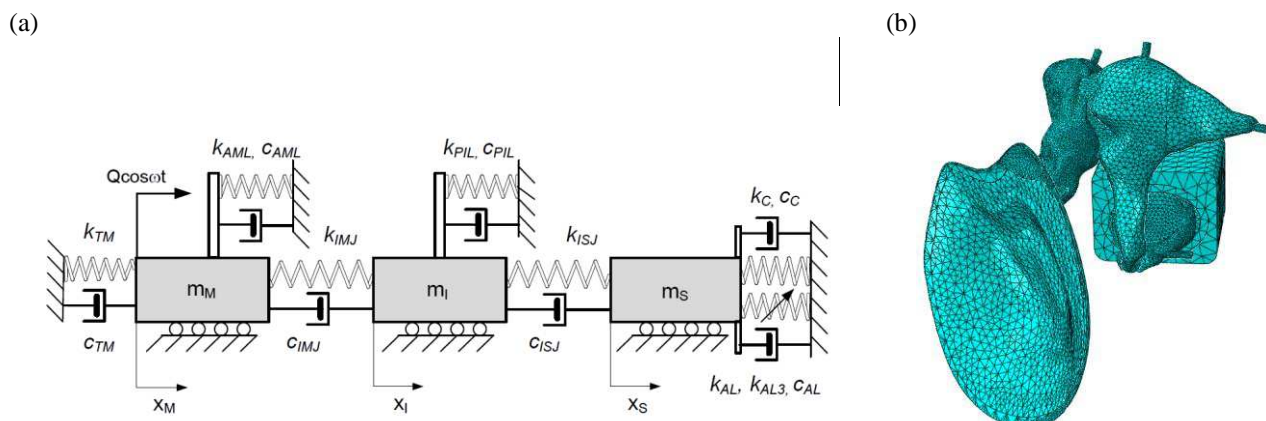

Figure 1: Models of intact human middle ear. (a) 3 degrees of freedom (dof) lumped mass model [3], (b) finite elements method model.

The most demanding aspect of Finite Elements Method modelling was setting the mesh in such a way that the objects do not interpenetrate during the simulation of motion. The next difficulty is determining the time of stabilization for the

system. Another demanding task is to set appropriate boundary conditions of the system which allow proper reproduction of the occurring movements in the middle ear as a result of being forced by an acoustic wave onto the eardrum. The FEM model is compared with the experiment results to assess its correctness.

Figure 2: Function of velocity versus time measured on stapes footplate for not-steady state of vibrations in Finite Elements Method model of intact human middle ear for the frequency equal to 200Hz.

In Figure 2, function of velocity versus time for not-steady state of vibrations of human middle ear in FEM model can be observed. For the undefined Rayleigh damping parameters for human middle ear the rumble phenomenon can be observed. By using the appropriate damping parameters velocity of the stapes can be obtained and compared to the experimental data.

Conclusion

A novelty in the Finite Elements Method model is obtaining parts by the Micro CT scanning, which gives an accurate representation of the geometry of the bones of the human middle ear. On the basis of the lumped mass model of intact human middle ear and experimental results, correctness of the FEM model is approved. For the FEM model of the human middle ear, the appropriate material parameters and the Rayleigh's damping parameters allow to shorten the calculation time and obtain results with a similar value to the results obtained experimentally. In the future FEM model will be used to develop model of the middle ear with active implant.

Computational model of Deep Brain Stimulation (DBS). Transitions from Healthy to Parkinsonian and DBS treatment.

Konstantinos Spiliotis*, Jens Starke *

**Institute of Mathematics, University of Rostock, D-18057 Rostock, Germany*

Summary. The basal ganglia network plays an important role in the movement and emotional control. Changes in the structure and dynamics of the network are closely related to pathological disorders (Parkinson, Dystonia, Depression etc). We developed a large scale biophysical neuronal model in order to study the effect of Deep Brain Stimulation (DBS) in Parkinson and Dystonia. The neural network model consists of 4 major areas of basal ganglia, Globus Pallidus External and Internal (GPE)-(GPI), Subthalamic nucleus (STN) and Thalamus. By changing several model parameters related to the synaptic weights, as well as the frequency of external DBS stimulus, the model switches the dynamics from normal to pathological (Parkinson-Dystonia) to DBS treatment behavior. Combining both, numerical bifurcation analysis and Equation Free Methodology (IEFM), we detect systematically in the parametric space, the dynamical regimes of different dynamics.

Introduction

Deep Brain Stimulation (DBS) consists a revolutionised treatment for movement and mental disorder. After 1997 when the Food and Drug Administration (FDA, USA) approved DBS as a treatment for tremor, the development was rapid including several diseases (Parkinson, Dystonia, Epilepsy) but also mental Disorders (Depression and Obsessive-Compulsive Disorder)[1]. Even in our days then main mechanism behind this treatment remain mysterious. One of the main obstacles is the lack of one coherent framework which joins the different levels-scales of mechanism ranging from microscopic (neurophysiology and genetic variations of the neurons), to macroscopic (i.e. tremor and dyskinesia). An intermediate level, the mesoscopic, is related with dynamics of specific networks of neurons in different nucleus of BG. The dynamics of these networks constitute the bridge of micro and macro behaviour since are affected from the neuron's properties and the emergent patterns which arise define the macroscopic action. In this spirit we propose a computational large-scale biophysical model related to the Parkinson Disease (PD) and DBS treatment. Based on the work presented in [2, 3] we model 4 areas of the Basal Ganglia (BG); the Globus Pallidus External and Internal (GPE-GPI) the Sub-Thalamic Nucleus (STN) and the Thalamus. We show how the variations in the synaptic weights connectivity between the BG areas affects the macroscopic dynamics, switches from normal to PD and how the DBS on the STN acts as a treatment affecting the whole network. In addition, during DBS the model reveals a de-synchronization of the GPI activity which is projected to Thalamus. Combining both, numerical bifurcation analysis and Equation Free Methodology (EFM) [4] and Implicit Equation Free Methodology [5] for multiscale modelling, we detect systematically in the parametric space, the dynamical regimes of different dynamics. Main parameters are the connectivity weights and frequency of DBS.

Description of the Basal Ganglia Network

All BG regions follow the Hodgkin Huxley current balanced formalism. The STN neurons follow the equation [2]

$$C \frac{dV_i}{dt} = -I_{Ca} - I_{Na} - I_K - I_T - I_L - I_{AHP} - I_{GS} - I_{SS} + I_{DBS} \quad (1)$$

where C is the membrane capacity, I_{Ca}, I_{Na}, I_K are the ionic currents, I_L is the leak current, I_{AHP} and I_T are the after hyperpolarized and T currents which are depended on the calcium concentration. The postsynaptic currents $I_{SS} = g_{SS}(V - V_S) \sum_j s_j$ and $I_{GS} = g_{GS}(V - V_G) \sum_j s_j$ correspond to internal STN excitation and inhibition from GPE respectively. The s_i is the activation variable [2, 3] and the summation is taken over the presynaptic neurons. The GPE-GPI neurons follow similar current balance equation

$$C \frac{dV_i}{dt} = I_{app} - I_{Ca} - I_{Na} - I_K - I_T - I_L - I_{AHP} - I_{SG} - I_{GG} \quad (2)$$

where the currents are defined in the same way as the STN [2]. I_{app} represents the input current from the striatum and has the same constant value for all GPE neurons. Finally the Thalamic neurons follows the equation

$$C \frac{dV_i}{dt} = I_L - I_{Ca} - I_{Na} - I_K - I_T - I_L - I_{GiTh} + I_{SM} \quad (3)$$

where the I_{SM} describes the input from sensory motor cortex. The detailed form of the currents and the values of parameters are described in [2].

The STN and GPE areas include $N=500$ neurons each while the GPI and Thalamus consist of $N=200$ neuron. For each area we use a small world of network with $k = 10$ and $p = 0.01$ [6]. The interconnections between different layers are 1-1 i.e. one STN neuron is adjacent with one GPE neuron and one GPI neuron communicate with one thalamic neuron. A representative image is depicted in Fig.1.

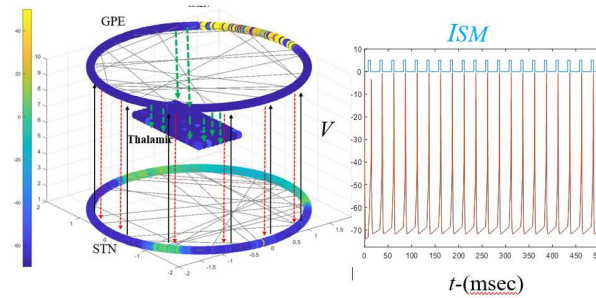

Figure 1: Illustrative image of the whole BG network. Different areas are depicted as small world network. (b) Dynamics of Thalamic neurons under the external input which comes from sensory motor cortex.

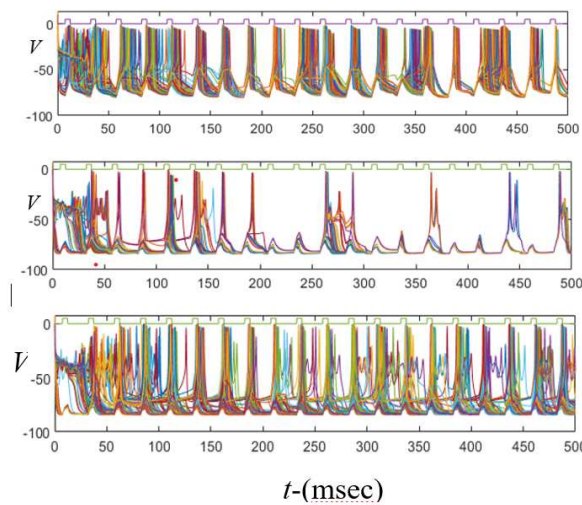

Figure 2: Dynamics of the Thalamic neurons in normal case(first row). During the PD (middle row) and finally under the DBS treatment.

Results

We investigate the dynamics with respect the connectivity weights between the GPI and thalamus. For small value of inhibition g_{GiTh} the thalamic neurons reacts in rights way to external sensory motors inputs see Fig 2. For higher value of g_{GiTh} i.e. higher inhibition, thalamus produces Parkinsonian behaviour: ineffective response to external sensory motor input, while with DBS on and with same connectivity parameters as the PD behaviour, the model shows dynamics close to normal case: The thalamus after transient period, reacts similar (approximately) to healthy normal case see Fig.2. In order to analyse the emergent dynamics we will perform numerical bifurcation analysis, under the Equation Free Methodology [5]. The macroscopic variables are the mean values of the membrane voltage of the four areas.

Cracking Down on Criminals: A Mathematical Model Expoloring Strategies for Curbing Criminal Behaviour

Joanna Sooknanan and Donna M. G. Comissiong

Department of Mathematics and Statistics, The University of the West Indies, St Augustine Campus, Trinidad, West Indies

Summary. Criminal behaviour is a rapidly growing challenge internationally. Policy makers are usually charged with developing strategies to control its spread - while limited by financial constraints. With the use of a model adapted from epidemiology, control strategies in the form of time dependent prevention and treatment efforts to curtail the spread of criminal behaviour may be evaluated. The first control strategy applied encourages potential criminals away from a life of crime while the second strategy targets criminals. We find that a combination of strategies leads to the biggest reduction in the number of criminals and of potential criminals. To be effective, strategies based on single controls require the implementation of more intensive efforts at the start of the control effort.

Extended Abstract

One of the greatest social challenges plaguing many countries nowadays is that of criminal behaviour and its ensuing prevention and reduction. Violent crime can have a negative effect on a countrys economy in a variety of ways. These include reduced economic growth, a decline in tourism, increased emigration in conjunction with a resulting brain drain, a reluctance to invest locally by foreign investors and a general feeling of fear and insecurity by the population. This is compounded when limited resources are available to policy makers. Especially in such instances, whatever measures are used must be cost effective.

An innovative approach to tackling crime that is rapidly gaining popularity is to consider criminal behaviour as an infectious disease and then to use a public health approach to mitigate its spread [1, 2]. This approach may also be used when designing strategies to prevent or disrupt the contagion process, which may then be tested using mathematical models from epidemiology - compartmental models.

Optimal control theory has been implemented to study strategies for the treatment of many diseases including waterborne diseases, HIV, Ebola, Dengue and Pandemic Influenza. In recent times [3], modelling of behaviour using an infectious disease approach has been done for fanatical and violent ideology, violent crime and burglary and gang membership. Our paper deals with the application of optimal control to a dynamic model of criminal behaviour treated as an infectious disease. Our aim is to find the best strategy in terms of combined efforts of prevention and treatment that would minimize the total number of criminals and its cost.

Model Formulation

The population under consideration $N(t)$ consists of people who are “at risk”for engaging in or have engaged in criminal behaviour. N is divided into four disjoint compartments/classes based on status with respect to criminal behavior. These are:

P : Members of the population who are susceptible to criminal behaviour - Potential Criminals.

C : Members of the population who are engaged in criminal behaviour - Criminals.

J : Members of the population who are in prison or in a juvenile delinquency centre.

R : Members of the population who were in an prevention or treatment program and have permanently left life of crime - Recovered people.

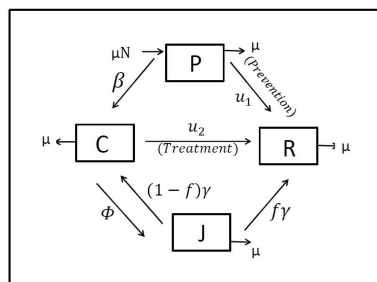

Figure 1: Model Diagram

We consider two separate control programs $u_1(t)$ and $u_2(t)$ applied to the P and C subgroups with the goal of “recovery”. These represent programs or strategies which encourage positive behaviour change and include programs designed by the government as well as outreach programs by social service groups, neighbourhood organizations, and the faith community.

The first control strategy $u_1(t)$ is applied to potential criminals P who may become criminals by interaction with criminals C at the rate $\frac{\beta CP}{N}$. However, since a prevention control scheme is applied to the P class, $u_1(t)P$ individuals progress to the recovered class R . Individuals in the criminal class may enter a treatment control program at the rate $u_2(t)$ or go to jail at the rate ϕ . On release from jail, a fraction $(1 - f)$ re-join the criminal class and the remainder enters the recovered class at a rate of $f\gamma$ where γ^{-1} represents the time spent in jail. For ease of analysis purposes, we assume a constant size population N with an entry and death rate into the population given by μ . The rate of entry into the system is proportional to the population size and is given by μN . Figure 1 shows the structure of flows within the model which is described by the following set of nonlinear differential equations:

$$P' = \mu N - \frac{\beta CP}{N} - u_1(t)P - \mu P \quad (1)$$

$$C' = \frac{\beta CP}{N} + (1 - f)\gamma J - u_2(t)C - \phi C - \mu C \quad (2)$$

$$J' = \phi C - \gamma J - \mu J \quad (3)$$

$$R' = u_1(t)P + u_2(t)C + f\gamma J - \mu R \quad (4)$$

$$N = P + C + J + R \quad (5)$$

Model Analysis – Equilibria and Stability

We study the existence and stability behaviour of the system at its equilibrium points. Two possible equilibrium states are found – the criminal-free equilibrium where the system only consists of potential criminals and the coexistence equilibrium. Coexistence (or endemic) equilibrium points are steady-state solutions where the disease “criminality” persists in the population.

The issue of whether or not a disease can invade a host population and persist or remain endemic involves the introduction of a threshold known as the basic reproductive number R_0 . In our model, R_0 represents the average number of potential criminals who are recruited to the criminal class c . If $R_0 < 1$, then the criminal-free equilibrium is locally asymptotically stable. If $R_0 > 1$, then the criminal-free equilibrium is unstable, and the introduction of a criminal will result in an outbreak. In the early stages of a crime outbreak, R_0 is the key quantity of interest, and our goal is to identify mitigation strategies to reduce it below the threshold $R_0 = 1$.

Formulation of the Optimal Control Problem

Our first control strategy ($0 \leq u_1(t) \leq 1$) includes programs and practices that target individuals who have an elevated risk for becoming criminals. The second control strategy ($0 \leq u_2(t) \leq 1$) includes programs to treat criminals. Our goal is to minimize the number of criminals while at the same time minimizing the cost of controls $u_1(t)$, $u_2(t)$ over a time period T given the initial population sizes of all three classes $p(0)$, $c(0)$ and $j(0)$. Thus, we are seeking the optimal control pair $(u_1^*(t), u_2^*(t))$ so that

$$J(u_1^*, u_2^*) = \min \{J(u_1, u_2) : (u_1, u_2) \in U\} \quad (6)$$

where the Lebesgue measurable control set U is defined as

$$U = \{u_1(t), u_2(t) : 0 \leq u_1 \leq 1, 0 \leq u_2 \leq 1, t \in [0, T]\} \quad (7)$$

subject to the model equations.

The objective functional is defined as

$$J(u_1, u_2) = \int_0^T \left[Kc(t) + \frac{B_1}{2} u_1^2 + \frac{B_2}{2} u_2^2 \right] dt \quad (8)$$

where B_1 and B_2 are the relative weights attached to the cost or effort required (human effort, material resources, infrastructural resources etc.) to implement each of the control measures. K measures the comparative importance of the criminal burden relative to the control costs. Pontryagin’s maximum principle [4] is used to solve this optimal control problem numerically using the backward-forward sweep method [5, 6] with the initial conditions given in [7] and reasonable estimates for the model parameters.

Summary. Control-based continuation (CBC) is a testing method that maps the nonlinear dynamic features of a physical system directly from experiments. The application of CBC has been so far limited to electro-mechanical systems. In this paper, we numerically investigate the application of CBC to a synthetic gene network, the toggle switch. The network's behaviour is simulated using a nonlinear model (with and without noise), and model predictive control (MPC) is exploited to control its dynamics, through the definition of an appropriate control objective function. Our preliminary results show that MPC-based CBC can accurately capture the continuation curve obtained numerically on the full nonlinear model.

Introduction

Mathematical modelling is widely used in System and Synthetic Biology to understand nonlinear biochemical phenomena (e.g. gene expression temporal oscillations), and to design and validate engineered gene circuits. Although widely used, biochemical models can be challenging in both their derivation and associated parameter identification [1, 2]. Parameter and model uncertainty can significantly alter the reliability of model predictions of nonlinear dynamic behaviours.

The application of control-based continuation (CBC) to biological systems, not attempted to date, has the potential to overcome these difficulties, improving the understanding of naturally-occurring nonlinear biochemical dynamics (e.g. oscillations in signalling pathways) and enabling the rapid prototyping of engineered gene regulatory network dynamics. CBC is a non-parametric method that combines feedback control with principles of numerical continuation to map out the dynamic features of a nonlinear physical system directly during experimental tests [3]. The fundamental principles of CBC are well established and the method has been applied to a wide range of non-living (i.e. electro-mechanical) systems [4, 5]. In this contribution, we investigate the use of CBC to detect and track the equilibria of the toggle switch, an engineered genetic circuit [6]. Model-predictive control (MPC), previously exploited to control biological systems [7], is employed to steer the system's dynamics towards steady-state and stabilise unstable responses of the underlying uncontrolled system.

Control-Based Continuation of a synthetic toggle switch's dynamics

We investigate the application of CBC on a toggle switch, one of the first and best characterised synthetic gene network implemented to date in living bacterial cells [6, 8]. The gene network consists of two repressors (*LacI* and *TetR*) and two inducers (*Atc* and *IPTG*). Each repressor affects the opposite gene's production, which can be externally tuned through the addition of chemical inducers. Levels of *LacI* and *TetR* can be observed thanks to fluorescent reporters (Figure 1A). The associated deterministic model is mathematically described by a set of four nonlinear differential equations taking into account mRNA transcription and translation of both repressors. For the stochastic scenario, a SDE model for the description of biochemical systems based on pseudo-reactions is considered [9].

We chose Model-Predictive Control (MPC) as control strategy to implement CBC; this method combines state estimation, model prediction and optimization algorithms to find the optimal actuation to apply to a system. At each time step i , the choice of the optimal sequence of N control inputs is based on the minimization of the cost function

$$J_i = \sum_{k=1}^N (N - k + 1) e(i + k)^2, \quad (1)$$

where the error $e(i + k)$ is defined as the difference between the control target and the prediction of the system's response over N samples. The system response to a particular sequence of control inputs is predicted by integrating in time a linear model of the system. This linear model was identified prior to closed-loop simulations using input-output *in-silico* data and time-domain subspace algorithms. At each time step i , the initial conditions required to initialise simulations are obtained using a Kalman filter that was also derived during the linear identification process. When an optimal sequence of inputs is found, only the actuation for the next time step is applied to the system. This whole optimization process is repeated at each actuation time step i .

Cost function (1) usually includes an additional term to balance tracking performance and control effort. This term is not considered here but replaced by optimization constraints limiting the control action u at time step i to be no more than 30% different from the control action at time step $i - 1$.

The inducer *IPTG* is considered to control the toggle switch's dynamics. *IPTG* regulates the expression of a fluorescent reporter gene, which is a proxy for the *TetR* concentration (see Fig. 1A). The controller based on the optimization of Eq. (1) with constraints allows to reach any meaningful value of the *TetR* concentration. At steady state, the value of the control input (*IPTG*) can be interpreted as the bifurcation parameter [10]. Recording *IPTG* for a range of target

Figure 1: MPC-based CBC of a synthetic toggle switch. A) Schematic representation of the toggle switch, adapted from [6], where **RFP** and **GFP** represent the fluorescent proteins binding with *LacI* and *TetR*. B) CBC results and numerical continuation bifurcation diagram (COCO software) are shown as red points \bullet and a dotted line (—), respectively; blue points \bullet design the bifurcation points. *IPTG* is the inducer, used as bifurcation parameter. C) CBC results on the stochastic model are represented as a density plot: 10 repetitions of the same experiment are run and 300 points are collected.

concentrations, the equilibrium curve of the uncontrolled toggle switch can be traced out. Fig. 1B shows the excellent agreement obtained between bifurcation diagram computed using standard numerical continuation algorithms (dashed line) and CBC results (red dots). Saddle-node bifurcations are highlighted in blue in Fig. 1B. For the stochastic case, multiple simulations are considered and 300 points are collected (Fig. 1C).

Conclusions

This paper investigates the use of CBC for tracking the equilibrium of synthetic gene regulatory networks. Our preliminary *in silico* results demonstrate the feasibility of the approach and the ability of CBC to capture both the stable and unstable behaviours of the original, uncontrolled system. In particular, in the absence of noise, the equilibrium curve measured using CBC perfectly agrees with the one computed using standard numerical continuation. In the stochastic scenario, CBC is still able to uncover the bistable nature of the system as data points qualitative follow the equilibrium curve of the underlying deterministic model. Unstable steady states collected using CBC also prove to be beneficial when estimating model parameters that reproduce bistability. The introduction of CBC to characterise cellular dynamics could benefit both the System and Synthetic Biology communities, providing a valuable tool to explore complex nonlinear dynamics and to gather important information that can eventually enable a more precise prototyping of those dynamics into novel synthetic gene circuits. The application of CBC to biochemical experiments could be done using microfluidics/microscopy platforms for real-time monitoring and control of gene expression in living cells via dynamic modulation of inducer molecules [11].

Summary. The architecture and quality of bone tissue in an adult organism predominantly depends on bone cellular organisation and communication processes that are highly driven by external mechanical loading. How physical forces and changes in the mechanical properties of cells and tissues contribute to development, cell differentiation, physiology, and disease, in general, is a major interest of mechanobiology. This paper outlines how mathematical models can help to improve current understanding of bone cellular mechanobiology. Here we introduce an adapted mathematical model for bone remodeling in the form of generalized S-system equations (Lotka-Volterra system) of fifth order that includes periodic received and transduced signal of external loading. Critically, we approach the modelling through both deterministic and stochastic methods, which allow us to consider the intrinsic noisiness of the process. In particular, this model includes osteocytes mechanobiology, which, apart from their biochemical processes and their interactions with other bone remodeling cells, includes external periodic signal transduction and influence that represents a significant advance to the field.

Background and Aims

The bone cell lineages are permanently active in the process of bone remodelling that resorbs old and forms the new content of bone. These activities happen on the daily base with a progression of several micrometres of local bone turnover. The bone architecture and quality depend on many biological, biochemical, hormonal and physical factors among which external static and dynamic loading play an important role. The bone adaptive mechanobiological processes are governed by the osteoblasts (OBs), osteoclasts (OCs), and osteocytes (OcYs) cells working in concert, all capable of transducing mechanical strain signals into biochemical cues for osteogenesis [1]. However, Osteocytes (OcYs) in particular have been shown in vitro to be the most mechanosensitive bone cell type, demonstrating a higher intrinsic sensitivity to loading than other osteogenic cells. They have also recently been shown to direct osteogenesis in other bone cell types, reinforcing the theory that osteocytes sense mechanical loading in the bone matrix and then orchestrate the adaptive bone remodeling response [2]. Owing to their presence deep within bone matrix, direct experimental observation of osteocytes in vivo has proven extremely challenging. As such, the precise mechanical stimuli, which they experience in vivo, and the mechanisms whereby they sense and transmit these stimuli, remain unknown. Although it is possible to mechanically stimulate bone and quantify the tissue-level changes that occur, it is still extremely challenging to simultaneously delineate the cellular and molecular mechanisms that give rise to these changes. Further, the complexity of the skeletal processes and their interactions with the rest of the body limits the ability of a single biological model to capture all of the relevant biological, biochemical, and biophysical mechanisms of remodelling on all scales simultaneously. Moreover, the parameterization of an established accompanying mathematical model is difficult, given its dependency on the accuracy and availability of data. However, in-silico experiments on established mathematical model reveal important features of nonlinear connections between variables and dependency on parameters of the system. In many cases, the quality of a scientific field depends on how well the mathematical models, developed on the theoretical side, agree with the results of repeatable experiments. Lack of agreement between theoretical mathematical models and experimental measurements often leads to important advances as better theories are developed. With this research, we wish to emphasize the importance, reliability and credibility of mathematical models as a great way of cementing biological intuition. Specifically, they provide causative mechanisms linking inputs and outputs, thereby illuminating underlying assumptions that determine a biological system's dynamics. Finally, they offer a means of predicting new outcomes, as well as highlighting the most sensitive modelled components, resulting in the construction of new experimental hypotheses and more focused experimentation.

Methods and mathematical models

To address the question of how different bone cells interact with each other and the bone microenvironment during remodelling, several cell population models have been proposed in Refs. [3-6]. These types of models are able to monitor changes in cell numbers and bone volume over time and they all modelled the free dynamics of the bone cell system. The formalism of a cell population model can be generalised to be of the form of a S-System of equations of n^{th} order that corresponds to the number of included cellular lineages,

$$\frac{du_i}{dx} = \alpha_i \prod_{j=1}^2 u_j^{g_{ij}} - \beta_i u_i, i = 1, 2, \dots, n. \quad (1)$$

If we include OcY, OB, OC and preosteoblastic (pOB) lineages of cells together with a bone mass equation it will be system of 5th order ($n = 5$). System (1) is a homogeneous system of coupled ordinary nonlinear differential equations that is more specifically. In one cycle of targeted remodeling the number of activator cells, both resorbing and forming, is bounded above by approximately 10 OCs and up to 300 OBs, so that in the dynamics of the system (1) the number of OCs drops below one, which occurs frequently. Of course, since we are dealing with exact numbers of cells, such a measurement is unrealistic.

Critically, the problem stems from the direct use of differential equations that assume a modelled population is large enough, for a continuum hypothesis to approximately hold. This hypothesis is obviously invalid at such small population sizes. Thus, for such low numbers of cells it is more correct to produce a discrete interaction model. Specifically, we use a stochastic analogue to simulate the creation and degradation, which encapsulates the noisy features of individual cell division and death [7-9]. From system (1) we are able to extract the stoichiometric creation and degradation relations, and present its probabilistic analogue:

Although parameter values exist in the literature they are mainly approximate and are proposed to simplify and justify the model. Further, in all of the literature it is assumed that the γ_{ij} parameters are constant. However, in real bone remodelling processes the γ_{ij} parameters may depend on time and other factors. Unfortunately, these parameters cannot be directly measured and have to be estimated. Based on these recent biological experimental findings we introduce the modification of the model by editing the power law term γ_{31} to time dependent oscillatory function $\gamma_{31}(1 + \sin(\theta t))$, what represent transduced signal of OcY, and inserting the mechanical periodic excitation $A(1 - \cos(\theta t))$ to the responding OcYs.

Results & Discussion

We find that the model can capture the essential autocrine, paracrine and synergistic characteristics of bone cell communication processes in response to the external incentives. Specifically, including oscillatory signals with small delays between received and send a signal by OcY provides the closest matches between mathematical data and biology theory. This can be seen from Fig. 1 where after the period of resorption, the depression of green z line below zero, come the significant changes in the activation of osteoblasts (yellow B line) that results in formation period, the green line above the zero. Comparing with the green line at Fig 1 a) that has no over formation above steady-state value $z_{ss} = 100$. We prove that under the influence of the external periodic signal the local formation of the newly remodelled bone will exceed the amount of resorbed old bone.

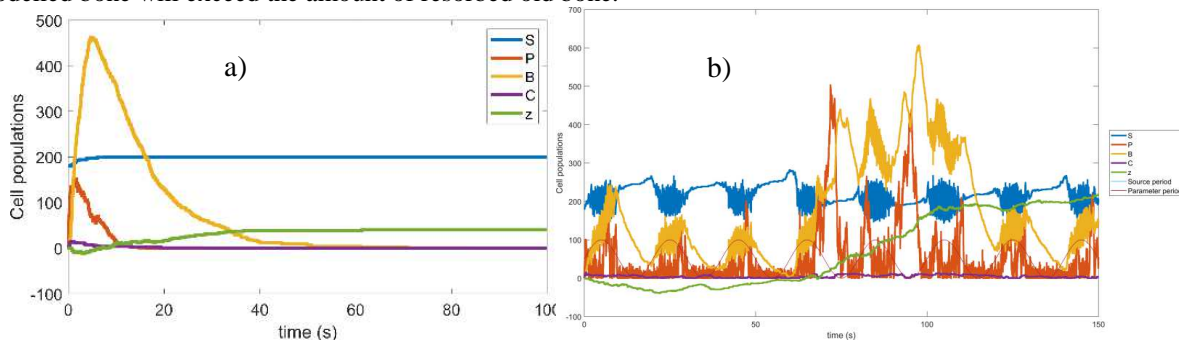

Figure 1: One cycle of bone remodeling: a) free cell communication; b) periodically forced dynamics with external periodic source and parameter γ_{31} out of synchronization by a factor of $\pi/2$, all parameter values are taken from [6] except $k_2 = 0.014$

Conclusions

The results of our research highlighted the importance of the external excitation and mechanotransduction of the signal by the bone cell in the regular bone turnover. The in-silico experiments with forced Lotka-Volterra system of population equations pinpointed the importance of nonlinear deterministic and stochastic analysis in the field of mechanobiology.

Summary. We present an efficient formulation of the path integration method to approximate the response probability density functions (PDF) of nonlinear stochastic differential systems. We obtain the time-dependent PDF at the next time point by solving the Chapman-Kolmogorov (CK) equation, where we integrate the probability density function (TPDF) of the transition from one state to another (TPDF), for all possible states, weighted by the PDF at the current time. We iteratively evaluate the CK equation via a partitioned formulation of the path integration method: the PDF is represented as an interpolated function, the TPDF from one state to the other is approximated using a numerical scheme, and the integral is evaluated using the Gauss-Legendre quadrature. We record the integration process in a so-called step matrix and transform the evaluation of the CK equation to a matrix-vector multiplication. We demonstrate that this approach increases the performance of the path integration method compared to previously established approaches and analyse the accuracy of different interpolation and time-stepping methods.

Introduction

The probability density function (PDF) is an important tool to investigate the response statistics of dynamical systems subjected to noise excitation. When the dynamical system is represented as a stochastic differential equation (SDE), a commonly used method to determine the response PDF is to solve the corresponding Fokker-Planck or Kolmogorov forward equation. This partial differential equation rarely has an exact analytical solution, and thus in most cases, we have to use a numerical approximation method to solve it. The simplest method to obtain the PDF is through time-domain Monte-Carlo simulations when we numerically integrate the SDE in time and use the realised trajectories to approximate the PDF.

Another method to obtain the PDF of an SDE is the path integration (PI) method. Here we have to solve the Chapman-Kolmogorov (CK) equation, formulated to describe the law of total probability for dynamical systems. The PI method has proven to provide an accurate estimate of the time evolution of the PDF of a dynamical system; however, the CPU time required to compute a PDF is still an issue. The computation time is a critical problem to address if the dimensionality of the state space of the investigated dynamical system is high or when we want to obtain the steady-state PDF for a slowly converging system. In previous formulations of the PI method [1, 2, 3, 4] the CK equation was directly solved in each time step, even in the case of time-invariant or time-periodic systems. There are works [5] that utilise FFT to speed up the time it requires to evaluate the CK equation for each time step; however, the CK equation is still evaluated at each time step.

In this work, we provide a modular approach to solve the CK equation and analyse the effect of different interpolation methods on the accuracy and the performance of the approximation of the PDF delivered by the numerical solution of the CK equation. Furthermore, we transform the process of evaluating the CK equation to a matrix multiplication which significantly speeds up the computation of PDFs of time-invariant and time-periodic systems.

Chapman-Kolmogorov Equation

We consider stochastic differential equations in the form

$$d\mathbf{x}(t) = \mathbf{f}(\mathbf{x}, t)dt + \mathbf{g}(\mathbf{x}, t)d\mathbf{W}_t, \quad (1)$$

where $\mathbf{x} = [x_1 \dots x_d]^\top$ is the \mathbb{R}^d -valued stochastic state variable, \mathbf{W}_t is the \mathbb{R} -valued Wiener process (Brownian motion), $\mathbf{f} : \mathbb{R}^d \times [0, T] \mapsto \mathbb{R}^d$, $\mathbf{g} : \mathbb{R}^d \times [0, T] \mapsto \mathbb{R}^d$. We can assume, that the diffusion term \mathbf{g} has only $d - k + 1$ nonzero terms:

$$g_i(\mathbf{x}, t) \equiv 0 \quad \text{for } i < k \leq d. \quad (2)$$

We use the Chapman-Kolmogorov equation to obtain the probability density function $p(\mathbf{x}, t)$ in discrete times t_n and t_{n+1} :

$$p(\mathbf{x}, t_{n+1}) = \int_{\mathbb{R}^d} p(\mathbf{x}, t_{n+1} | \mathbf{x}_0, t_n) p(\mathbf{x}_0, t_n) d\mathbf{x}_0. \quad (3)$$

As the solution of the Chapman-Kolmogorov equation is not available in an analytical form for a general smooth \mathbf{f} and \mathbf{g} , we need to discretise (3) using the path-integration approach. We approximate the transitional probability density function (TPDF) $p(\mathbf{x}, t | \mathbf{x}_0, t_0)$ with the help of a numerical stepping scheme, interpolate the probability density function (PDF) $p(\mathbf{x}, t)$, and evaluate of the integral with the help of the Gauss-Legendre quadrature.

We record the whole calculation process in a step matrix \mathbf{S}_n and substitute the evaluation of the integral (3) with a matrix-vector multiplication:

$$\mathbf{p}_{n+1} = \mathbf{S}_n \mathbf{p}_n. \quad (4)$$

In \mathbf{p}_n we record the interpolation values describing the PDF $p(\mathbf{x}, t)$. In case the SDE in (1) is time-invariant or time-periodic, this approach will lead to a very performant method to solve (3).

Accuracy and Performance

Due to the partitioned formulation of the PI method we are able to separately investigate the effect of the time stepping method used for the approximation of the TPDF $p(\mathbf{x}, t_{n+1} | \mathbf{x}_0, t_n)$ and the interpolation method of the PDF $p(\mathbf{x}, t_n)$ on the accuracy of the approximation. We analyse the different time stepping and interpolation methods through the response PDF of a cubic oscillator:

$$\ddot{x}(t) + 0.3\dot{x}(t) - x(t) + 0.25x(t)^3 = \sqrt{0.075}\xi(t). \quad (5)$$

The steady-state PDF $p_{st}(x, \dot{x})$ of (5) is approximated with the help of the path integration method and is compared with the true solution [6]. To characterise the accuracy of the PI method we use ε_1 that is obtained by integrating the absolute error between the true and approximated steady state PDF $p_{st}(x, \dot{x})$ for the all the states $x, \dot{x} \in \mathbb{R}$.

Figure 1: Steady state PDF $p_{st}(x, \dot{x})$ of the cubic oscillator (5)

Figure 2: Error ε_1 as a function of (a) time step Δt and (b) number of interpolation nodes N / CPU time of the approximated steady state response PDF $p_{st}(x, \dot{x})$ of the cubic oscillator (5)

We demonstrate that our new formulation allows accurate computation of the PDF of noise-driven nonlinear dynamical systems significantly faster than previous formulations. Additionally, we show that the increased performance of the PI method allows the parametric analysis of a vibro-impact energy harvesting device that is used to harvest energy from noisy ambient vibrations.

Summary. A central goal of synthetic biology is the design of molecular controllers that can manipulate the dynamics of intracellular networks in a stable and accurate manner. To address the fact that detailed knowledge about intracellular networks is unavailable, integral-feedback controllers (IFCs) have been put forward for controlling molecular abundances. These controllers can maintain accuracy in spite of the uncertainties in the controlled networks. However, this desirable feature is achieved only if stability is also maintained. In this paper, we show that molecular IFCs can suffer from a hazardous instability called *negative-equilibrium catastrophe* (NEC), whereby all nonnegative equilibria vanish under the action of the controllers, and some of the molecular abundances blow up. We show that NECs place a fundamental limit to design and control of molecular networks.

Extended Abstract

A main objective in synthetic biology is to control living cells [1, 2]. This challenging problem requires addressing a number of complicating factors displayed by intracellular networks:

- (N) **Nonlinearity.** Intracellular networks are *bimolecular* (nonlinear), i.e. they include reactions involving two reacting molecules.
- (HD) **Higher-dimensionality.** Intracellular networks are *higher-dimensional*, i.e. they contain larger number of coupled molecular species.
- (U) **Uncertainty.** The experimental information about the structure, rate coefficients and initial conditions of intracellular networks is *uncertain* (noisy).

To mitigate challenge (U), molecular *integral-feedback controllers* (IFCs) have been put forward, which can maintain accurate control of molecular abundances in spite of some of the uncertainties in the controlled networks [3, 4]. However, this desirable feature is achieved only if stability is also maintained - an important problem which has been predominantly studied when unimolecular and/or lower-dimensional networks are controlled [4, 5, 6, 7]; in contrast, intracellular networks are generally bimolecular and higher-dimensional (challenges (N) and (HD) stated above). To bridge the gap, in this paper we focus on the question of fundamental importance to intracellular control: How do molecular IFCs perform when applied to biochemical networks which are bimolecular, higher-dimensional and uncertain?

We show that at the center of this question are equilibria - stationary solutions of the reaction-rate equations that govern the deterministic dynamics of biochemical networks. In particular, molecular concentrations can reach only equilibria that are nonnegative. In this context, we show that molecular IFCs can destroy all nonnegative equilibria of the controlled system and lead to a control failure; furthermore, this failure can be catastrophic, as some of the molecular abundances can then experience an unbounded increase with time (blow-up) at both deterministic and stochastic (chemical master equation) levels. We call this hazardous phenomenon, involving absence of nonnegative equilibria and blow-up of some of the underlying species abundances, a *negative-equilibrium catastrophe* (NEC), which we outline in Figure 1. In context of electro-mechanical systems, analogous phenomenon is known as integrator windup. We show that unimolecular IFCs do not exist due to a NEC. We then derive a family of bimolecular IFCs that are safeguarded against NECs when uncertain unimolecular networks, with any number of molecular species, are controlled. However, when IFCs are applied on uncertain bimolecular (and hence most intracellular) networks, we show that the problem of preventing NECs generally suffers from the *curse of dimensionality* - the problem becomes intractable as the number of interacting molecular species increases. NECs therefore have broad implications for design and control of molecular networks at both deterministic and stochastic levels.

Successful control

Negative-equilibrium catastrophe

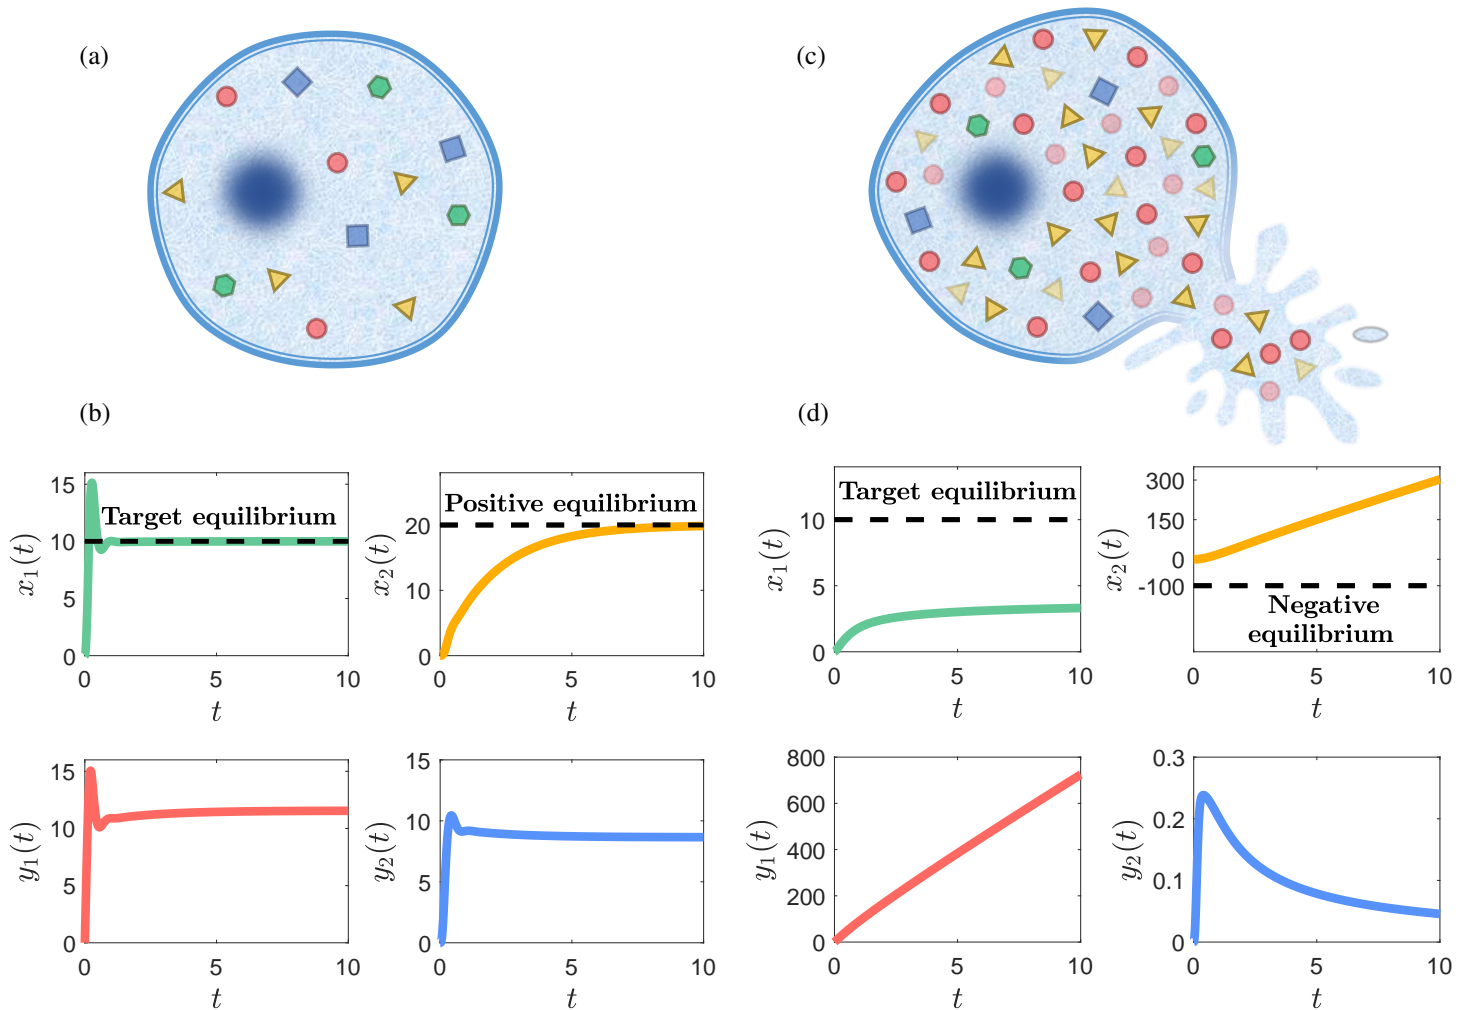

Figure 1: Caricature representation of a successful and catastrophically failed intracellular control. Shown are mean-field concentrations of two intracellular species, denoted by X_1 (green) and X_2 (yellow), and two controller species, denoted by Y_1 (red) and Y_2 (blue); the goal is to steer the equilibrium of X_1 to a desired set-point.

Panels (a)–(b) display a cell successfully controlled with a molecular IFC. In particular, panel (b) shows that the species X_1 approaches a desired equilibrium, shown as a black dashed line, while the equilibria for the remaining species X_2 , Y_1 and Y_2 are positive.

Panels (c)–(d) display a cell that has taken lethal damage due to a failure of the IFC. In particular, as shown in panel (d), the target equilibrium for X_1 enforces a negative equilibrium for the species X_2 . However, since molecular concentrations are nonnegative, this equilibrium cannot be reached and, therefore, control fails. Furthermore, the failure is catastrophic, as concentrations of some of the underlying species (in this example, species X_2 and Y_1) blow up, placing a lethal burden on the cell. Analogous phenomenon occurs at the stochastic level.

Dynamical Analysis of a Multibody Wave Energy Converter excited by Random Waves

Marten Hollm*, Leo Dostal*, Joshua Höhne* and Robert Seifried*

**Institute of Mechanics and Ocean Engineering, Hamburg University of Technology, Hamburg, Germany*

Summary. The dynamics of a novel multibody wave energy converter based on inclined single modules connected to a frame are investigated, on which generators convert the corresponding relative motion into electrical power. Thereby, it is studied under which conditions the inclined individual modules perform the largest relative motions in regular and irregular waves. For this, different setups are analyzed in the presence of wave excitations, which is generated by a random non-white Gaussian stochastic process.

Introduction

Renewable energies play an increasingly important role in modern energy systems. As a consequence, hydropower, solar and wind energy are becoming more and more important. In addition to these well-known examples of renewable energy generation, there is also the possibility to obtain energy from ocean waves. Since wave energy has a high power density compared to wind and solar energy, it is also promising for energy generation [1]. Therefore, several new concepts of wave energy converters (WEC) have been studied in the last years. For example a pendulum energy converter was investigated, whereby its pivot is excited by water waves in such a way that a rotational motion of the pendulum is generated, which can be converted to electrical energy, cf. [2, 3, 4, 5].

This paper deals with the analysis of the dynamical behavior of a multibody WEC, where generators mounted on a frame are each excited by a randomly moving cylindrical floating body (CFB). The CFBs are floating in ocean waves and the energy generation of the generators results in additional damping. Our results consider the case of excitation by a non-white Gaussian random process, which can for example be encountered in real sea states.

Description of the mechanical system

The mechanical system mainly consists of a frame and N CFBs. Figure 1 shows the side view of the structure for the case of $N = 2$ in still water and in the presence of harmonic water waves. In this work, only the motion of the system in the xy -plane with horizontal coordinate x and vertical coordinate y is considered. Each CFB moves along guided rods with corresponding displacement ξ_i in a plane, which is inclined with respect to the frame by the corresponding adjustable inclination angle ε_i , $i \in \{1, \dots, N\}$. The frame can freely move in the xy -plane, whereby the angle of rotation is denoted by β and the horizontal and vertical displacements of the frame are denoted by x_F and y_F , respectively. It is assumed that the frame is in contact with the sea surface and that only the CFBs are excited by water waves. Thereby, the CFBs and the frame are connected by springs and mechanical friction is accounted for by a velocity dependent damping force. Generators convert the relative motion between the CFBs and the frame to electrical energy, leading to an additional electrical damping force.

Let

$$\mathbf{z} = [x_F, y_F, \beta, \xi_1, \dots, \xi_N]^T \quad (1)$$

be the vector of all degrees of freedom of the multi body WEC. Then, the general equation of motion of the mechanical system can be written as

$$\mathbf{M}(\mathbf{z}, t)\ddot{\mathbf{z}} + \mathbf{k}(\mathbf{z}, \dot{\mathbf{z}}, t) = \mathbf{q}(\mathbf{z}, \dot{\mathbf{z}}, t), \quad (2)$$

whereby t is the time, \mathbf{M} is the generalized mass matrix, \mathbf{k} is the vector of Coriolis, centrifugal and gyroscopic forces and \mathbf{q} is the vector of the applied forces.

In order to compute the hydrodynamic forces, the water pressure p must be integrated over the wetted surface of each CFB. Using potential flow theory and Bernoulli's equation of fluid dynamics, the radiation problem as well as the diffraction problem of a moving cylinder has to be solved in order to calculate the hydrodynamic forces [6]. For incoming harmonic water waves with wave amplitude A and wave frequency ω , the corresponding sea surface is given by

$$\eta(x, t) = \text{Re}\{A \exp(i(\kappa x - \omega t))\} \quad \text{with} \quad \omega^2 = \kappa g \tanh(\kappa H), \quad (3)$$

whereby κ denotes the wave number, g the gravity constant and H the water depth. For this type of water waves, Yeung [7] and Garrett [8] have computed the velocity potential of radiation and diffraction by expressing them as a series of eigenfunctions for the case of a single truncated cylinder. Using this theory, it is assumed that the motion of CFBs does not lead to hydrodynamic forces, which affect other CFBs.

Description of random sea waves

A well-known model of random long-crested sea waves is given by the superposition of harmonic waves with wave frequencies ω and corresponding wave numbers $\kappa(\omega)$. With this, the wave amplitude of each harmonic wave component depends on the underlying sea state, which is given by the corresponding one-sided spectral density $S(\omega)$, cf. [9, 10]. Then, a one dimensional irregular long-crested wave surface can be written as

Figure 1: Sketch of the mechanical system in still water position (a) and in the presence of harmonic water waves (b).

$$Z(x, t) = \int_0^\infty \cos(\omega t - \kappa(\omega)x + \varepsilon(\omega)) \sqrt{2S(\omega)} d\omega, \quad (4)$$

whereby the integral is not Riemann integral but a summation rule over the frequencies ω . An example for such generated sea waves is shown in Figure 2, where either the space or time is fixed at $x = 0$ or $t = 0$, respectively.

With this developed mechanical model and the study of corresponding numerical results, a detailed analysis is performed showing the influence of design parameters, like the inclination angles ε_i or the number N of CFBs, in order to maximize the harvested energy.

Figure 2: Evolution of a random sea surface in time and space.

Stochastic excitation source modeling for roughness-induced normal vibration at dry sliding conformal contacts under light load

Joël Perret-Liaudet, Nicolas Ponthus, Chaïma Zouabi and Julien Scheibert
Ecole Centrale de Lyon, UMR CNRS 5513, LTDS, France

Summary. This study deals with the roughness-induced normal vibration problem occurring when a rigid rough body slides on a rigid rough surface. To predict this dynamic behaviour, we propose to model the effective random excitation source under the assumption of a very small number of contacts, each affected by a statistically independent stochastic process. Each process is obtained by considering the separation between both topographies when they touch in a single point. Statistical and spectral properties of the vibrational excitation are characterized. On this basis, we demonstrate the relevance of the proposed modelling to reproduce the experimental observations.

Introduction

When a rigid rough body slides on a rigid rough surface, it exhibits random vibrations normal to the nominal contact surfaces. Under light contact pressure, this behaviour is known as roughness-induced vibrations leading to a broadband noise, so-called roughness noise [1]. This problem is a huge nonlinear and stochastic dynamic problem. Indeed, it includes both microscopic and macroscopic scales (roughness versus slider macro-size), short time scales, non-smooth dynamics (loss of contact) and stochastic excitations induced by roughness. Depending on the sliding velocity, recent experimental works about this vibrational problem have clearly shown two main dynamic regimes, observable on the dynamic motion of the slider normal to the surfaces in contact [2,3]. For low sliding velocities, the slider remains very close to the above solid, like a grazing regime, with negligible probability of contact losses. Conversely, for high sliding velocities, the slider jumps above the track with free flights, like a bouncing regime, leading to numerous mechanical shocks between asperities. As an example, these two regimes can be identified on figure 1 which shows the evolution of the slider's free flight time rate Π versus the sliding velocity V . This experiment concerns a stainless steel upper slider in dry contact under its own weight (104 g mass) with a 25x25 mm² apparent surface and a 30 μ m RMS roughness. The antagonist stainless steel 25x300 mm² surface is also with a 30 μ m RMS roughness. The slider was either pulled or pushed with 20 tests per operating way, which is presented in figure 1 through the uncertainty bars. Further, an example of the vertical acceleration history \ddot{z} of the slider observed in the bouncing regime is shown in figure 2. We can clearly observe long free flights for which $\ddot{z} = g$, and short impacts.

Figure 1: Slider's free flight time rate versus the sliding velocity

Figure 2: Vertical acceleration in the bouncing regime

The vertical dynamic behavior of the upper slider under its own weight, i.e. submitted to a light normal force, can be heuristically modelled by an equivalent randomly excited bouncing ball system [2,3]. On the basis of this assumption, the transition velocity which separates the two regimes can be predicted by the knowledge of an equivalent random excitation source. This excitation is directly related to the characteristics of the tribological system, defined by the surface topographies, the size of the upper slider, the sliding velocity, and so on. So, being able to model such an excitation constitutes one of the keys to a better knowledge of the nonlinear and stochastic roughness-induced dynamics of sliding bodies. Precisely, the main goal of this paper is to address this question. In particular, we have proceeded to describe the probability density function and the power spectral density of this stochastic excitation as a result of the two sliding conformal rough surfaces in the case of light normal load.

The proposed approach for modelling the excitation source

The excitation source results from interactions between the two rough surfaces in sliding contact. It can be viewed as the normal displacement z_G of the center of mass of the slider G . When the applied pressure is very low compared to the material stiffness, one can reasonably assume that the contact is ensured by only three points of contact. Such three-points contact situations are the focus of the present study.

3-points contact modelling and normal displacement of the slider's center of mass

The 3 points in contact necessarily surround the center of mass of the slider. Normal displacements z_j under the points correspond to the separation of the associated antagonist asperities. The schetch in figure 3 represents this scenario. Now, assume that the altitude of each contact, z_j , and also their respective positions (points P_j) are known, the vertical motion of the center of mass is given by $z_G = \alpha_{12}z_3 + \alpha_{23}z_1 + \alpha_{31}z_2$, where α_{ij} represents the absolute barycentric coordinates, or area coordinates. Considering isotropic surfaces, the three barycentric coordinates are statistically equivalent. Furthermore, one assumes that displacements z_j and coordinates α_{ij} are independent random variables. So, the displacement of the center of mass behaves like the following random variable $\ddot{z}_G = (z_1 + z_2 + z_3)/3$.

Figure 3: (a) Slider and location of its center of mass G , location of each contact point P_j , and area coordinates α_{ij} ; (b) the equivalent sliding system.

Finally, if we assume that points P_j are sufficiently separated with distances larger than a characteristic topography wavelength to ensure that displacements z_j are independent, and if we assume that the probability density functions $f_{z_j}(z)$ are almost the same $f_z(z)$, one obtains the probability density function of \tilde{z}_G , i.e. $f_{\tilde{z}_G}(z) = 3(f_z * f_z * f_z)(3z)$. In the same way, one can calculate the power spectral density $S_{\tilde{z}_G\tilde{z}_G}(k)$ as follows $S_{\tilde{z}_G\tilde{z}_G}(k) = S_{zz}(k)/3$.

One-point contact modelling

In this frame, we need to characterize the probability density function $f_z(z)$ and the power spectral density $S_{zz}(k)$. It was done in the case of the separation at single-point contact between self-affine topographies. The main results [4] obtained by direct simulations and extreme value theory approach are: (i) the normal motion RMS amplitude is much smaller than that of the equivalent roughness of the two topographies and depends on the ratio of the slider's lateral size over a characteristic wavelength of the topography; (ii) due to the nonlinearity of the sliding contact process, the power spectral density contains wavelengths smaller than the smallest wavelength present in the underlying topographies.

Results and conclusion

In order to validate the proposed scenario, we compared the predicted characteristics of the vertical motion of the center of mass of the slider to the results during grazing regimes obtained through sliding experiments described in the introduction section and direct simulations of the sliding contact.

Figure 4: Pdf of the vertical motion of G ; blue: experimental result; yellow: direct simulation; red: extreme value theory.

Figure 5: PSD of the vertical motion of G ; blue: experimental result; yellow: direct simulation; red: analytical.

As we can observe, the statistical properties (see figure 4) as well as the spectral contents (see figure 5) are well captured by the proposed modelling. Within its framework, it was therefore also possible to accurately predict the velocity threshold separating the grazing regime to the bouncing regime. For this, the vertical motion of the slider has been heuristically described with good agreement by the dynamics of an equivalent random bouncing ball system for which the characteristics were given in a previous work [5], including memory effect related to a combination between the sliding velocity and characteristic wavelengths of the equivalent excitation.

To conclude, we have proposed a complete modelling to describe the roughness-induced normal vibration at a dry sliding conformal contacts under light load. Good agreements were obtained with respect to experiments as well as direct simulations. More generally, we provide an improved understanding of roughness-induced vibration problems and a better knowledge of the associated friction and noise.

ANALYSIS OF COUPLED NON-LINEAR OSCILLATORS BY THE ASYMPTOTIC NUMERICAL METHOD

Léopold Calbrix*, Jean-Marc Cadou*, Grégory Girault*

*Univ Bretagne Sud, CNRS UMR6027, IRDL, France

Summary. This study is based on the theoretical and experimental works of Cadiou et al. [1, 2] who designed a non-linear vibration absorber using an electro-magnetomechanical coupling. The present work limits itself to the pure mechanical response of a 2 degrees-of-freedom oscillator with a cubic non-linear coupling between the Linear Oscillator (LO) and the non-linear energy sink (NES). The numerical analysis is performed using the Harmonic Balance Method (HBM) in association with the Asymptotic Numerical Method (ANM), following the initial idea proposed by Cochelin et al. [3]. This approach offers an understanding of resonance mechanisms of the LO and energy transfers to the NES. Numerical experiments are performed in order to identify influence of the parameter values. Numerical results are also compared to theoretical ones. They confirm the relevancy of the numerical approach which may be retained to the design of a non-linear vibration absorber.

Extended Abstract

Non-linear energy sinks (NES) are known for their efficiency in the vibration mitigation as they do not have to be tuned to the natural frequency of the supporting structure. In this study, a 2 degrees-of-freedom (DOF) model is analysed (Fig.1). It is composed of a Linear Oscillator (LO) non-linearly coupled with the absorber (NES). The LO is defined with its mass m_1 , a constant stiffness k_1 and a viscous damping parameter c_1 . The absorber is defined through its mass m_2 , its viscous damping parameter c_2 and its cubic stiffness k_{2c} . The LO is directly excited by an harmonic force $f(t) = F \cos(\omega t)$. Finally, $x_1(t)$ and $x_2(t)$ denote the LO and NES displacement, respectively. Thus, the problem to be solved reads:

$$\begin{cases} m_1 \ddot{x}_1 + c_1 \dot{x}_1 + k_1 x_1 + c_2 (\dot{x}_1 - \dot{x}_2) + k_{2c} (x_1 - x_2)^3 = F \cos(\omega t) \\ m_2 \ddot{x}_2 - c_2 (\dot{x}_1 - \dot{x}_2) - k_{2c} (x_1 - x_2)^3 = 0 \end{cases}$$

In this study, the problem is solved coupling the Asymptotic Numerical Method (ANM) with the Harmonic Balance Method (HBM). The former is a continuation technique based on Taylor series of the unknowns while the later is a decomposition of unknowns into truncated Fourier series.

In order to efficiently apply the ANM, quadratic recast of equations is a preliminary stage. So, auxiliary variables $y_k = x_k^2$ and velocity variables $v_k = \dot{x}_k$ ($k = 1, 2$) are defined and the non-linear dynamic problem formally reads:

$$\dot{\underline{Y}} = \underline{G}(\underline{Y}, \omega) \text{ with: } \underline{Y} = \{x_1, x_2, v_1, v_2, y_1, y_2\}^\top$$

The HBM is then applied and the unknown \underline{Y} is decomposed into truncated Fourier series with H harmonics:

$$\underline{Y} = \underline{Y}_0 + \sum_{p=1}^H [\underline{Y}_p^c \cos(p\omega t) + \underline{Y}_p^s \sin(p\omega t)]$$

Fourier series are introduced into the non-linear dynamic problem. After balancing terms of the same harmonic index, the components \underline{Y}_0 , \underline{Y}_p^c and \underline{Y}_p^s are identified and collected into one single unknown vector \underline{X} . Thus, the non-linear problem reads:

$$\underline{R}(\underline{X}, \omega) = \underline{0} \text{ with: } \underline{R}(\underline{X}, \omega) = -\omega \underline{M}(\underline{X}) + \underline{C} + \underline{L}(\underline{X}) + \underline{Q}(\underline{X}, \underline{X})$$

where $\underline{M}(\underline{X})$, \underline{C} , $\underline{L}(\underline{X})$ and $\underline{Q}(\underline{X}, \underline{X})$ stand for, respectively, the mass operator, the constant external forcing, the linear operator and the quadratic one. The convenient quadratic expression of the residual \underline{R} allows to solve the problem using the ANM in order to continue solution \underline{X} in respect to the parameter ω . The main advantage of this approach is to compute exactly the associated Jacobian matrix of the residual \underline{R} . So, unknowns \underline{X} and ω are sought as truncated series of the path-parameter a :

$$\underline{X} = \sum_{k=1}^N a^k \underline{X}_k \quad \text{and} \quad \omega = \sum_{k=1}^N a^k \omega_k \quad \text{with} \quad a = \langle \underline{X} - \underline{X}_0, \underline{X}_1 \rangle + (\omega - \omega_0) \omega_1$$

Then, the validity domain of one ANM step is evaluated according to: $a_{\max} = (\epsilon \|\underline{X}_1\| / \|\underline{X}_N\|)^{1/(N-1)}$ and a new continuation step can be performed: $\underline{X}_0^{\text{new}} = \underline{X}(a_{\max})$ and $\omega_0^{\text{new}} = \omega(a_{\max})$. More details can be found, for example, in [4, 5, 6, 7, 8].

This procedure is applied to analyse the dynamic response of the LO and the NES. The response curves are in good agreement with the numerical ones established in [1, 9] for a non-linear vibration absorber without electro-magnetomechanical coupling (Fig.2).

Additional simulation are performed, for different values of the force F , to identify the appropriate values of the ANM parameters, mainly the number of harmonics H , the truncation order N and the tolerance threshold ϵ (Fig.3).

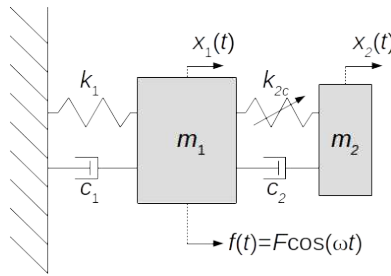

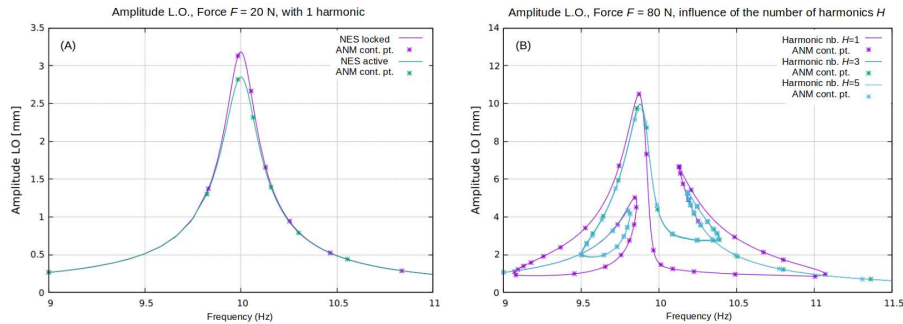

Figure 1: Single-degree-of-freedom oscillator non-linearly coupled with a NES

In particular, continuous solutions are obtained and several dynamic behaviours are highlighted according to the excitation force level F . Bifurcations (Hopf and Neimark-Sacker) are also computed in accordance with theoretical predictions obtained through a combination of the Complexification-Averaging method and the Multiple Scales method [1, 9]. The very first results show the relevancy of the numerical approach which is going to be used in order to study the dynamic behaviour of composite hydrofoil coupled to a NES [10].

Control-based continuation of orbits with complex time profile

Jan Sieber*, Courtney Quinn†

*Department of Mathematics, University of Exeter, UK

†CSIRO, Hobart, Australia

Summary. We illustrate how unstable trajectories with complex time profiles and large period can be tracked using feedback control-based continuation. The experimental or computational effort is proportional to the period. The approach requires the feedback control to be stabilizing within time of order 1 uniformly along the orbit. The approach is illustrated with a stochastic simulation of a delay model for the Mid-Pleistocene transition of the palaeoclimate ice ages.

Control-based continuation

Control-based continuation applies feedback control to turn a controllable nonlinear dynamical system with inputs and outputs into a system of nonlinear equations, which can then potentially be solved by general-purpose nonlinear solvers or continuation (curve tracking) algorithms; see [2, 6, 7] by Renson, Barton *et al* and Schilder *et al* for detailed descriptions of the methodology. The approach assumes that the user (e.g., experimenter) has implemented a stabilizing feedback control loop. One may assume that the dynamical system follows an ODE of the type

$$\dot{x}(t) = f(t, x(t), \mu, u(t)) \quad \text{where } x(t) \in \mathbb{R}^n \quad \text{with output } y(t) = g(t, x(t), \mu) \quad \text{where (e.g.) } y(t) \in \mathbb{R}, \quad (1)$$

and μ are system parameters. In the experiments of [2, 6, 7] the dynamical systems were forced oscillators, the output y was a position coordinate and the feedback control was in the form of a PD control, $u(t) = k_p[y(t) - y_r(t)] + k_d[\dot{y}(t) - \dot{y}_r(t)]$, with a reference time profile y_r . The control is said to be stabilizing the (for example) T -periodic trajectory $x_*(t)$ (with output $y_*(t) = g(t, x_*(t), \mu)$) of the uncontrolled system $\dot{x} = f(t, x, \mu, 0)$, if for every T -periodic reference $y_r \approx y_*$ and initial conditions (t, x) close to $(t, x_*(t))$ the controlled system (1) converges to a unique T -periodic limit $y_{\text{lim}}(t) \approx y_*(t)$. Moreover, the approach requires that the *asymptotic input-output map* $Y : (y_r, \mu) \mapsto y_{\text{lim}}$ is continuously differentiable in the space of T -periodic functions. If the stabilization condition is satisfied for the feedback control $y - y_r \mapsto u$, then one may find the periodic orbit y_* of the uncontrolled system as fixed point of the map Y : $y_r = Y(y_r, \mu)$ if and only if $y_r = y_*$, regardless of the dynamical stability of y_* . This enabled the authors of [1, 2, 5, 6, 7] to track response curves through limit (fold/saddle-node) bifurcations, track fold bifurcations in two parameters, and detect stable and unstable directions of saddle-type orbits in mechanical oscillator experiments.

Solving the nonlinear fixed-point problem $y = Y(y, \mu)$

One difficulty when solving for (or tracking) fixed points of the input-output map Y is that the Jacobian of $Y(y_r, \mu)$ with respect to its arguments, which Newton iteration-based solvers require, is not known, and can generally be obtained only by performing repeated experiments for small deviations of the inputs, $(y_r + \delta y_r, \mu + \delta \mu)$. For mechanical oscillator experiments the periodic orbits are nearly harmonic such that [7] approximated y_r with low-order harmonics: $y_r(t) \approx P_N[y_r](t) := \sum_{\ell=-N}^N y_\ell b_\ell(t)$, where, in their case, $b_\ell(t) = \cos(\ell \omega t)$ for $\ell \leq 0$, $b_\ell(t) = \sin(\ell \omega t)$ for $\ell > 0$, $\omega = 2\pi/T$ and $N \leq 10$ typically. Barton, Renson *et al* used a (Newton-)Picard iteration, splitting $y_r = y_P + y_Q$ with $y_P \in \text{rg } P_1$ and $y_Q \in \text{rg } Q_1$ ($Q_N = I - P_N$). They observed that, for fixed (y_P, μ) , the iteration $y_Q \mapsto Q_1 Y(y_P + y_Q, \mu)$ converges to a limit y_Q within measurement accuracy in one or two iterations, defining a map $Y_Q(y_P, \mu)$. This reduced the fixed point problem to the low-dimensional $y_P = P_1 Y(y_P + Y_Q(y_P, \mu), \mu)$ in $\text{rg } P_1$, for which a finite-difference approximation of the Jacobian is feasible.

We generalize this Newton-Picard approach to problems where we expect a severely non-harmonic fixed point y_* , that is, typically problems with large period T . Our illustrating example below considers a forced system with forcing as shown in fig. 1(top-left). The Picard iteration $y_Q \mapsto Q_N Y(y_P + Q_N y_Q, \mu)$ suffers a linear low-frequency instability for increasing periods T and fixed N . This is best illustrated considering the simplest case $\dot{x} = ax - k[y - y_r]$ with $y = g(x) = x$ and $0 < a < k$ for (1) on an interval $[0, T]$. In this case the map Y is linear and commutes with P_N and Q_N , and the map $y \mapsto Yy$ has unstable eigenvalues corresponding to eigenfunctions of the form $\exp(2\pi i \ell t / T)$ for all $\ell < T\sqrt{a(2k-a)}/(2\pi) =: m$. Thus, for the Picard iteration $y \mapsto Q_N Y(y_P + y)$ (with fixed y_P) to converge, the projection P_N must be injective on the space spanned by the m lowest harmonic modes. This criterion determines the necessary dimension of the space $\text{rg } P_N$ of variables in which one has to formulate the nonlinear problem for the Newton iteration, which is in general high-dimensional for large periods T :

$$y_P = P_N Y(y_P + Y_Q(y_P, \mu), \mu) \quad \text{for } y_P \in \text{rg } P_N, \text{ where } \dim \text{rg } P_N \sim N \gg 1 \text{ for } T \gg 1, \text{ such that } N \sim T. \quad (2)$$

The problem can be addressed if the control law $y_r - y \mapsto u$ stabilizes such that perturbations decay on a time horizon h of order 1 uniformly in $[0, T]$ (using the additional arguments in y to indicate initial time and initial condition for state x):

$$|y(t; t_0, x_1) - y(t; t_0, x_2)| \leq C \exp(-\gamma(t - t_0)) |x_1 - x_2| \quad (3)$$

in (1) for $\gamma > 0$, C of order 1, independent of the period T . In this case perturbations at time t_0 do not have noticeable influence anymore at time $t_0 + h$ (where h is s.t. $C \exp(-\gamma h) \ll 1$). If criterion (3) is satisfied, we may choose for $\text{rg } P_N$,

for example, the space of piecewise constant functions: $[P_N y](t) = T/N \int_{t_{\ell-1}}^{t_{\ell}} y(s) ds =: y_{\ell}$ if $t \in J_{\ell} = [t_{\ell-1}, t_{\ell})$, where $t_{\ell} = \ell T/N$. The variable for the nonlinear problem (2) is then (y_1, \dots, y_N, μ) , and (2) poses an equation on each interval J_{ℓ} . Due to the finite-time decay condition (3), $[\partial/\partial y_{\ell}]P_N Y|_{J_{\nu}}$ is small if the distance between ν and ℓ satisfies $|\nu - \ell| > hN/T =: q = O(1)$. Hence the Jacobian $\partial P_N Y/\partial y_P$ has only q non-zero diagonals. This implies that deviations δy_{ℓ} and δy_{ν} can be applied simultaneously if $|\ell - \nu| > q$ when determining the finite difference approximation for $\partial P_N Y/\partial y_P$. Consequently, the fixed point problem (2) with a projection P_N chosen such that the Picard iteration is linearly stable on $\text{rg}[I - P_N]$ can be solved with a (computational or experimental) effort that grows linearly in the period T because the number of necessary evaluations of Y is independent of the period T .

Example — quasiperiodically forced delay differential equation (DDE) modelling the Mid-Pleistocene transition

We demonstrate the feasibility for a simple quasiperiodically forced model for palaeoclimate ice ages, modelling the Mid-Pleistocene transition, which is a simplification of a model originally proposed by Saltzman & Maasch, see [3, 4],

$$dx(t) = [-px(t - \tau) + rx(t) - sx(t - \tau)^2 - x(t - \tau)^2 x(t) - aI(t)] dt + \sigma dW_t, \quad (4)$$

for the global ice mass anomaly x over the last 2 million years. Quinn *et al* [3, 4] observed that the forcing by variability of solar insolation $I(t)$, shown in fig. 1(top-left), causes a transition at time t_c from small-amplitude fluctuations around an equilibrium (at $x = -0.5$) to a large-amplitude limit cycle for forcing amplitudes a greater than some critical value a_c ($a_c = 0.1$ for transitions without noise). The time t_c is close to where the Mid-pleistocene transition from rapid to slow ice ages occurs in data sets. Continuation of the saddle and the attractor for positive a without noise (using DDE-Biftool) shows that the two non-autonomous trajectories pinch at t_c . In the infinite-time limit, saddle and node form a strange non-chaotic attractor at the critical amplitude a_c . We track the saddle for the non-autonomous system (enforcing artificially periodic boundary conditions) as a test case for the control-based continuation of complex time profiles with random disturbances of size σ . Feedback control was trivially applicable by adding it to the solar insolation: $aI(t) + k[y_r - y]$, where output $y = x$. A typical time profile is shown (in red) in fig. 1(bottom-left), the partial bifurcation diagram is in fig. 1(bottom-right). Note that saddle and node do not form a smooth saddle-node near $a = a_c$ without noise.

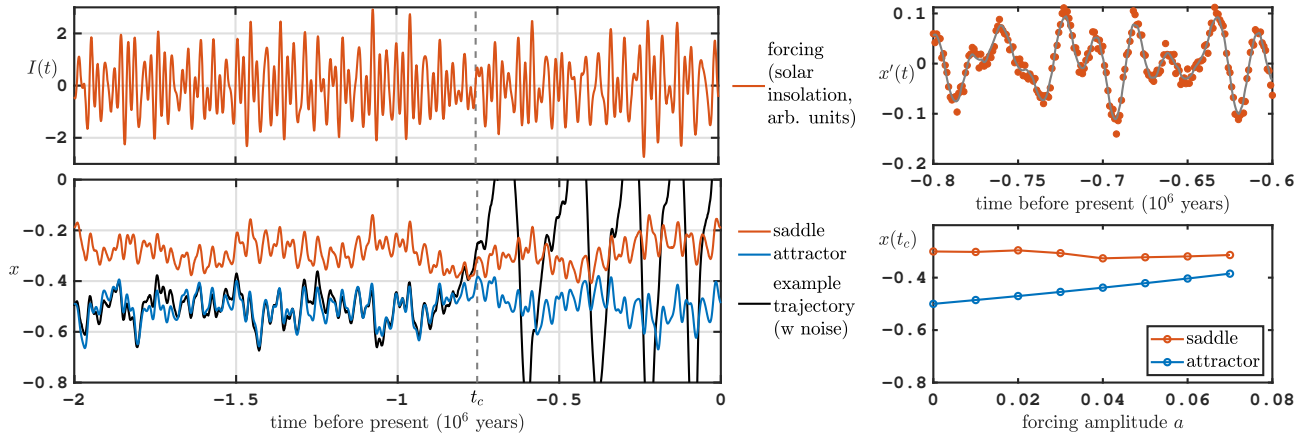

Figure 1: (top-left) Solar insolation $I(t)$ at 65° degree North in the summer [4]; (bottom-left) nonautonomous attractor and saddle, and large-noise ($\sigma = 6 \times 10^{-3}$) trajectory illustrating transition near time t_c , caused by saddle-node pinching; (top-right) approximate dx/dt illustrating magnitude of disturbance; (bottom-right) partial bifurcation diagram for value of saddle and attractor at t_c . Parameters as in [3]: $p = 0.95$, $r = s = 0.8$, $\tau = 1.31$, Euler-Maruyama scheme stepsize 0.1, $\sigma = 3 \times 10^{-3}$, $N = 200$, gain $k = 2$.

Potential future experimental test cases are forced mechanical single-degree-of-freedom oscillators with hardening non-linearity where one may track connecting orbits caused by brief spikes of the forcing amplitude.

Summary. We discuss the new GUI environment of the MATLAB software package MatCont for numerical bifurcation studies of continuous dynamical systems. It is built upon the corresponding command line package CL_MatCont. The package is freely available via sourceforge.net/projects/matcont and offers both interfaces. Mathematically, the functionalities of MatCont with respect to bifurcation techniques are unrivalled. For instance, no other software allows to compute the normal forms of codimension two bifurcations of periodic orbits, or to start curves of codimension one bifurcations of periodic orbits from codimension two equilibrium points. Though widely used, the previous version of MatCont was at the end of its life span of maintainability and the new MatCont gives it a fresh start. It is completely reorganized with a better documentation and an improved data handling with a Data Browser, a Diagram Organizer and a Spreadsheet Viewer. Other new features are the Command Line Interface, the functionality of computing Poincaré maps and many facilities to simplify the use of the software. As an application we discuss a computational model that describes the stabilization of percept choices under intermittent viewing of an ambiguous visual stimulus at long interstimulus intervals. Unlike previous studies we incorporate the time that the stimulus is on (T_{on}) and off (T_{off}) explicitly as bifurcation parameters of the model. We compute the bifurcations of periodic orbits responsible for switching between alternating and repetitive sequences. We show that the region of bistability of repeating and alternating behavior is a wedge in the parameter plane bounded by two curves of limit point bifurcations of periodic orbits and one curve of period-doubling bifurcations.

Introduction

We consider smooth continuous dynamical systems of the form

$$\frac{dx}{dt} \equiv \dot{x} = f(x, \alpha), \quad x \in \mathbb{R}^n, \alpha \in \mathbb{R}^m, \quad (1)$$

with state variable x , parameter α and f a sufficiently smooth function (continuous derivatives up to order 5 are needed in some cases). The numerical bifurcation analysis of (1) requires a dedicated software package. For this purpose MATCONT was developed, a MATLAB continuation toolbox available at <http://sourceforge.net/projects/matcont/>. It is a successor package to CONTENT [7] and LINBLF [6].

Bifurcation analysis usually starts with equilibria and periodic orbits (limit cycles). The stable ones can be found by time integration of the system, see the MATCONT manual [4], §6.2 and §7.4. By numerical continuation under variation of a single system parameter one can detect and study the codimension one bifurcations, i.e. limit points and Hopf points for equilibria, limit points of cycles, period-doubling and Neimark-Sacker (torus) bifurcation points for periodic orbits. Further continuation of these codimension one bifurcations under variation of two system parameters leads to the detection and study of codimension two bifurcation points; there are 5 codimension two types of bifurcations of equilibria and 11 types for periodic orbits. MATCONT allows to study all these bifurcations numerically and perform many related tasks, including the study of orbits homoclinic to saddle, homoclinic to saddle-node and heteroclinic orbits. Critical normal form coefficients are computed at bifurcation points. For this we rely on symbolic derivatives or if these are not available, on finite difference approximations. Bifurcation curves are defined by a system of equations consisting of fixed point and bifurcation conditions. The continuation curves can be visualized using the plot capabilities of the GUI; this can be done during and after the continuation. Special windows are provided to help with maintaining systems, diagrams and curves when generating a large amount of data.

Earlier versions of MATCONT and their functionalities were described in [1] and [2]. We will restrict to the new features in the renovated 2019 environment MATCONT7.1 and later versions. From a computer science point of view MATCONT7.1 is a completely new creation. It has a clear separation of computational and control routines to facilitate the maintainability. Its GUI allows a maximal flexibility to reprogram the layout of windows, buttons and input fields on the screen. It contains automatic tests to check if a new MATLAB version produces the same results as the previous version. Error handling of plots is much improved so that malfunctioning of plots (for any reason) does not crash the computations. Unlike the previous versions, it has an external documentation ([8], Ch. 6) and a detailed internal documentation. The internal documentation of a source file is accessed by typing ‘doc filename.m’ on the command line; a reference page is then generated based on the comments in the source file.

The core mechanism of the new MATCONT environment is an intermediate layer of routines between CL_MATCONT and the GUI as seen by the user. It is described in [8], Chapter 6; the main elements in this mechanism are the MATLAB

classes *settings*, *session* and *solution*, cf. the section **Command Line Interface**. This layer also protects against nonsense input in the CL_MATCONT routines.

Important other parts, which can be used semi-autonomously are the generator of the system m-files (*SysGUI.m*), the spreadsheet viewer (*GUISimCurveTable.m* and *GUIContCurveTable.m*) and the GUI subsystems *Data Browser* and *Diagram Organizer*, which are stored in subfolders of the *GUI* folder. The main driver files are *matcont.m*, *GUI/MATCONTGUI.m* and *GUI/Session.m*.

For the practical use of MATCONT it is best to start with the tutorials which are provided with the software; the manual [4] is a good reference to the command line version CL_MATCONT.

To study a system in MATCONT one has to describe it in a *system m-file*, which serves as a handle to the system. MATCONT provides an interface to build such m-files, see the manual [4], §4 or the first tutorial.

The MATCONT panels are described in [8], Ch. 5. The main MATCONT panel is shown in Figure 1. We note in particular the tab line at the top with the six tabs **Select, Type, Window/Output, Compute, Options, and Help**.

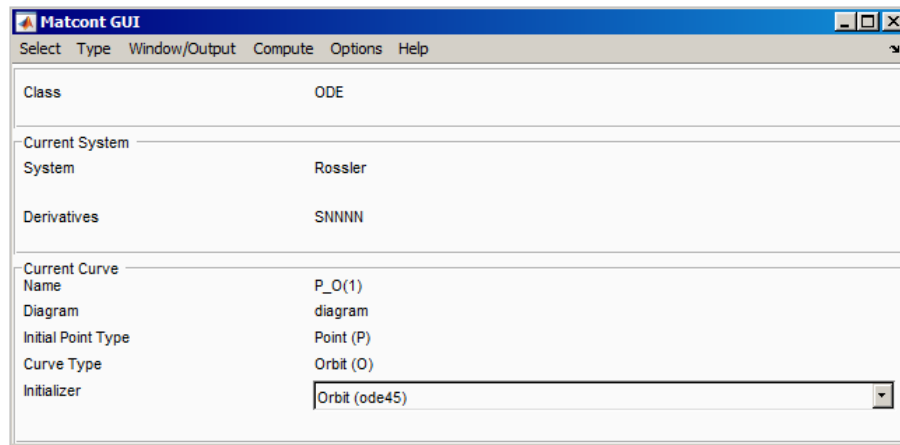

Figure 1: The main MATCONT panel.

Data management in MATCONT

The Diagram Organizer

The database of MATCONT consists of an archive of systems one of which is the *current system*.

A system is internally characterized by a system m-file, a system mat-file and a system directory, all with the name of the system. They are all in the subdirectory **Systems** of MATCONT. When a MATCONT session is closed (**Select|Exit**) then the session information is stored in a file *session.mat* in the **Systems** directory. This allows to restart the MATLAB session at the point where it was stopped.

The m-file is a readable file that contains all defining information on the system; the mat-file contains the same information in a structured way that is accessible to the MATCONT software. Both stay unchanged as long as the system is not changed or deleted.

The directory of each system also contains a file *session.mat* which contains the information that is necessary to restart or reproduce the computations on that system at the stage where it was left, including the position and contents of all windows. However, plots have to be redrawn.

The system directory also has at least one default subdirectory called *diagram*. This and other subdirectories of the system directory are called *diagrams*. Each diagram contains a number of mat-files and each mat-file describes a computed curve with enough information to recompute the curve. Each computed curve contains a number of special points, which includes the first point, the last point, bifurcation points, and zeros of userfunctions but other entities may also be defined as special points. An important example of this is the case of an orbit where a **Select Cycle** object is identified as a special point (for more details see the section **Other New Features**).

Clicking **Select|Organize Diagrams** in the main MATCONT panel opens the Diagram Organizer which allows to move curves from one diagram to another, see Figure 2.

The Spreadsheet Viewer

The Spreadsheet Viewer allows to inspect all stored data of a computed curve. It can be accessed by pressing the **View Curve** button in a Curve window that is opened in the Data Browser. However, it is not possible to load data from the Spreadsheet Viewer for further use in MATCONT.

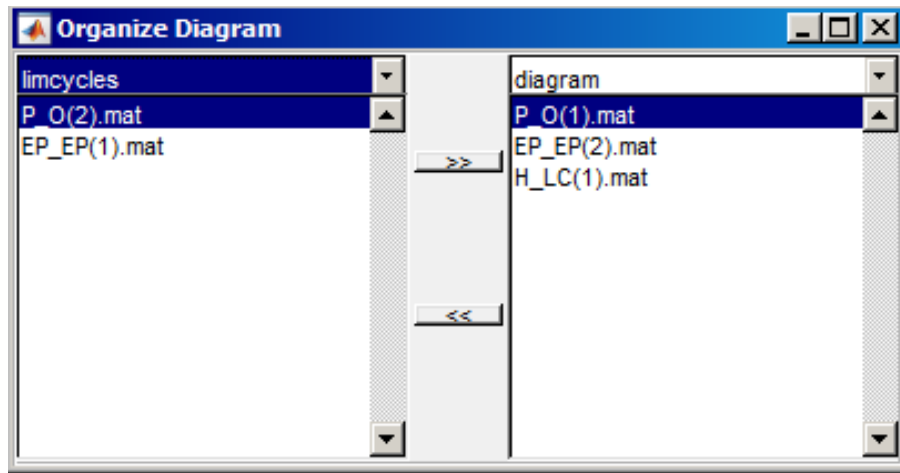

Figure 2: The Diagram Organizer panel.

The Command Line Interface

The Command Line Interface (cli) is a collection of MATLAB commands that allow to use practically all GUI functionalities from the command line in an interactive way.

This has a number of advantages. First, if the number of state variables or parameters is large and provided by an external file, then it is possible to load them as vectors directly into MATCONT. Second, it allows to write a MATLAB script that uses MATCONT in a semi-automatic way, for example to perform a bifurcation analysis for a range of values of parameters which are fixed in each particular bifurcation analysis. Third, it allows to load the raw computed data of a continuation or simulation directly into the Matlab workspace.

In the cli we address directly the intermediate layer of routines. This requires to set one or more of the class variables `settings`, `session`, `solution` as global.

To illustrate the use of the cli we introduce the *Rössler* system [10]:

$$\begin{cases} \dot{x} &= -y - z \\ \dot{y} &= x + Ay \\ \dot{z} &= Bx - Cz + xz, \end{cases} \quad (2)$$

where (x, y, z) are the phase variables, and (A, B, C) are the parameters. We introduce it in MATCONT under the name *ROESSLERTest* and let the derivatives of order 1, 2 and 3 be computed symbolically. To perform a time integration we select the initial point type 'Point' and input $x = 1, y = 2, z = 3, A = 0.2, B = 0.4, C = 0.7$ as initial values. In the **Integrator** window we set the interval to 200. We then turn to the MATLAB command line to inspect the settings:

```
>> global settings
>> settings
settings =

      system: ROESSLERTest
        IP: Point (P)

  option_pause: At Special Points
option_archive: 2
  option_output: 1
=====
      time: 0
      co_x: 1
      co_y: 2
      co_z: 3
    coord: [ 1, 2, 3 ]

  parameters: [ 0.2, 0.4, 0.7 ]
      pa_A: 0.2
      pa_B: 0.4
      pa_C: 0.7
=====
      Interval: 200
```

```

        eventfunction: <disabled>
InitStepSize_sim: <automatic>
MaxStepSize_sim: <automatic>
    RelTolerance: 0.001
    AbsTolerance: 1e-06
        Refine: 4
    Normcontrol: false

>> settings.co_x
ans =
    1
>> settings.coord
ans =
    1     2     3

```

We can also change some of the settings:

```

>> settings.coord.set([-5 5 10])
>> settings.parameters.set([0 0.4 4.5])

```

In the GUI we can check that these changes are visible in the **Starter** window. There we can also perform the computation. The outcome is stored in the `solution` class. We inspect it in the MATLAB command window:

```

>> global solution
>> solution
solution=
  SimCompSolution with properties:
    t: [1477x1 double]
    y: [1477x3 double]
  method: @ode45
    tspan: [0 200]
  options: [1x1 struct]
    param: [0 0.4000 4.5000]
    tE: []
    yE: []
    iE: []

>> solution.y
ans=
-5.0000  5.0000 10.0000
-5.0763  4.9739  9.5078
...

```

We return to the GUI, select the last point of the computed orbit (use the **View Result** button in the **Control** panel) and declare it to be an equilibrium. By default the Curve Type will now be 'Equilibrium'. We again inspect the `settings`:

```

>> settings
settings =
    system: ROESSLERTest
        IP: Equilibrium (EP)

pa_C_select: false

test_EP_BP: true
test_EP_H: true
test_EP_LP: true

eigenvalues: true
=====

```

We need to select an active parameter in the equilibrium continuation. This can be done via the **Starter** window or via the command line:

```
>> settings.pa_A_select.set(true)
```

We will also restrict the number of computed points to 49. This can be done either via the **Continuer** window or via the command line:

```
>> settings.MaxNumPoints.set(49)
```

We execute the continuation in the GUI. The solution data can be obtained in the MATLAB Command window:

```

>> solution
solution=
ContCurve with properties:

x: [4x49 double]
v: [4x49 double]
s: [3x1 struct]
h: [5x49 double]
f: [3x49 double]

>> size(solution.x)
ans=
     4     49

```

So far all driving steps were executed in the GUI, where they were relegated to the `session` class. In a more advanced use of the cli we can also perform these steps from the command line by declaring the `session` class global. We then add the commands:

```

>> global session
>> session

```

The `session` output recalls the settings and then offers a choice of three buttons, labeled

```
View Computations  View Actions  View Switches
```

Clicking the first button is equivalent to executing the command

```
>> session.select()
```

It provides the numbered list of computations (usually time integrations or continuation runs) that can be selected from the given Initial Point type. They can be selected by clicking, or by typing

```
>> session.select(k)
```

where k is the list number.

Clicking the second button is equivalent to executing the command

```
>> session.compute()
```

It provides a fixed list of options, namely **Forward**, **Backward**, and **Extend**. The list can be handled as in the previous case.

Clicking the third button is equivalent to executing the command

```
>> session.switches()
```

It provides the list of objects that can be chosen as new Initial Points. The list can be handled as in the previous cases. One can change the type of an initial point from the command-line by using the instruction

```
>> session.changeInitPoint('H') %force IP type to be 'Hopf (H)'
```

We note that it is always possible to get information about the current system:

```
>> settings.system
ans =
    CLSystem with properties:
name: 'RoesslerTest'
coordinates: {'x' 'y' 'z'}
parameters: {'A' 'B' 'C'}
dim: 3
time: 't'
handle: @ROESSLERTest
userfunctions: {}
ufdata: []
diagramlocation: 'H:\MatCont7p1\System\ROESSLERTest'
derstr: 'SSSNN'
equations: [3x14 char]
```

Event functions and Poincaré maps

A Poincaré section is a (in general, curved) surface in phase space that cuts across the flow of a dynamical system. The Poincaré map transforms the Poincaré section onto itself by relating two consecutive intersection points. Only those intersection points count, which come from the same side of the section. In this way, a Poincaré map turns a continuous-time dynamical system into a discrete-time one. If the Poincaré section is carefully chosen no information is lost concerning the qualitative behaviour of the dynamics. For example, if the system's state is attracted to a limit cycle, one observes dots converging to a fixed point in the Poincaré section as in Figure 5.

When computing an orbit $(t, y(t))$ in MATLAB an event can be defined as going through a zero of a scalar event function $G(t, y)$. If G does not explicitly depend on time in an autonomous dynamical system, this functionality can be used to see the Poincaré map in action. However, one shortcoming of the MATLAB solvers is that they do not interactively report on these events.

In the 6.11 and earlier versions of MATCONT, Poincaré maps were therefore computed by using a specific curve type, called Discrete Orbit (DO). For this type of orbits the ODE solvers were manipulated to use an explicitly implemented approximation strategy to locate the Poincaré intersection points.

In the new GUI, there is no longer a specific curve type. In order to allow for interactive plotting of events, the plot routine monitors sign changes of the values of the event function. Whenever a sign change is observed, the solver is called again on a smaller part of the curve to extract the event. Due to the implementation of this workaround, the list of detected events after computation in rare cases might contain more events than were displayed on an interactive plot.

For the sake of generality MATLAB allows to define vector-valued event functions whereby each component function defines its own event. This is done by setting the Events property to a handle to a function, e.g. `@events` with the syntax `[value, isterminal, direction] = events(t, y, varargin)`

where y is a state vector. The input variable `varargin` is a cell array that contains the values of the parameters. If parameters are explicitly used in the definition of the event function, then `varargin` should be replaced by an explicit list of parameter names.

If there are k event functions then for $i \in \{1, \dots, k\}$:

- `value(i)` is the value of the i -th event function.
- `isterminal(i) = 1` if the integration is to terminate at a zero of the i -th event function and 0 otherwise.
- `direction(i) = 0` if all zeros of the i -th component are to be computed (the default), +1 if only the zeros are needed where the event function increases, and -1 if only the zeros are needed where the event function decreases.

The use of event functions to compute Poincaré maps in CL_MATCONT is discussed in the manual [4]. We now illustrate the GUI implementation by example. We consider again the *Rössler* system (2).

Suppose that we want to compute an orbit and detect two events along it, namely $x = 0.2$ and $y = 0.3$. We need only the events where x , respectively y , are increasing and the integration will not be terminated if an event is detected.

We then define an event function `testEV` as follows:

```
function [value,isterminal,direction]= testEV(t,y,varargin)
value=[y(1)-0.2;y(2)-0.3];
isterminal=zeros(2,1);
direction=ones(2,1);
end
```

The function `testEV.m` is placed in the MATCONT main directory (or anywhere else on the MATCONT path)

We integrate the *Rössler* system from 0 to 100 starting from the point $[-5; 5; 10]$ with parameter values (0.25, 0.4, 4.5) and input the name 'testEV' (without quotes) in the EventFunction field of the **Integrator**, see Figure 3.

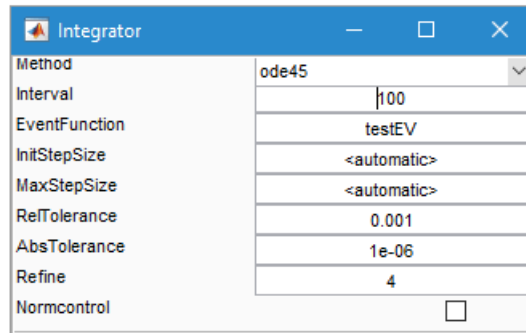

Figure 3: Integrator with an Event function.

We also open a MATCONT **Plot3D** window to display the state variables in the range $\{-9 \leq x \leq 9, -9 \leq y \leq 9, -2 \leq z \leq 11\}$. The 3D output is shown in Figure 4. We note that zeros of the first event function are marked as 'E1', those of the second as 'E2' and so on.

In Figure 5 we show the convergence of the iterates if the Poincaré map to a fixed point in a **Plot2D** window with $\{4.22 \leq x \leq 4.32, 2.3 \leq z \leq 2.8\}$,

The computed output is stored in the mat-file of the computed curve, from where it can be recovered for further use. It can also be sent directly to the MATLAB workspace by pressing the **Export** button in the **Data Browser** window that is opened by pressing the **View Curve** button in the **Control** window after the integration run. In the latter case we get the following output in the MATLAB command window :

```
exported=
  SimCompSolution with properties
    t: [1461x1 double]
  y: [1461x3 double]
  method: @ode45
  tspan: [0 100]
  options: [1x1 struct]
  param: [0.2500 0.4000 4.5000]
  tE: [33x1 double]
  yE: [33x3 double]
  iE: [33x1 double]
```

Here `tE` is the vector of time points where events were discovered, `yE` is the corresponding matrix of state variables and `iE` is a vector of ones and twos which refer to either the first or the second event.

Event points can also be selected as special points in the data browser and by double-clicking on the labels in the plots.

Figure 4: Time integration with event points that converge to fixed points.

Figure 5: Convergence of the iterates of the Poincaré map to a fixed point, alternating between points at the bottom left side and the top right side.

Other new features

The new MATCONT has been improved and extended with many new functionalities:

1. The Select Cycle object is presented as a Special Point after each time integration. Selecting it as an initial point opens a subpanel with two fields that allow to choose a convergence criterion and a number of mesh intervals for initializing a curve of periodic orbits that starts from the periodic orbit found by time integration. The number of collocation points is always 4 by default. We note that this requires that the computed orbit covers between one and two periods of the periodic orbit.
2. Graphical 2D and 3D plots are reorganized: only one layout window is presented and nearly everything can be plotted, i.e. many earlier restrictions are lifted.
3. Clicking **Options|Plot Properties** in the main panel (Figure 1) opens an edit box panel which allows to assign plot properties (color, linestyle, ...) to each type of computed curve. Defaults are provided for all types of computed curves, which can be overwritten using MATLAB code in the edit boxes. For curves of equilibria and curves of limit cycles, it is possible to differentiate between stable and unstable parts of the curves. Advanced MATLAB users can edit the file *GUICurveModifications.m* to add new differentiations of the plot properties within a curve.
4. Error handling of plots is improved so that plot errors caused by command line interference, or by GUI interference

when computations are suspended, do not crash the computations.

5. Each input field has input restrictions and these are checked to minimize input errors. So for example it will not be possible to input a float or a question mark if a positive integer value is required. Errors are reported in the MATLAB command line. On the other hand, numerical fields can be filled with MATLAB expressions, provided they can be evaluated in the command line. So one can insert $2 * \pi$ instead of its decimal expansion 6.283184...
6. In continuation plots it is possible to click on a found singular point to obtain information on the curve where it was found, the type of point and the normal form coefficients. By double clicking one selects the point as an initial point for another continuation.
7. The Scroll - key can be used to scroll through MATCONT windows. This functionality had to be implemented separately as MATLAB does not provide this functionality as part of their standard library.
8. Several special keys can be used to control continuation computations, namely: **Escape** to stop, **Space bar** to resume, **Enter** to pause and **Control** to continue (when pressed) or to pause (when released). The use of the **Control** key is new.

Example: Percept switching in the human visual system

Percept switching under the action of an ambiguous visual stimulus is a well-known phenomenon in psychophysics, see e.g. [5, 9]. In [9] the authors discuss a neural explanation of the stabilization of percept choices under intermittent viewing of an ambiguous stimulus. They consider the following system:

$$\begin{cases} X_1' &= (Stim - (1 + A_1)X_1 + \beta A_1 - \gamma S(X_2))/\tau \\ X_2' &= (Stim - (1 + A_2)X_2 + \beta A_2 - \gamma S(X_1))/\tau \\ A_1' &= -A_1 + \alpha S(X_1) \\ A_2' &= -A_2 + \alpha S(X_2) \end{cases} \quad (3)$$

with state variables X_1, X_2, A_1, A_2 and fixed parameters $\alpha = 5$, $\beta = 4/15$, $\gamma = 10/3$, and $\tau = 1/50$. The primary dynamical variables X_1, X_2 are the ‘local fields’, which correspond to the percept-related components of the membrane potentials of the neurons that encode the two competing percepts, indicated by 1 or 2 respectively. To each primary variable an adaptation variable is associated, called A_1, A_2 respectively. In the local field interpretation these correspond to the (averaged and scaled) gating variables of the neurons. $Stim$ is the amplitude of the stimulus. $S(X_1)$ is a sigmoidal function of X_1 , zero for negative values of X_1 and equal to $X_1^2/(1 + X_1^2)$ for nonnegative values of X_1 . $S(X_2)$ is to be interpreted similarly. The precise choice of the sigmoid function does not influence the qualitative behavior of (3).

Line 1 of (3) specifies how X_1 integrates the stimulus with its adaptation variable A_1 and the subtractive cross-inhibition $S(X_2)$. Lines 2 and 4 are dual to Lines 1 and 3.

In [9] the authors consider a 128 by 128 grid of points in a (T_{off}, T_{on}) space. For each point a simulation of (3) is done with the stimulus alternatingly switched off during a time span T_{off} and on during a time span T_{on} . The eventual behavior (after a transient) varies with the choice of T_{off} and T_{on} but also depends on the initial values of the state variables. It includes repeating and alternating patterns and bistability. An important observation is that for fixed T_{on} the behavior can be stabilized by increasing T_{off} , i.e. it leads to a situation where the percept is the same whenever the stimulus switches on (but may still depend on the initial state at the very beginning.)

Modelling of the percept switching system in MATCONT

In MATCONT we approximate the on/off switching by a continuous system with a periodic forcing with period $T_{off} + T_{on}$. This involves the inclusion of T_{off} and T_{on} as new parameters in the system and avoids the need of an enormous number of time integrations, in each of which the resulting stable behaviour can depend upon the initial state values.

Instead we make numerical computations based on the theory of bifurcations of periodic orbits. Boundaries of behavior regions in the (T_{off}, T_{on}) -plane are obtained as curves of codimension 1 bifurcations of periodic orbits which meet in codimension 2 points. The periodic forcing is implemented with new independent state variables Y_1, Y_2 . More precisely, we consider the following system (in the notation of the MATCONT input field):

```
S1=(X1^2)/(1+X1^2)/(1+exp(-exp*X1))
S2=(X2^2)/(1+X2^2)/(1+exp(-exp*X2))
omega=2*pi/(Ton+Toff)
Stim=1/(1+exp(-exp*(Y1-cos(2*pi*Ton/2/(Ton+Toff))))))
X1'=(Stim-(1+A1)*X1+beta*A1-gamma*S2)/tau
X2'=(Stim-(1+A2)*X2+beta*A2-gamma*S1)/tau
A1'=-A1+alpha*S1
A2'=-A2+alpha*S2

```

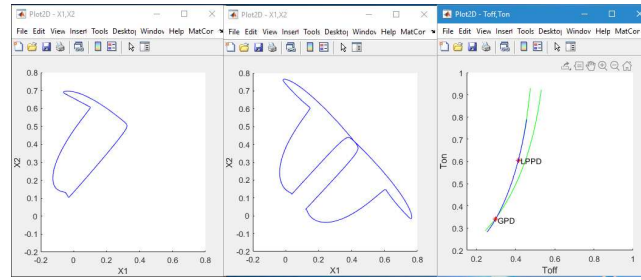

Figure 6: Left: repeating orbit with period $T_{off} + T_{on}$. Middle: alternating orbit with period $2(T_{off} + T_{on})$. Right: wedge of bistability.

with state variables $X_1, X_2, A_1, A_2, Y_1, Y_2$. The auxiliary variables S_1, S_2 approximate the sigmoid functions $S(X_1), S(X_2)$, respectively. They help to facilitate the implementation and increase the readability of the MATCONT input. We have also introduced an additional parameter $expp$ to the system, appearing in the equations for S_1, S_2 and $Stim$. By increasing its value, the analytical functions for S_1 and S_2 in the MATCONT system converge to the non-analytical step sigmoid functions that are used in (3). In our computations $expp = 60$. More details are given in [3].

The state variables Y_1 and Y_2 are decoupled from the other state variables. Their stable behaviour (after a transient) is a periodic orbit of the form $Y_1 = \cos(\omega t + P), Y_2 = \sin(\omega t + P)$ with a time shift P that depends only on the initial values of Y_1, Y_2 . The period of this orbit is $T_{off} + T_{on}$.

When Y_1, Y_2 evolve along the unit circle then from the fourth line in the MATCONT system it follows that $Stim$ is alternately close to one during a time span T_{on} and close to zero during a time span T_{off} . The stimulus term thus acts as an on/off switch in a periodic forcing of (3).

Fig. 6 (left) shows the (X_1, X_2) projection of a stable periodic orbit computed by time integration for $T_{off} = 0.6, T_{on} = 0.8$ (after a transient, starting with values of (Y_1, Y_2) which are not both zero). The time evolution is repeating, i.e. after each on/off cycle we see the same partial trajectory which corresponds to the percept X_1 (for a different choice of the initial values of the state variables it can be the percept X_2). Fig. 6 (middle) shows the projection of a stable periodic orbit computed by time integration for $T_{off} = 0.2, T_{on} = 0.8$. The time evolution is alternating, i.e. X_1 and X_2 dominate in turns.

To study the stability regions of repeating and alternating periodic orbits we use the Select Cycle functionality of MATCONT. We start the continuation of limit cycles from the stable limit cycles in Fig. 6 under variation of T_{off} . By using the branch switching functionalities of MATCONT we then construct the bifurcation diagram and find that in (T_{off}, T_{on}) -space the stability regions of repeating and alternating orbits overlap in the wedge shown in Fig. 6 (right). The wedge is bounded at the right by a curve (green) of limit points of cycles of alternating periodic orbits. At the left, the boundary consists partly of a curve (green) of limit points of cycles of repeating periodic orbits and a curve (blue) of period-doubling points of repeating periodic orbits. The green and blue curves meet in a fold-flip bifurcation point of cycles denoted by LPPD. The blue curve contains a generalized period-doubling point (GPD) of repeating periodic orbits. The LPPD point is situated at $(0.41416, 0.60659)$, the GPD point at $(0.29837, 0.34146)$.

Conclusion

The MATCONT implementation greatly minimizes the computational work in the study of the perception problem. It confirms and explains the stabilization effect observed in the numerical simulations and allows easy extensions to similar studies with other models or other parameters.

Finding connecting orbits between saddle periodic orbits as organising centres of complicated dynamics

Nelson Wong*, Hinke M. Osinga* and Bernd Krauskopf*

*Department of Mathematics, University of Auckland, Auckland, New Zealand

Summary. We study heterodimensional cycles between two periodic orbits in a four-dimensional vector field. Such cycles are characterised by a connecting orbit that lies in the intersection of two two-dimensional manifolds; the returning connection is given by a family of connecting orbits in the generic two-dimensional intersection of two three-dimensional manifolds. Heterodimensional cycles are known to organise highly complicated dynamics, which persist under C^1 -perturbations of the vector field. There are very few explicit examples known from applications; we study one such example, namely, a vector field model for calcium dynamics in a cell. We employ Lin's method to compute heterodimensional cycles and associated nearby global bifurcations. We present a cycle that is non-orientable and compute its locus in a two-parameter plane. In this way, we explore how it contributes to the organisation of the overall bifurcation structure, which, in turn, elucidates mechanisms behind the generation of C^1 -robust chaotic dynamics.

A connecting cycle between two saddle periodic orbits is *heterodimensional* if the periodic orbits have unstable manifolds of different dimensions. Heterodimensional cycles can only exist in vector fields of dimension at least four, and are known to generate highly complicated dynamics [1, 2, 3, 5], including infinitely many periodic and/or homoclinic orbits. Furthermore, if a system has a codimension-one heterodimensional cycle, then every other system in a C^1 -neighbourhood about the original system also has a heterodimensional cycle. We are interested in the mechanism behind such C^1 -robustness, and study the existence and properties of heterodimensional cycles in an explicit four-dimensional vector field.

Heterodimensional cycles are primarily studied abstractly. In particular, there are very few known examples arising out of applications. We study a model for intracellular calcium oscillations that is known to feature a heterodimensional cycle [7]. The equations are given by

$$\begin{cases} \dot{c} &= v, \\ D_c \dot{v} &= s v - \left(\alpha + \frac{k_f c^2}{c^2 + \varphi_1^2} n \right) \left(\frac{\gamma (c_t + D_c v - s c)}{s} - c \right) + k_s c - \delta (J - k_p c), \\ \dot{c}_t &= \delta (J - k_p c), \\ s \dot{n} &= \frac{1}{\tau} \left(\frac{\varphi_2}{\varphi_2 + c} - n \right). \end{cases} \quad (1)$$

Here, c represents the calcium concentration in the main part of the cell body (the cytosol) and c_t the total calcium concentration inside the cell (including that in an internal calcium store, known as the endoplasmic reticulum or ER); v is the membrane potential; and n is a gating variable that represents the fraction of open channels through which calcium enters the cytosol from the ER. System (1) is written in a moving-frame coordinate system and the differentiation is with respect to the travelling-wave coordinate. We choose the same parameters as in [7] with $s = 9.0$ fixed, and we vary the flux J of calcium entering from outside the cell as our bifurcation parameter; see Table 1.

α	k_s	k_f	k_p	φ_1	φ_2	τ	γ	D_c	δ	s
0.05	20.0	20.0	20.0	2.0	1.0	2.0	5.0	25.0	0.2	9.0

Table 1: Parameter values for the intracellular calcium model (1).

With this explicit model, we can leverage advanced numerical methods to study heterodimensional cycles in a concrete setting. To this end, we set up a two-point boundary value problem (2PBVP) based on Lin's method that represents the (non-robust) connecting orbit. More precisely, we define an orbit segment that starts near a saddle periodic orbit and ends in a three-dimensional cross-section Σ , which we choose to be locally transverse to the flow [6]. We also define a second orbit segment that starts in Σ and ends near another saddle periodic orbit. Here, we fix parameters as in Table 1 and start with $J = 2.957$, which we estimate to be close to the actual bifurcation value. The two orbit segments are restricted such that the difference between their end points in Σ lies in a prescribed *Lin direction*. This 2PBVP can be solved by pseudo-arclength continuation techniques in AUTO [4]. As we vary J , we detect the connecting orbit as a zero of the distance between the end points in Σ . Once the connecting orbit has been found, its locus can be computed by varying two system parameters while keeping the distance at zero.

We find a heterodimensional cycle in system (1) for $J \approx 2.95748$; this cycle is shown in Figure 1 in projection onto (c, v, c_t) -space. Specifically, we show the single connecting orbit Ω_1^{PD} (blue) from the saddle periodic orbit Γ_1 (green) to the saddle periodic orbit Γ_{PD} (green), and the family S of orbits from Γ_{PD} to Γ_1 that forms a two-dimensional surface (red).

Figure 1: Three-dimensional projection onto (c, v, c_t) -space of the non-orientable heterodimensional cycle in system (1) with $J \approx 2.95748$. Shown are saddle periodic orbits (green) Γ_1 and Γ_{PD} , the codimension-one connecting orbit Ω_1^{PD} (blue) from Γ_1 to Γ_{PD} , and the returning surface S (red) of robust connections.

Importantly, the heterodimensional cycle in Figure 1 is different from the one found in [7]. Its distinguishing feature is that Γ_1 is non-orientable. As we decrease J from near the Hopf bifurcation that creates Γ_1 , this periodic orbit undergoes a period-doubling bifurcation, so that it has one negative unstable, one negative stable, and one positive stable Floquet multiplier, with the positive one being associated with the strongest contracting direction. This period-doubling bifurcation is subcritical, and gives rise to a period-doubled orbit that undergoes its own period-doubling bifurcation before merging with Γ_{PD} at a fold bifurcation. The periodic orbit Γ_{PD} in Figure 1 has one negative stable, one negative unstable, and one positive unstable Floquet multiplier. The closure of S is non-orientable since it is tangent to the weakly stable linear bundle of Γ_1 , which is associated with the negative stable Floquet multiplier. The non-orientability complicates the geometry of S : S accumulates onto Γ_1 in a twisting fashion, since the weakly stable linear bundle of Γ_1 locally forms a Möbius band.

Starting from the heterodimensional cycle for $J \approx 2.95748$, we can compute the one-parameter family of this cycle in a two-parameter plane. By studying the bifurcation structure of system (1) locally about this locus, we examine how the parameter plane is organised to give rise to open regions where heterodimensional cycles are found robustly.

Summary. The aim of this research is to investigate and determine how a geometrically nonlinear boundary condition, i.e., a strong local nonlinearity, “redistributes” an input energy in the form of an impulsive load, among the modes of vibration of a cantilever beam, thereby increasing its efficacy of energy dissipation. The nonlinear boundary condition is created by grounding the free end of the cantilever beam through a linear spring-damper element at an angle relative to the neutral axis of the beam while at rest. By tracking the time-averaged energy and the effective instantaneous damping ratio of each mode of the beam, we numerically and experimentally show that there are sustained energy exchanges among the modes of vibration of the cantilever beam, the intensity of which depend on the degree of nonlinearity of the boundary condition.

Experimental setup and reduced-order finite-element modeling via system identification

Figures 1a and 1b depict the fully instrumented experimental apparatus consisting of the linear cantilever steel beam with Young’s modulus of 192 GPa, density of 7784 kg/m³, cross-sectional area of 8×44.6 mm², length of 1.76 m, and the geometrically nonlinear boundary condition and its corresponding reduced-order model (ROM), respectively. Moreover, figure 1c shows a closeup of the geometrically nonlinear boundary condition, studied in [1], achieved by grounding the free end of the cantilever through a ¼ inch diameter steel rod whose bending stiffness and inherent damping provide the compliance and dissipation of the boundary condition.

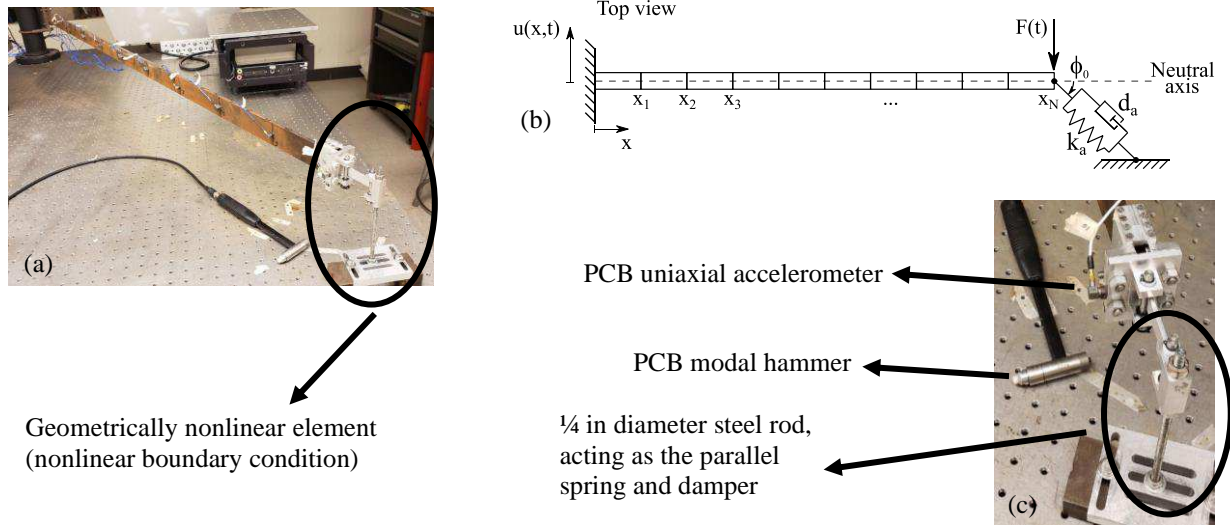

Figure1. Fully instrumented cantilever beam, grounded at its free end through a geometrically nonlinear boundary condition (a), the corresponding reduced-order model (ROM) (b), and zoomed-in view of the geometrically nonlinear boundary condition (c).

In order to create an accurate ROM of the apparatus, we implemented a two-step system identification approach: 1) By applying the Multi-input Multi-output Frequency Domain Identification (MFDID) [2] technique to the response of the cantilever beam, excited by an impulse as shown in figure 1b, we identified the modal parameters, i.e., natural frequencies and modal damping ratios, of the cantilever beam, uncoupled from the nonlinear attachment. 2) Next, we attached the nonlinear element to the fully identified cantilever beam and configured it such that $\phi_0 = 90^\circ$. Then, through time series optimization, we identified the unknown stiffness and damping parameters associated with the nonlinear attachment, k_a and d_a , after which we were able to accurately reproduce the experimentally measured response of the beam by the ROM, the governing equation of which can be expressed as:

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{C}\dot{\mathbf{u}} + \mathbf{K}\mathbf{u} + \mathbf{f}_{nl} = \mathbf{F}(\mathbf{t}), \quad \mathbf{u}(0) = \mathbf{0}, \quad \dot{\mathbf{u}}(0) = \mathbf{0}, \quad (1)$$

where $\mathbf{u} = [u_1, u_2, \dots, u_N]^T$ is the displacement vector corresponding to each node, $x_i, i = 1, 2, \dots, N$ (cf. figure 1b); \mathbf{M} , \mathbf{K} are mass and stiffness matrices of the finite element model of the Euler-Bernoulli beam, and \mathbf{C} is the proportional damping matrix of the beam, all obtained from the first step of the identification process. Moreover, \mathbf{f}_{nl} , denotes the nonlinear force vector whose elements, except the N-th, are uniformly zero in time. The N-th element of \mathbf{f}_{nl} , f_b , is expressed as

$$f_b = d_a \left[\frac{(x_N + l_0 \sin \phi_0)^2}{(l_0 \cos \phi_0)^2 + (x_N + l_0 \sin \phi_0)^2} \right] \dot{x}_N + k_a (x_N + l_0 \sin \phi_0) \left[1 - \frac{l_0}{\sqrt{(l_0 \cos \phi_0)^2 + (x_N + l_0 \sin \phi_0)^2}} \right], \quad (2)$$

where l_0 is the natural length of the nonlinear attachment.

It can be shown that the nonlinear force, (2), in the limit of $x_N \ll l_0$ (low energy levels) can be linearized as

$$f_b|_{x_N \ll l_0} = (d_a \sin^2 \phi_0) \dot{x}_N + (k_a \sin^2 \phi_0) x_N. \quad (3)$$

Combining (1)-(3) and assuming low energy, i.e., $x_N \ll l_0$, we can construct the eigenvalue problem

$$[-\omega^2 \mathbf{M} + (\mathbf{K} + \mathbf{I} \cdot \mathbf{f}_{nl}|_{x_N \ll l_0})] \mathbf{u} = \mathbf{0}, \quad (4)$$

where \mathbf{I} is the identity matrix, and consequently, find the so-called “linearized” modal basis of the system.

Modal energy scattering due to nonlinear boundary conditions

In order to compute the modal response of the nonlinear beam (both the experimental and computational models), we projected each measured response along the beam onto the linearized modal basis of the system. Following this we computed the time-averaged modal energies as described in [3]. By doing so, we can observe not only how much of the total energy of the beam is allocated to each mode, but also follow their variations with time and measure the maximum energy exchange among them for different angles of attachment, ϕ_0 .

Finally, we defined a measure of energy exchange among modes by computing and comparing the maximum fluctuation in the percentage of each of the instantaneous modal energies, which corresponds to the maximum percentage of energy being exchanged among the modes. Figure 2 shows the energy exchange measure for the first two modes, for both the experimental system and the ROM.

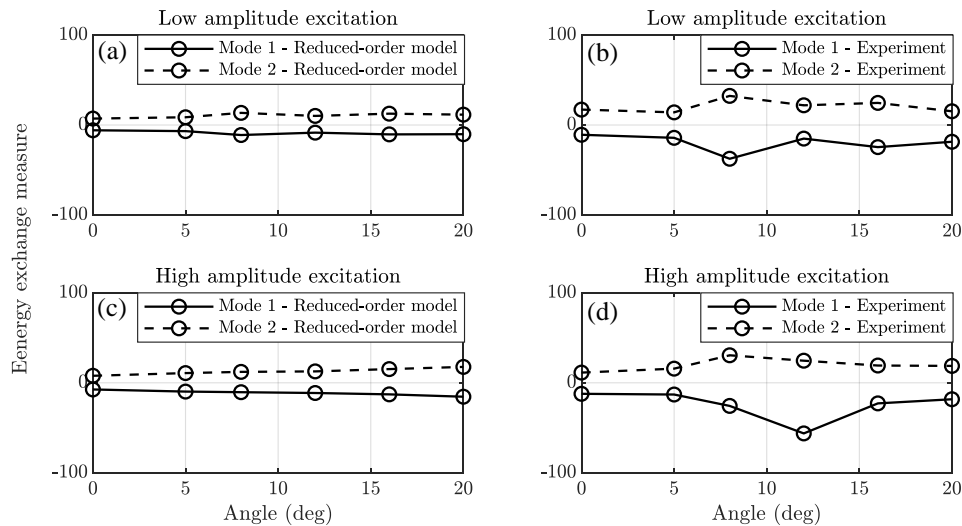

Figure 2. Energy exchange measures of the first two modes as a function of ϕ_0 , computed from the ROM (a) and the experiment (b), for a low intensity impulse; (c) and (d) show similar graphs for a high intensity impulse.

Figure 2, especially the energy exchange measures computed from the experimental results, shows that, for a certain range of angle of inclination, $8^\circ < \phi_0 < 12^\circ$, the percentage of energy exchanged between modes 1 and 2, is maximized. This effect is achieved not only due to energy tunability of the nonlinearity but also due mainly to the existence of the angle of inclination, ϕ_0 , which can be tuned to directly affect the degree of nonlinearity of the boundary condition.

Conclusions

In this research we investigated the effects of a strong local geometric nonlinearity on the modal interactions that occurred in a cantilever beam whose free end was grounded through a geometrically nonlinear element, which consisted of a linear spring-damper element at an angle, ϕ_0 , relative to the neutral axis of the beam while at rest. After building an experimental apparatus, we created a reduced-order finite element model for the experiment and updated its parameters by implementing frequency domain and time domain system identification techniques. Next, we projected the response of the nonlinear beam onto the modal space obtained from the updated computational model, and calculated the amount of energy in each of the projected modes. We recorded the maximum energy exchange among the projected modes for different values of ϕ_0 and showed that by tuning this parameter properly it is possible to achieve the maximum amount of energy exchange from the low-frequency modes to high-frequency modes, thereby increasing the dissipation capabilities of the system.

Intermodal targeted energy transfer in a blast-excited 2D linear system with an elliptical hole

Yuval Veltman, Majdi Gzal and Oleg V. Gendelman

Faculty of Mechanical Engineering, Technion – Israel Institute of Technology, Haifa, Israel

Summary. This work explores the implementation of the intermodal targeted energy transfer (IMTET) concept for passive mitigation of a 2D linear oscillator subjected to blast excitation in its weak direction. The considered model contains 3 degrees-of-freedom, namely, two directions of translation (i.e., horizontal and transversal), and rotational direction. The passive mitigation here is achieved by inducing extreme, fast time scale energy transfers from weak structural mode (characterized by lower-frequency and large amplitude) which was initially excited by the blast excitation to strong structural modes (i.e., higher-frequency ones with a small amplitudes). These targeted (directed) energy transfers are governed by a non-resonant nonlinear dynamical mechanism induced by vibro-impacts between the main structure and a rigid barrier which constrained the structure to move within an elliptical hole. By redistributing the blast energy from low- to high-frequency structural modes the amplitude of the overall structural response is reduced in an extremely fast time scale, and the intrinsic dissipative modal capacity of the structure itself is better utilized. Additional blast energy dissipation is achieved by inelastic vibro-impacts.

Introduction

Passive mitigation of engineering structures subjected to extreme loads is of considerable interest in real life applications for preventing structural damage and human loss. Several linear and nonlinear absorbers have been investigated in the literature for this purpose [1,2]. Recently, a new concept was introduced [3] for blast mitigation through intermodal targeted energy transfer (IMTET) mechanism which based on irreversible nonlinear non-resonance energy scattering that passively transfers a significant portion of the blast energy from low-frequency structural modes (in particular, the fundamental mode) to high-frequency modes of the structure. Such passive IMTET was achieved by introducing local strong nonlinearities, in the form of vibro-impacts. The IMTET concept was first implemented on a benchmark blast-excited two-degree of freedom (DOF) linear system by introducing to the system a single impact clearance [3]. Then, an extension of IMTET mechanism in multi-DOF systems was conducted in [4], in which a computationally study to explore the concept of IMTET to mitigate the effect of blast loading on a nine-story steel structure was performed.

Here in this study, the IMTET concept will be extended to two-dimensional structures, with the rationale of channeling energy from “weak” to “strong” direction, thus utilizing much more effectively the intrinsic dissipative capacity of the structure itself.

Model description and governing equations

Here we consider a 3DOF oscillator with two directions of translation (i.e., horizontal and transversal) and one of rotational direction. The oscillator consists of a mass m with moment of inertia I moving on both horizontal and vertical directions. The mass is connected to two linear dampers with coefficients c_1 and c_2 , and a torsional damper with coefficient γ . Two linear springs with stiffness k_1 and k_2 and a torsional spring with stiffness k_3 are attached to the mass as well. The mass movement is constrained by a rigid element, in center of an elliptical hole going through the mass, with width $2a$ and height $2b$, and rotated by an angle α , as shown in Figure 1.

Figure 1: Schematic of the considered system

Let q_1 and q_2 denote the horizontal and the transversal displacements, respectively, the equations of motion between the impacts are given by:

$$m \frac{\partial^2 q_1}{\partial t^2} + c_1 \frac{\partial q_1}{\partial t} + k_1 q_1 = 0 \quad (1)$$

$$m \frac{\partial^2 q_2}{\partial t^2} + c_2 \frac{\partial q_2}{\partial t} + k_2 q_2 = 0$$

$$I \frac{\partial^2 \theta}{\partial t^2} + \gamma \frac{\partial \theta}{\partial t} + k_3 \theta = 0$$

When the rigid element location satisfies the equation of the ellipse in respect to the center of mass, collision happens and the mass changes its velocity instantaneously according to the Newtonian impact law. The collision is defined using coefficient of restitution and coefficient of friction and take under consideration angular impulse. After numerically solving the equations of motion we can explore the efficiency of the mechanism. The simulation parameters are chosen with respect to a real steel beam with rectangular cross section. We have simulated the system for different coefficients of restitution, namely, $r = 0.6, 1$ and compared the results with the linear case, i.e., without the constraint, for an equal initial condition of impact. To explore the efficiency here we the normalized energy η as the ratio between the instantaneous energy $E(t)$ and the initial energy $E(0)$:

$$\eta(t) = \frac{E(t)}{E(0)} \quad (2)$$

We define the characteristic damping time of the system τ as $\ln(\eta(\tau)) = -1$, in other words, it is the time in which the energy drops by a factor of $1/e$ of its initial value in a time inverse to the damping coefficient.

Results

As a preliminary results, the horizontal and transversal responses subject to initial conditions that excite only the horizontal direction are shown in Figure 2(left). It is clear that when the vibro-impacts occur, the modes interact immediately, and a substantial amount of energy is transferred from the horizontal to the transversal mode. The latter is characterized by a substantially higher modal dissipative capacity. Thus, an enhancement of the damping properties of the system is realized through utilization of the intrinsic modal structure and excitation of the higher-frequency transversal mode. Figure 2(right) shows the logarithm of the normalized energy as a function of time for the following three cases: linear, nonlinear with purely elastic impacts, and nonlinear with inelastic impacts. It can be seen that the presence of the impacts in the system leads to a significant decrease in the characteristic damping time, even when purely elastic impacts are considered.

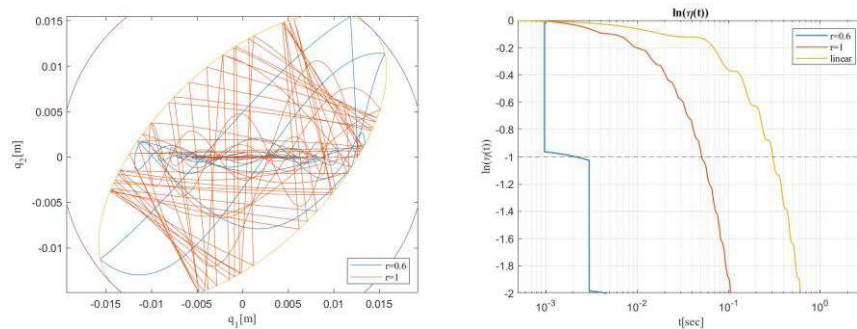

Figure 2: The center of mass trajectory in the $q_1 q_2$ plane (left); The instantaneous energy of the system (right)

Conclusions

In this work, the non-resonance nonlinear mechanism for efficient and rapid low- to high-frequency energy scattering, which is referred to as intermodal targeted energy transfer—IMTET, is implemented for passive mitigation of a 2D linear oscillator subjected to blast excitation in its weak direction. The numerical exploration revealed that channeling the blast energy, within the modal space, from low- to high-frequency structural modes enables an extremely fast mitigation of the overall structural response, and a drastic reduction of the characteristic damping time in the benchmark system.

Such observations open up an entirely new domain of research on constructive utilization of different directions for possible displacement of the structure, in particular channeling energy from “weak” to “strong” direction by means of the IMTET.

Kapitza resistance in basic chain models with isolated defects

Jithu Paul* and O. V. Gendelman*

*Faculty of Mechanical Engineering, Technion–Israel Institute of Technology, Haifa, Israel

Summary. Kapitza resistance due to isolated defect is explored numerically in benchmark chain models (linear, β -FPU, rotator and Frenkel-Kontorova). Kapitza resistance is found independent on chain length and temperature in linear model, but dependent on thermostat characteristics. In β -FPU model, the anomaly as in the heat conductivity continues, Kapitza resistance vanishes with the chain length and depend on temperature and thermostat. In Rotator and Frenkel-Kontorova models, which are characterized by normal heat conductivity, Kapitza resistance also shows convergence with chain length and independent on thermostat. Except for the linear model, the findings are similar to the heat conductivity characteristics in the respective models.

Kapitza resistance/Interfacial thermal resistance is defined as the ratio of discontinuity in the temperature gradient at the material interface to the heat flux flowing across the interface. It was first observed by Kapitza, in the junction between liquid helium II and a solid, during his experiments on superfluidity. Although numerous theoretical works have been devoted to explain Kapitza resistance, the two widely known models are Acoustic Mismatch Model (AMM) which is defined for very low temperatures and Diffuse Mismatch Model (DMM) which is defined for very high temperatures. Majority of the analytical, numerical works were based on AMM. The heat management problem, especially in nanoscale devices, involves the bulk conduction as well as the interfacial heat conduction. In this regard, Kapitza resistance and heat conductivity are two sides of a coin. We have well-known results for one-dimensional heat conduction problem and the studies divide models based on convergence and divergence of heat conductivity in the thermodynamic limit. But the behavior of Kapitza resistance in these models is less understood. More than just a theoretical concept, the divergence of heat conductivity is already established by experimental studies [1] for quasi-one-dimensional systems. Since interfacial thermal resistance is also a crucial factor that deciding the heat transport, the current study can shed light into thermal management problems in nano-scale devices. The present study conducted for Kapitza resistance behavior in basic benchmark models: linear, β -FPU, rotator and Frenkel-Kontorova. We choose isolated defect (isotopic defect/coupling defect) to create the interfacial boundary and to avoid the complications of the non-reciprocity.

We follow two numerical approaches: first, a semi-analytical method for linear model, which is based on the famous Rieder-Lebowitz-Lieb (RLL) method [2]; second, molecular dynamics simulations. In all cases, the non-equilibrium heat transport is established by connecting the chain to Langevin thermostats at both ends. In RLL method, the basic idea is to numerically solve the necessary and sufficient condition for the stationary state of a harmonic crystal from the generalized Liouville equation. In molecular dynamics simulations, we follow numerically the time evolution of the Hamiltonian with discrete time interval. We use Verlet algorithm to solve the equations of motion using homemade FORTRAN-95 codes. The results obtained for linear, β -FPU, rotator and Frenkel-Kontorova models are very-briefly discussed below.

It is well-known that in linear model, phonon does not exchange energy between modes and the phonon spectra is totally dependent on thermostat characteristics. We observed the heat flux and the temperature drop at the interface scales with the temperature and the Kapitza resistance is independent on chain length and temperature. We know heat conductivity was diverging with chain length in linear model. But we cannot say Kapitza resistance is normal for linear model because the Kapitza resistance is totally dependent on the thermostat since nothing in the chain can influence the phonons. Another observation for the linear model (more or less similar in other models also) is Kapitza resistance shows diverging behavior with the strength of the isolated defect when the strength goes to infinity.

Figure 1: Power law decrease of the Kapitza resistance with the chain length for the chain with β -FPU interaction.

Heat transport in β -FPU model is always a puzzling problem since the observation of absence of thermalization by Fermi-Pasta-Ulam. Heat conductivity shows divergence with an exponent close to $1/3$ [3]. The anomaly continues in the case of Kapitza resistance which demands normalization of heat flux. Although the exponent dependent on the defect strength, still it is closer to $-1/3$ (Figure 1). The Kapitza resistance decreases with increase in temperature, which shows the temperature

affects the phonon scattering process at the interface. As in the linear model, Kapitza resistance here also dependent on thermostat.

Figure 2: Temperature dependence of the Kapitza resistance in the chain of rotators.

Rotator model are well-known for momentum conserving models which obey convergence of thermal conductivity [4]. Kapitza resistance showed normal behavior here, that is, converges in the thermodynamic limit and independent thermostat characteristics at a temperature above the rotobreathers can get excited. The strong nonlinearity allows the system to forget about the thermostat characteristics and the phonon locking by the rotobreathers allows the normal diffusion. The activation of rotobreathers and its effect on the Kapitza resistance can be observed as a dip in the Kapitza resistance-temperature plot (Figure 2).

Figure 3: Dependence of the Kapitza resistance on the chain average temperature in the Frenkel-Kontorova model.

Coming to the Frenkel-Kontorova model, Kapitza resistance is normal and independent of thermostat characteristics at intermediate temperatures (Figure 3). We know the similar observation for heat conductivity since activation of topological kinks only happens at intermediate temperature range [5]. The linear characteristics at very low temperatures happens due to the weak nonlinearity and at high temperatures the chain detaches from the substrate.

In conclusion, linear model showed Kapitza resistance that is independent of chain size (contrary to heat conductivity) and temperature, but dependent on thermostat. The addition of cubic linearity makes the Kapitza resistance anomalous, that is, dependent on thermostat and chain length in the thermodynamic limit (need of normalized heat flux). Rotator and Frenkel-Kontorova models showed normal Kapitza resistance. In all the nonlinear models Kapitza resistance decreases, immediately after the very low temperature regime (linear regime) which needed to be investigated further.

Modal interactions in a non-linear mass-in-mass periodic chain

Jean Flosi[†], Alireza Ture Savadkoobi[†] and Claude Henri Lamarque[†]

[†]Univ Lyon, ENTPE, CNRS UMR5513, LTDS, France

Summary. The multiple-scale dynamics of a forced periodic chain composed of 2 degree of freedom mass-in-mass cells with cubic non-linearity is studied. A continuous approach leads to dispersion equations and allows to define the modal decomposition of continuous physical coordinates of the system. Because of the system nonlinearity, a 1 : 3 internal resonance is considered. The continuous model is projected on these two modes in order to study associated energy exchanges. Fast and slow dynamics leads to detection of slow invariant manifolds (SIM) and frequency responses of the chain.

Considered model of the chain

Meta-materials are developed to present unusual non natural responses against external or internal actions. In the vibro-acoustics domain, mass-in-mass systems are an example of meta-materials [1, 2]. We are considering the system presented in Fig.1: a L -periodic chain composed of mass-in-mass cells linearly linked two by two. Each cell is composed of a principal mass m_1 linked non-linearly to its inner mass m_2 .

Figure 1: Scheme of the L -periodic chain composed by cubic nonlinear mass-in-mass cells

Governing equations are:

$$\left\{ \begin{array}{l} m_1 \frac{d^2 u_1}{dt^2} + k_1(2u_1 - u_L - u_2) + k_3(u_1 - v_1)^3 + c_1(2\frac{du_1}{dt} - \frac{du_L}{dt} - \frac{du_2}{dt}) \\ + c_2(\frac{du_1}{dt} - \frac{dv_1}{dt}) = F_1 \sin(\Omega t) \\ \\ m_1 \frac{d^2 u_j}{dt^2} + k_1(2u_j - u_{j-1} - u_{j+1}) + k_3(u_j - v_j)^3 + c_1(2\frac{du_j}{dt} - \frac{du_{j-1}}{dt} - \frac{du_{j+1}}{dt}) \\ + c_2(\frac{du_j}{dt} - \frac{dv_j}{dt}) = F_j \sin(\Omega t) \text{ for } j \in [2, \dots, L-1] \\ \\ m_1 \frac{d^2 u_L}{dt^2} + k_1(2u_L - u_{L-1} - u_1) + k_3(u_L - v_L)^3 + c_1(2\frac{du_L}{dt} - \frac{du_{L-1}}{dt} - \frac{du_1}{dt}) \\ + c_2(\frac{du_L}{dt} - \frac{dv_L}{dt}) = F_L \sin(\Omega t) \\ \\ m_2 \frac{d^2 v_j}{dt^2} + k_3(v_j - u_j)^3 + c_2(\frac{dv_j}{dt} - \frac{du_j}{dt}) = 0 \text{ for } j \in [1, \dots, L] \end{array} \right. \quad (1)$$

The periodicity leads to following boundary conditions:

$$\left\{ \begin{array}{l} u_j(t) = u_{L+j}(t) \\ \frac{du_j(t)}{dt} = \frac{du_{L+j}(t)}{dt} \end{array} \right. \text{ pour } j \in [1, \dots, L] \quad (2)$$

Continuous approach

X is the initial spatial variable and the distance of two adjacent cells at rest is Δx . We introduce the continuous normalized space variable $x = \frac{X}{\Delta x}$ and new continuous functions:

$$\left\{ \begin{array}{l} u(x, \tau) = u(x = j - 1, \tau), x \in [0, L], j = \{1, \dots, L+1\} \\ v(x, \tau) = v(x = j - 1, \tau), x \in [0, L], j = \{1, \dots, L+1\} \end{array} \right. \quad (3)$$

We use the new continuous coordinates:

$$\left\{ \begin{array}{l} U(x, t) = u(x, t) \\ V(x, t) = u(x, t) - v(x, t) \end{array} \right. \quad (4)$$

and applying change of variables $\tau = \omega t = \sqrt{\frac{k_1}{m_1}}t$, $\varepsilon\Lambda = \frac{k_3}{k_1}$, $\varepsilon\chi_1 = \frac{c_1}{\sqrt{k_1 m_1}}$, $\varepsilon\chi_2 = \frac{c_2}{\sqrt{k_1 m_1}}$, $\varepsilon f_j = \frac{F_j}{k_1}$ and $\mu = \frac{\Omega}{\omega}$, continuous expression of system 1 is:

$$\begin{cases} \frac{\partial^2 U}{\partial \tau^2}(x, \tau) - \frac{\partial^2 U}{\partial x^2}(x, \tau) + \varepsilon\Lambda V^3(x, \tau) - \varepsilon\chi_1 \frac{\partial}{\partial \tau} \frac{\partial^2 U}{\partial x^2}(x, \tau) + \varepsilon\chi_2 \frac{\partial}{\partial \tau} V(x, \tau) \\ = \varepsilon f(x) \sin(\mu\tau) \\ \frac{d^2(U - V)}{d\tau^2}(x, \tau) - \Lambda V^3(x, \tau) - \chi_2 \frac{\partial V}{\partial \tau}(x, \tau) = 0 \end{cases} \quad (5)$$

The study of the linearized system leads to the dispersion equation of the system. We consider a 1 : 3 internal resonance and we define:

$$\begin{cases} U(x, \tau) = p_1(\tau) \cos(\omega_1 x + \Theta_1) + p_3(\tau) \cos(\omega_3 x + \Theta_3) \\ V(x, \tau) = q_1(\tau) \cos(\omega_1 x + \Theta_1) + q_3(\tau) \cos(\omega_3 x + \Theta_3) \end{cases} \quad \omega_k = \frac{2k\pi}{L}, k \in [1, \dots, L] \quad (6)$$

Fast and slow dynamics study

In order to detect the different dynamics of the system, multiple scale method [3] is applied. Modal projection allows to obtain different set of governing equations from the continuous Eq.5 and asymptotic responses of the system are considered [4]. Detection of fast dynamics [5] leads to the determination of the two SIMs associated to projected system on the first and third mode. Example of SIM obtain from projection on first mode is plotted in Fig.2 from two different angles, where N_1 stands for associated amplitude of the outer mass for first mode and M_1 and M_3 stand for associated amplitudes of the inner mass for first and third modes respectively. Analytical SIM is plotted in blue while numerical integration using Runge Kutta is plotted in red. Slow dynamics study at the order ε^1 allows to determine singular and

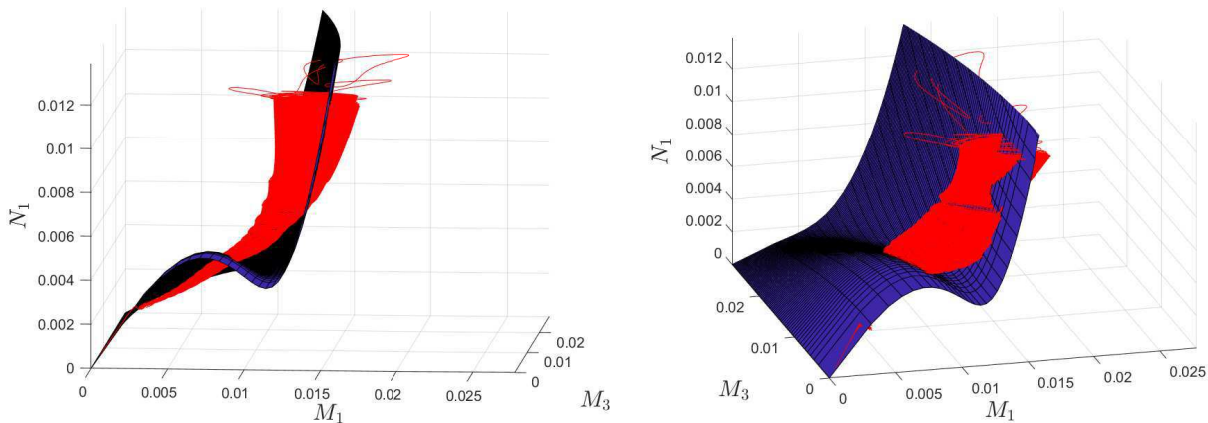

Figure 2: Multiangle representation of the SIM obtained after projection on first mode for free system with initial deformation.

equilibrium points. These points lead to the prediction of periodic and quasi-periodic behaviors. Study can be generalized for the 1 : k resonance.

Nonlinear dynamics of a resiliently propped cantilevered beam with a tip mass

M. Reza Talebi Bidhendi*, A. Srikantha Phani*

*Department of Mechanical Engineering, University of British Columbia, Vancouver, Canada

Summary. A practical friction control application in railway industry lead us to consider a cantilever beam with a tip mass and a spring support— a problem least studied in the literature from nonlinear dynamics perspective. We study the harmonically forced nonlinear dynamic response of this prototypical system using a reduced two degree of freedom model and compare its bifurcation characteristics, computed by AUTO, with that of the full system. The tip spring couples the first two flexural modes through a length dependent kinematic nonlinearity and brings their frequency ratio to nearly 2:1. We find (a) the reduced order model is adequate to understand the first bifurcation (pitchfork) and the subsequent Hopf bifurcation and (b) The threshold force for the nonlinear response grows with the initial length of the spring.

Problem statement

Cantilevered beam with tip mass is a canonical problem extensively studied under the tip excitation and under the base excitation [1]. Nonetheless, the present problem of an end excited cantilevered beam with a tip mass mounted on an external elastic support has not received attention, and we are led to it through a friction control application in railways [2, 3]. Similar situations can arise in the vibration energy harvesting, vibration mitigation, and sensing mechanisms [4]. Restoring force due to the elastic support has been shown to produce nonlinear terms of kinematic origin in the governing differential equations (DEs) [5, 6]. A similar situation arises in our problem, sketched in Fig.1(a). A long steel beam with a diameter of 4 mm and length of 254 mm is loaded by an aluminum tip mass ($70 \times 50 \times 20 \text{ mm}^3$) and a rigid rod of density of 7800 kg/m^3 and diameter of 4 mm and length of 40 mm. The external support at tip ($k_{ext} = 1000 \text{ N/m}$) with an initial length (L) imposes a two-to-one ratio between the first vertical (f_1) and the lateral (f_2) natural frequencies of the structure, $f_1 \approx 2f_2$. The linear modal parameters of the structure (damping ratio(ζ), stiffness(k), natural frequency (f)) without the addition of the external support are obtained using a finite element model as $k_1 = 317.98 \text{ N/m}$, $\zeta_1 = 0.097$, $f_1 = 6.12 \text{ Hz}$, $k_2 = 362.58 \text{ N/m}$, $\zeta_2 = 0.129$, $f_2 = 6.59 \text{ Hz}$. Indices one and two refer to the vertical and the lateral directions, respectively. After the attachment of the elastic support to the structure, the vertical linear natural frequency becomes $f_1 = 12.46 \text{ Hz}$ while the other linear modal parameters do not change. Using the linear modal properties of the structure, a minimal model as shown in Fig.1(b) can be identified, with the governing equations:

$$\ddot{\tilde{y}} + 2\zeta_1\omega_1\dot{\tilde{y}} + \omega_1^2\tilde{y} + \frac{k_{ext}(1+\tilde{y})}{m_1}\left(1 - \frac{1}{\sqrt{(1+\tilde{y})^2 + \tilde{x}^2}}\right) = \frac{F}{m_1L}\cos(\Omega t) \quad (1)$$

$$\ddot{\tilde{x}} + 2\zeta_2\omega_2\dot{\tilde{x}} + \omega_2^2\tilde{x} + \frac{k_{ext}\tilde{x}}{m_2}\left(1 - \frac{1}{\sqrt{(1+\tilde{y})^2 + \tilde{x}^2}}\right) = 0 \quad (2)$$

where $\tilde{y} = y/L$, $\tilde{x} = x/L$, $\omega_i = \sqrt{k_i/m_i}$; $m_i, i = 1, 2$ are the masses; F is the excitation amplitude, and Ω is the excitation frequency. The above equations are solved numerically for non-zero initial conditions, and compared with the full-scale multi-body dynamics model in ADAMS software which accounts for all the modes of the structure, i.e., no modal truncation.

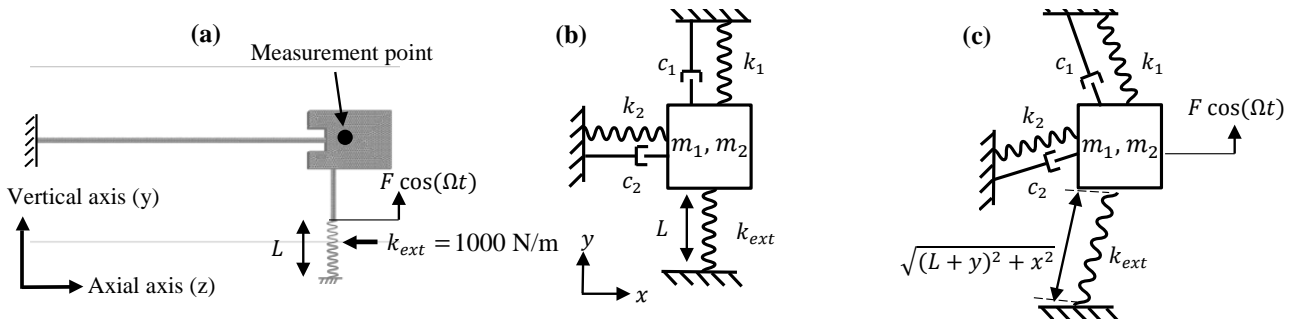

Figure 1: (a) Model of end excited cantilevered beam with tip mass mounted on the elastic support. (b) A minimal two-DOF model of the structure: $c_i = 4\pi\zeta_i m_i f_i$. (c) Deformed structure under the vertical excitation force. Note that the first vertical and lateral modes have almost the same natural frequencies ($f_1 \approx f_2$) without the external spring. The external support introduces kinematic nonlinearities and imposes 2:1 internal resonance in the structure ($f_1 \approx 2f_2$). Note that x and y are the lateral and the vertical axis, respectively.

Results

Force-response curves are calculated by fixing the excitation frequency (Ω) and increasing the excitation amplitude (F), and vice versa [7]. When the excitation frequency is close to the first vertical natural frequency, $\Omega \approx 2\pi f_1$, the first lateral mode is excited through a 2:1 resonance (pitchfork bifurcation) as shown in Fig.2(a). The vertical displacement decreases initially, in Fig.2(b), and then increases. A further increase in F will produce a Hopf bifurcation leading to the aperiodic response of the structure, see the dotted line in Fig.2(a). Fixing the excitation amplitude and sweeping the excitation frequency, Fig.2(d) and Fig.2(e), we can observe that there is a frequency interval over which the lateral mode is activated. Internal resonance property is evident through the frequency splitting in Fig.2(f). The sensitivity of the force threshold to the initial length of the external spring is shown in Fig.2(c), where we observe that the force amplitude divided by the length remains constant, for the two lengths shown. Note that Fig.2(c) is a magnified version of Fig.2(a) near the onset of first bifurcation. We note that while the reduced order model is adequate for $L = 0.5 \text{ mm}$, discrepancies exist for $L = 2.5 \text{ mm}$, indicating the limit of the reduced model.

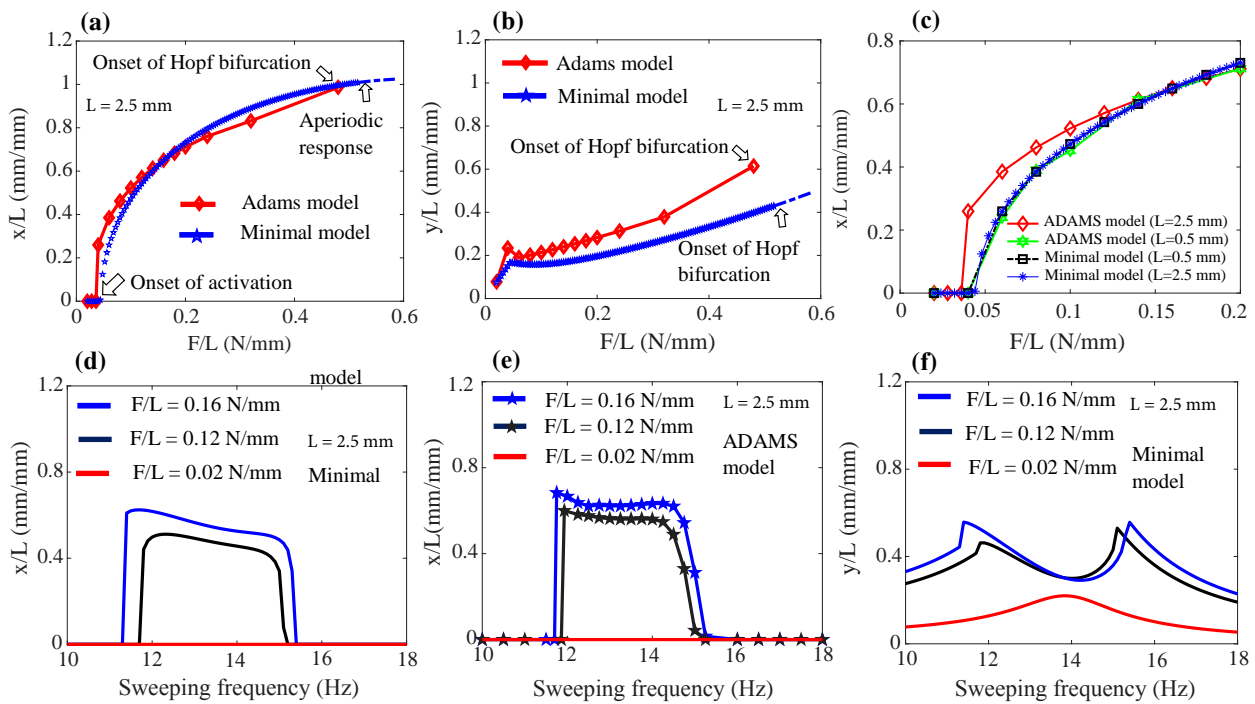

Figure 2: (a) Force-response curve of the lateral response with $\Omega = 2\pi \times 12 \text{ Hz}$. (b) Force-response curve of the vertical response with $\Omega = 2\pi \times 12 \text{ Hz}$. (c) Sensitivity of the force threshold to the initial length of the external spring. (d) Lateral response of the minimal model due to the different excitation levels and frequencies. (e) Lateral response of the Adams model for the different excitation levels and frequencies. (f) Vertical response of the minimal model due to the different excitation levels and frequencies.

Conclusions

The elastically propped cantilever beam with a tip mass, subjected to harmonic excitation, shows pitchfork and Hopf bifurcations when the forcing amplitude is increased at a fixed frequency, and vice versa. The 2:1 internal resonance between two flexural modes with displacements in mutually orthogonal planes are superficially similar to Froude oscillations of a ship, but without saturation since we retain all nonlinear terms here, albeit in the first two modes in our reduced model. We find (a) the reduced order model is adequate to understand the first bifurcation (pitchfork) and the subsequent Hopf bifurcation and (b) initial length of the spring acts as a design tuning parameter to activate the first lateral mode.

Passive control of galloping vibrations by means nonlinear energy sinks

José Augusto Ignácio da Silva[†], Leonardo Sanches^{*} and Flávio Donizeti Marques[†]

[†] *School of Engineering of São Carlos, University of São Paulo, Brazil*

^{*} *Univesité de Toulouse, Institut Clement Ader - ISAE - Supaero, France*

Summary. The present paper aims to analyze the passive control of a structure subject to aeroelastic galloping by using nonlinear energy sinks (NES). A lumped parameter model is adopted, and a steady approach to the aerodynamic loads is considered. A pure cubic stiffness NES is placed inside the prismatic structure. A mathematical model is established, and the Method of Multiple Scales (MMS) is used to build analytical solutions. Bifurcation diagrams can be drawn with these solutions, which allows characterizing the suppression regimes induced by the absorber. The use of coupled NES seems reasonable to passively control the nonlinear aeroelastic galloping.

Introduction

The galloping phenomenon comprises one of several engineering problems ruled by flow-induced vibrations. This phenomenon is essentially nonlinear and characterized by a self-excited mechanism. Limit cycle oscillations (LCO) take place from a particular flow speed, highlighting the galloping bifurcation. These motions can present very large amplitude, leading to fatigue and failure of structural components [1]. In this way, the present paper aims to investigate the application of NES to passive control galloping vibrations. NES consists of a dynamic vibration absorber with nonlinear characteristics that works according with the Target Energy Transfer (TET) theory [2]. In particular to this work, a pure cubic NES stiffness is considered and placed inside a prismatic body subjected to galloping excitation. A steady and nonlinear approach to the aerodynamic loads is considered [1]. Asymptotic analysis is carried out using MMS. The built analytical solutions allow accessing the amplitude and stability of the system's motion with efficiency. Bifurcation diagrams can be generated with these solutions, and the suppression regimes induced by NES can be characterized.

Mathematical Modeling and Asymptotic Analysis with MMS

The model assumes a rigid square prism with mass m , height h , and is supported by a suspension with linear stiffness k and viscous damper coefficient c . An NES is embedded inside of the structure to promote a passive control effect, which consists of an oscillator with a small mass m_n linked to the prism by a pure cubic spring (k_n), and a linear viscous damper (c_n). The motion of prism and NES masses are accounted for by the $y(t)$ and $y_n(t)$ degrees of freedom in the y -direction. Figure 1 presents an illustration of a system immersed in airflow with velocity U aligned to the x -direction, promoting the motion only in the y -direction.

Figure 1: Sprung prism coupled with NES to passive control of the galloping phenomenon.

The governing system's equations of motion are given by:

$$\begin{cases} (1 - \epsilon \hat{\mu}_n) \eta''(\tau) + \eta(\tau) = \epsilon \hat{n} [\mathcal{A}_1 \eta'(\tau) - \mathcal{A}_3 \eta'^3(\tau)] - \epsilon \hat{\lambda}_n v'(\tau) - \epsilon \hat{\gamma}_n v^3(\tau) \\ \epsilon \hat{\mu}_n v''(\tau) + \hat{\lambda}_n v'(\tau) + \epsilon \hat{\gamma}_n v^3(\tau) = \epsilon \hat{\mu}_n \eta''(\tau) \end{cases} \quad (1)$$

with $\tau = \omega_n t$, $(\cdot)' = d(\cdot)/d\tau$, $(\cdot)'' = d^2(\cdot)/d\tau^2$, $\eta(\tau) = y(\tau)/h$, $\omega_n = \sqrt{k/m}$, $v(\tau) = (y(\tau) - y_n(\tau))/h$, $\mu_n = m_n/m$, $\gamma_n = k_n h^2/(m \omega_n^2)$, $\lambda_n = c_n/(m \omega_n)$, $n = \rho h^2/(2m)$, $V = U/(\omega_n h)$, $\mathcal{A}_1 = V C_f^l - 2\zeta/n$, $\mathcal{A}_3 = C_f^c/V$, $\zeta = c/(2m \omega_n)$, and $(\cdot) = (\cdot)/\epsilon$.

The MMS assumes the following expansion of the generalized coordinates, $\eta(\tau) = \eta_0(\tau_0, \tau_1) + \epsilon \eta_1(\tau_0, \tau_1)$ and $v(\tau) = v_0(\tau_0, \tau_1) + \epsilon v_1(\tau_0, \tau_1)$ [3]. Replacing this result in Eq. (1), and collecting the common terms with ϵ^0 and ϵ , two set of equations are obtained. The set ϵ^0 comprises only the equivalent linear undamped motion of the prism, and its solution can be written by $\eta_0(\tau_0, \tau_1) = C(\tau_1) e^{j\tau_0} + [c.c.]$, where $C(\tau_1)$ is the prism complex-slowly amplitude, $j = \sqrt{-1}$ is the imaginary unity and $[c.c.]$ referees to the complex conjugate. Similarly, the NES motion is assumed to be $v_0(\tau_0, \tau_1) = B(\tau_1) e^{j\tau_0} + [c.c.]$, with $B(\tau_1)$ being the NES complex-slowly amplitude [3]. The ϵ -order problem can be solved by using the previous expressions, and considering $C = (1/2) a e^{j\alpha}$, $B(\tau_1) = (1/2) b e^{j\beta}$. Thence, NES motion results in:

$$X_a = \theta_1 X_b + \theta_2 X_b^2 + \theta_3 X_b^3 \quad (2)$$

where $X_a = a^2$, $X_b = b^2$, $\theta_1 = 1 + \hat{\lambda}_n^2/\hat{\mu}_n^2$, $\theta_2 = -\frac{3}{2}(\hat{\gamma}_n/\hat{\mu}_n)$, and $\theta_3 = \frac{9}{16}(\hat{\gamma}_n^2/\hat{\mu}_n^2)$. Equation (2) defines the Slow Invariant Manifold (SIM) structure, two folding points can be characterized, and a maximum NES critical damping can be defined by $\lambda_{n_{crit}} = (\sqrt{3}/3)\mu_n$ (i.e., $\lambda_n \leq \lambda_{n_{crit}}$) [3]. Similarly, the equation that describes the prism motion can be combined with Eq. (2), and for the steady state condition the equilibrium points can be calculated by solving the following polynomial equation:

$$X_b^5 + \Gamma_1 X_b^4 + \Gamma_2 X_b^3 + \Gamma_3 X_b^2 + \Gamma_4 X_b + \Gamma_5 = 0, \quad (3)$$

with $\Gamma_1 = \frac{2\theta_2}{\theta_3}$, $\Gamma_2 = \frac{2\theta_1}{\theta_3} + \frac{\theta_2^2}{\theta_3^2}$, $\Gamma_3 = \frac{2\theta_1\theta_2}{\theta_3^2} + \frac{\psi_1}{\psi_2\theta_3}$, $\Gamma_4 = \frac{\theta_1^2}{\theta_3^2} + \frac{\theta_2\psi_1}{\theta_3^2\psi_2}$, $\Gamma_5 = \frac{(\theta_1\psi_1-1)}{\psi_2\theta_3^2}$, $\psi_1 = \frac{\hat{n}A_1}{\lambda_n}$ and $\psi_2 = -\frac{3\hat{n}A_3}{4\lambda_n}$. Considering the airspeed with parameter, bifurcations diagrams can be draft based on the solutions of Eqs. (2), (3), allowing to access both amplitude and stability of the motions. These diagrams are essential to characterize the suppression regime responses induced by NES and yours boundaries.

Results and Discussions

The system under study was analyzed considering the following parameters: $n = 4.3 \times 10^{-4}$, $\zeta = 1.96 \times 10^{-3}$, $C_f^l = 2.69$, and $C_f^c = 168$ [1]. To validate the analytical approach, time integration results were obtained using the fourth-order Runge-Kutta method with a time step of a 10^{-2} seconds. For each simulated case, an arbitrary initial condition is used to find the steady state motions.

Figure 2(a) compares analytical and numerical bifurcations (\diamond , \times , \blacksquare) of the system considering $\mu_n = 0.05$, $\gamma_n = 1.5$ and $\lambda_n = 0.03\lambda_{n_{crit}}$, where a good agreement between the results is observed. Furthermore, a new bifurcation behavior is induced in the structure by its dynamic interaction with the NES. Unstable branches take place, and new response regimes are detected along the non-linear galloping boundary. The characterization of these suppression regimes is depicted in Figure 2(b). The first one, referred to as CR, comprises a complete suppression of phenomenon. The second regime (PS) occurs when partial suppression is observed through stable LCOs with small amplitudes. The third regime (SMR) is distinguished by competing two different response regimes driven by the initial condition. When small perturbations are imposed, the system exhibits strongly modulated responses (SMR) [2] with lower amplitudes. In contrast, for higher levels, the system jumps to LCOs with larger amplitudes (WS), which results in a weak suppression performance. The upper unstable branch depicts the basin of attraction that delimits these two different behaviors.

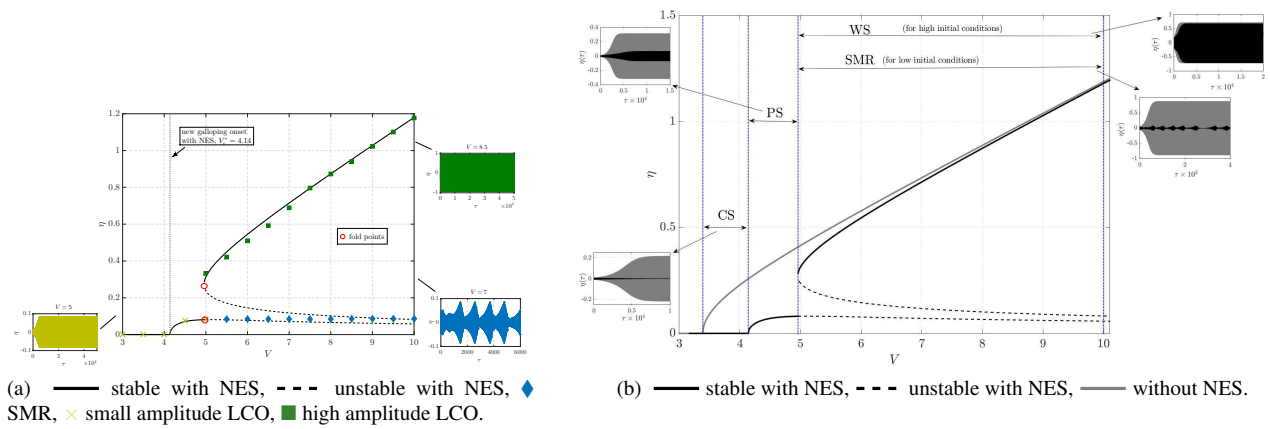

Figure 2: (a) Validation of MMS-based bifurcation analysis of the system, (b) Characterization of suppression regimes.

Conclusions

The paper investigated the application of an NES with pure cubic stiffness to the passive control of the nonlinear aeroelastic galloping. A benchmark lumped parameter model is used, and the aerodynamic loads are calculated through a nonlinear steady approach. Analytical treatments are carried out based on the MMS, and the solutions are numerically validated. Results comprise a study of the impact of the NES inclusion to the structure and the influence on the nonlinear response in post-galloping with NES. Suppression regimes are characterized based on the bifurcation diagrams in the function of responses induced by NES. To use this type of vibration absorber seems reasonable to control the galloping phenomenon. Further investigation will comprehensively analyze the effect of NES parameters on the boundaries of suppression regimes induced by it and establish the relationship between these regimes and the TET phenomenon.

Summary. Nonlinear mechanical resonators combined with piezoelectric transducers are widely used in vibration energy harvesting applications for their broadband behavior. Such nonlinear vibration energy harvesters may exhibit various orbits for a given excitation, each of them being associated with a given harvested power. Thus, in order to optimize the harvested power, it is crucial to find ways to jump from low power orbits to high power orbits, and to remain on them as long as possible. In this paper, we present a mathematical framework to test and study how effective is a given orbit jump strategy. Starting from the analytical model of a Duffing-type nonlinear mechanical energy harvester, we describe some of its dynamics, and we introduce a command function that can be used to impact the dynamics of the harvester. Thereafter, we will test and evaluate a set of command functions based on sinusoidal current injection.

Introduction

Vibrations are ubiquitous in nature and their energy can be scavenged via vibration energy harvesters (VEH) to replace batteries in low power electronic systems [1]. Nonlinear VEH have attracted the energy harvesting community because of their frequency behaviors that allow to harvest a relatively large power even if the vibration frequency shifts away from the harvester resonant frequency (for review, see e.g. [2]). However, such nonlinear VEH exhibit complex dynamical behaviors. Indeed, for a given excitation, they can oscillate on several orbits, often very different [3]. It is then necessary to find ways to stay in higher energy orbits to maximize the harvested power. For instance, [4] and [5] proposed to dynamically modify the buckling level of the VEH. [6] and [7] proposed to implement such orbit jump with a perturbation of the electrical load or with electrical impulses, respectively. While there are many existing orbit jump strategies in the literature [4, 5, 6, 7], there is a lack of mathematical framework that would allow their comparison in a unified way. In this paper, we introduce the nonlinear VEH model with an additional command function that allows to test and evaluate electrically-induced orbit jump strategies. The proposed modeling framework will allow to evaluate orbit jump strategies based on two major criteria: their potential for orbit jump and their energy consumption.

Electromechanical dynamics nonlinear vibration energy harvesters

A vibration energy harvester usually involves 3 sub-systems: a mechanical resonator, an electronic energy extraction circuit and a storage unit. In this study, we focus on the Duffing-type resonator and the influence of the extraction circuit on its dynamical behavior. A complete scheme of the system is given in Fig.1(a). The resonator consists of buckled steel beams on which a proof mass M is fixed. A piezoelectric transducer is used for mechanical-to-electrical energy conversion. It has a force factor α and a blocked capacitance C_p . The piezoelectric element is connected to the extraction circuit drawing an electrical current i . The piezoelectric voltage is noted v . The harvested power corresponds to the one collected in the electronic extraction circuit connected to the piezoelectric element.

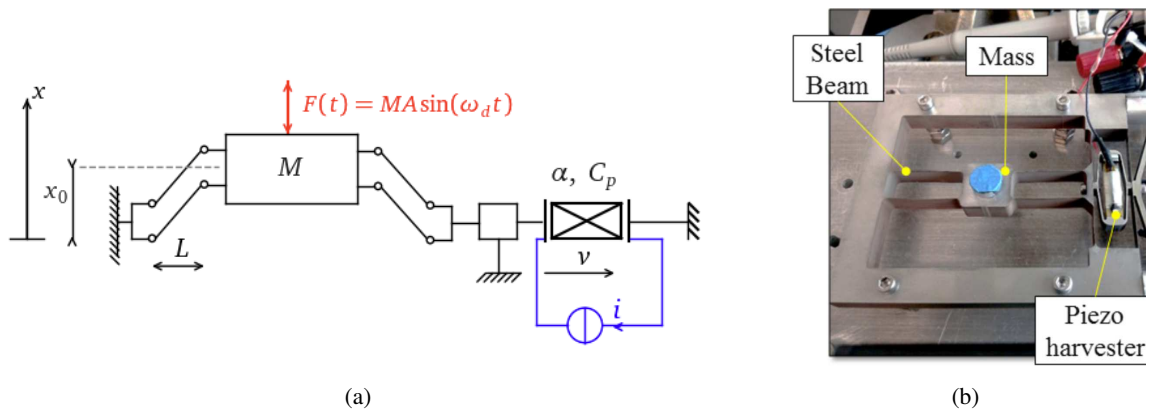

Figure 1: (a) Schematic of the vibration energy harvester (b). Experimental prototype of a Duffing-type VEH [8].

The electromechanical dynamics of this nonlinear VEH can be modeled as follows:

$$\begin{cases} \ddot{x} = -\frac{\omega_0^2}{2} \left(\frac{x^2}{x_0^2} - 1 \right) x - \frac{\omega_0}{Q} \dot{x} - 2\frac{\alpha}{ML} xv + A \sin(2\pi f_d t) \\ \dot{v} = 2\frac{\alpha}{LC_p} x \dot{x} - \frac{1}{C_p} i \end{cases} \quad (1)$$

where x is the position of the mass M . The resonator presents two stable positions at $x = \pm x_0$ (each corresponding to a

local minimum of the elastic potential energy and associated with a potential well). From the linearized behavior obtained from small oscillations around $x \approx x_0$, a natural angular frequency ω_0 and a mechanical quality factor $Q > 0$ can be found. The resonator is submitted to a sinusoidal ambient acceleration of amplitude A and frequency f_d . The nonlinear ordinary differential equations (1) were numerically solved for different vibration frequency values f_d and from different initial states $\mathbf{X}(0) = (x^0 \ \dot{x}^0 \ v^0)^\top$. Each simulation was performed until convergence to a periodic or a chaotic regime. The orbits were deduced and classified by type (periodic or chaotic) and, when periodic, by their harmonic or subharmonic order. These subharmonic orbits correspond to the case where the mass oscillates at a frequency which is a submultiple of the vibration frequency. An orbit is high when the mass oscillates around the two stable equilibrium positions. On the other hand, an orbit is low when the mass oscillates around one of the two stable equilibrium positions. In this paper, we take the following notations: H1H (resp. H1L) for a first order high (resp. low) harmonic and SH5H (resp. SH5L) for a fifth order high (resp. low) subharmonic. In the case where the electronic circuit is a simple resistor $R = 7.8 \text{ k}\Omega$, the current is given by $i = v/R$. The average harvested power corresponds to the power dissipated in the resistor and can be computed by calculating the mean value of $v \cdot i = v^2/R$.

Figure 2: Basins of attraction for $f_d = 50 \text{ Hz}$ with a grid of 400 000 starting points [9].

The basins of attraction of the bistable (for $f_d = 50 \text{ Hz}$) are shown in Fig.2. As seen in Fig.2, for a given vibration frequency and for some initial conditions, one can start on a low energy orbit. For example, at $f_d = 50 \text{ Hz}$ the system can start on H1L, SH3L, SH5H, SH3H or H1H (best case), and when the system stabilizes on H1L it is interesting to perturb the system by means of an orbit jump strategy in order to converge to a highest orbit (SH3L, SH5H, SH3H or H1H). In Fig.3, we can observe that multiple orbits of various powers coexist for a given vibration frequency. The longer one stays on highest power orbits, the better the performance. The goal of our study is to define a command function i_u that enables to jump from low power orbits to high power orbits.¹

Dynamics adjustment by current injection

One way to induce such orbit jump is to dynamically modify one of the state-variable of the electromechanical system (i.e., x , \dot{x} or v). From a practical point of view, it is much easier to implement a change of v than a change of x or \dot{x} , thanks to an adaptive electrical circuit. To modify the piezoelectric voltage v and to avoid any voltage discontinuities, we add an injection current i_u to the load current i_L . In this case, the total current flowing in the piezoelectric material i is given by $i = i_L - i_u$. We then end up with an optimal control problem where the output to control is the orbit and the command function is the injected current $i_u : t \mapsto \mathbb{R}$ which is assumed to be a continuous piecewise function.

¹In this analysis the jump from chaotic orbits (present around 25 Hz, see Fig.3) will not be discussed.

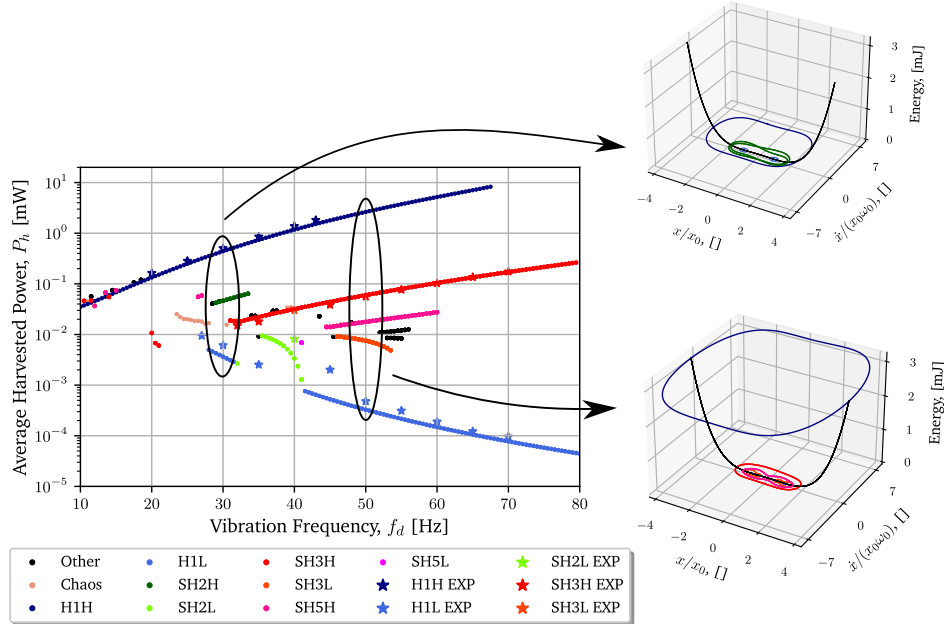

Figure 3: Simulated average harvested power as a function of the vibration frequency f_d for the different existing orbits [9].

$$\begin{cases} \ddot{x} = -\frac{\omega_0^2}{2} \left(\frac{x^2}{x_0^2} - 1 \right) x - \frac{\omega_0}{Q} \dot{x} - 2\frac{\alpha}{ML} xv + A \sin(2\pi f_d t) \\ \dot{v} = 2\frac{\alpha}{LC_p} x\dot{x} - \frac{1}{C_p} i_L + \frac{1}{C_p} i_u \\ \dot{E} = \frac{2\alpha}{L} x\dot{x}v - C_p v\dot{v} = v \cdot \dot{i} = v \cdot i_L - v \cdot i_u \\ \mathbf{X}(0) = (x^0 \quad \dot{x}^0 \quad v^0)^\top \end{cases} \quad (2)$$

Where E is the total harvested energy. The instantaneous harvested power \dot{E} can be calculated from the power consumption of the load $v \cdot i_L \geq 0$ minus the injected power $v \cdot i_u$. If we control the injected current function i_u , we can change the trajectory $t \mapsto \mathbf{X}(t)$ by punctually modifying the piezoelectric voltage v . Starting from this mathematical framework, the next section will present the analysis and evaluation of electrically-induced orbit jump strategies.

Results and discussion

We define a command function that consists in injecting a sinusoidal current at a certain time t_0 . This injected current presents an amplitude I_e , a phase shift ψ_e with respect to the ambient excitation and an angular frequency ω_e . Moreover, the current is injected for a duration Δt , such as the orbit jump stops at $t_0 + \Delta t$. Since the excitation of the system is harmonic, we define dimensionless parameters k_{t_0} and $k_{\Delta t}$ as follows: $k_{t_0} = t_0/T_d$ and $k_{\Delta t} = \Delta t/T_d$. Therefore, there are five influence orbit jump parameters ($k_{t_0}, k_{\Delta t}, I_e, \psi_e, \omega_e$) to study.

$$i_u(t) = \begin{cases} I_e \sin(\omega_e t + \psi_e), & \text{for } t/T_d \in [k_{t_0}, k_{t_0} + k_{\Delta t}] \\ 0, & \text{otherwise} \end{cases} \quad (3)$$

To analyze the effectiveness of this orbit jump technique consisting in the injection of current (3), we start on a low energy orbit. Thereafter, we simulate different combinations of $(k_{t_0}, k_{\Delta t}, I_e, \psi_e, \omega_e)$ and analyze their influence on the dynamics of the harvester. Figure 4 presents an example of the orbit jump strategy for $f_d = 50$ Hz with arbitrary parameter values $(k_{t_0}, k_{\Delta t}, I_e, \psi_e, \omega_e) = (0.35, 2.5, 0.18, 1.6\pi, 2\omega_d)$. Figure 4(a) shows the corresponding injected current waveform (3) during the first few periods and after 1 000 periods. At the beginning of the simulation, the system oscillates on the lowest existing orbit (H1L) during 5 vibration periods T_d . For $t = (5 + k_{t_0})T_d = 5.35T_d$, the orbit jump strategy using the injected current described in Fig.4(a) is applied for a duration of $\Delta t = 2.5T_d$. Fig.4(b,c) show that there is no transient and the VEH converges almost directly to the H1H steady state (green and red curves). This convergence is similar to the one obtained with a buckling level modification (see [4, 5]).

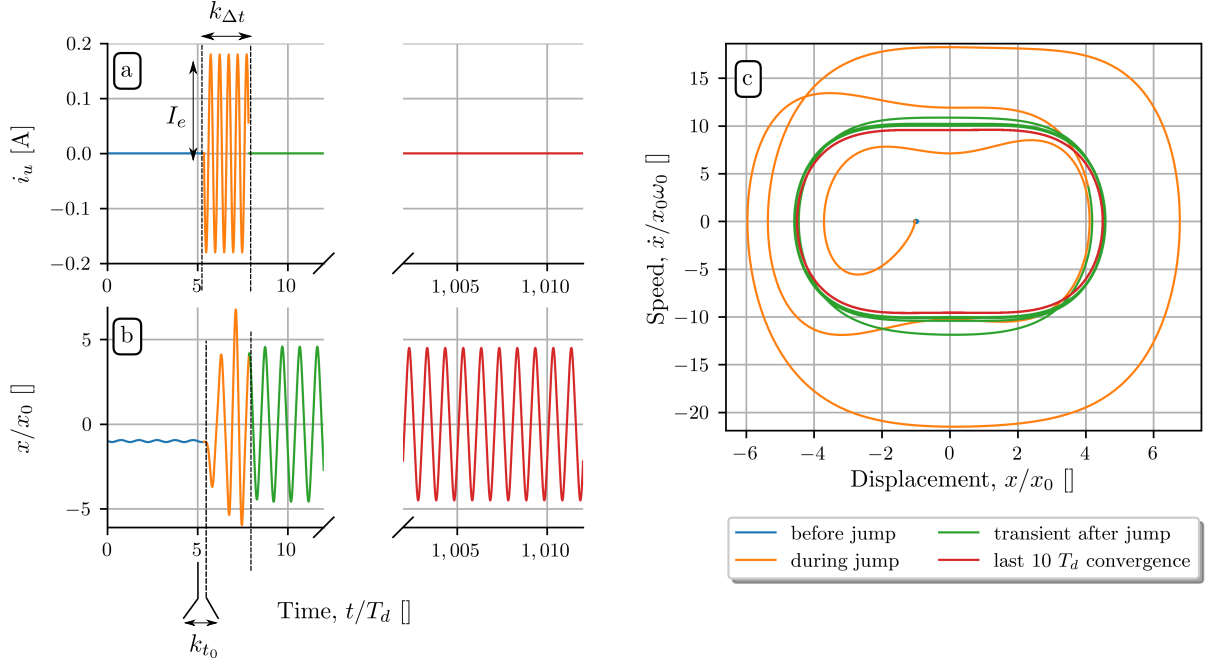

Figure 4: (a) Sinusoidal injected current (3) as a function of time with parameter values $(k_{t_0}, k_{\Delta t}, I_e, \psi_e, \omega_e) = (0.35, 2.5, 0.18, 1.6\pi, 2\omega_d)$, (b) displacement as a function of time for $f_d = 50$ Hz before (H1L in blue), during (in orange) and after (in green and red) the orbit jump. (c) Trajectory in the dimensionless phase plane $(x/x_0, \dot{x}/x_0\omega_0)$.

The invested energy during the orbit jump E_{inv} (4) consists in the integral of the instantaneous harvested power subtracted from the instantaneous injected power over the jump duration. (5) computes total injected energy during the orbit jump, considering both the current flowing in the piezoelectric material and the current flowing in the load R .

$$E_{inv} = \int_{t_0}^{t_0+\Delta t} [v(t) \cdot i_u(t) - v(t) \cdot i_L(t)] dt \quad (4)$$

$$E_{inj} = \int_{t_0}^{t_0+\Delta t} v(t) \cdot i_u(t) dt = E_{inv} + \int_{t_0}^{t_0+\Delta t} v(t) \cdot i_L(t) dt \quad (5)$$

Thereafter, an evolutionary algorithm inspired from natural selecting process [10, 11] is used for investigating optimal orbit jump parameters $(k_{t_0}, k_{\Delta t}, I_e, \psi_e, \omega_e)$ that belong to $[0, 1] \times [0, 50] \times [0, 0.2] \times [0, 2\pi] \times [0, 4\omega_0]$ where $\omega_0 = 121 \text{ rad.s}^{-1}$. Using the glossary of evolutionary strategies, the *population* is an orbit jump parameters (*individuals*) collection, the *fitness* corresponds to the objective function value that is the total injected energy (5) under the constraint that individuals have converged to the targeted orbit (of higher energy than the initial orbit). The best 10% of individuals are selected for the next generation and the classic operations of crossing (single point crossover) and mutation are applied. By means of evolutionary strategy, optimum orbit jump parameters values are obtained at 50 Hz: $(k_{t_0}^{\text{opt}}, k_{\Delta t}^{\text{opt}}, I_e^{\text{opt}}, \psi_e^{\text{opt}}, \omega_e^{\text{opt}}) = (0.80, 2.08, 0.04, 2.49, 415.34)$.

Running simulations with identical initial condition $\mathbf{X}(0)$ that belongs to the basin of attraction of the H1L at 50 Hz and taking $(k_{t_0}, k_{\Delta t}, I_e, \psi_e, \omega_e)$ in $\{k_{t_0}^{\text{opt}}\} \times \{k_{\Delta t}^{\text{opt}}\} \times [0, 0.2] \times [0, 2\pi] \times \{\omega_e^{\text{opt}}\}$ gives Fig.5 scatter plot $(\psi_e/2\pi, I_e)$. Note that, if the injected current amplitude I_e is almost zero, the injection of current is too low and the system remains stuck on the initial orbit H1L (light blue area in the bottom of Fig.5). To jump from H1L to SH3H (resp. H1H), it is necessary to consider the parameter values that are associated with red (resp. dark blue) areas in Fig.5 (for example, area in the upper right (resp. in the middle left)). Arrows in Fig.5 give examples of parameters combinations (materialized by stars) assuring jump from H1L to H1H, SH3H and SH3L, respectively. Generally, the injected current amplitude increases with the energy level of the targeted orbit. For example, in order to reach H1H when starting from H1L, the value of I_e needs to be higher than those to reach SH3L or SH5H.

Figure 6 presents this optimal orbit jump solution parameters obtained by using the aforementioned algorithm. Figure 6(a) shows that the injected current is applied on a relatively short instant. Note that the injection of current is stopped when the VEh is in the neighbourhood of the basin of attraction of H1H.

For each initial orbit, optimum orbit jump parameters that allow to reach the highest energy orbit are found by means of aforementioned algorithm. Table 1 gives invested energy values associated with optimal orbit jump parameters for jumping from a given initial orbit to a given targeted orbit for $f_d = 47$ Hz. For example, invested energy required to jump from H1L to H1H is 2.54 mJ. Table 1 underlines, for some frequencies, the interest of jumping in “ k -times” ($k > 1$, integer), i.e., in k low cost jumps. As a matter of example, for jumping from H1L to H1H, one might imagine jumping from H1L to SH3L, to SH5H, to SH3H, then to H1H. The sum of the invested energies associated to each step is equal to 1.79 mJ, which is lower than the invested energy for jumping directly from H1L to H1H (2.54 mJ).

Figure 5: Map $(k_{t_0}^{\text{opt}}, k_{\Delta t}^{\text{opt}}, I_e, \psi_e/2\pi, \omega_e^{\text{opt}})$ starting from H1L for $f_d = 50$ Hz. Arrows from left to right illustrate candidate values for $(\psi_e/2\pi, I_e)$ in order to jump from H1L to SH3L, from H1L to H1H or H1L to SH3H. The map has been computed with 50 000 quintuplets $(k_{t_0}^{\text{opt}}, k_{\Delta t}^{\text{opt}}, I_e, \psi_e, \omega_e^{\text{opt}})$ where $(I_e, \psi_e) \in [0, 0.2] \times [0, 2\pi]$.

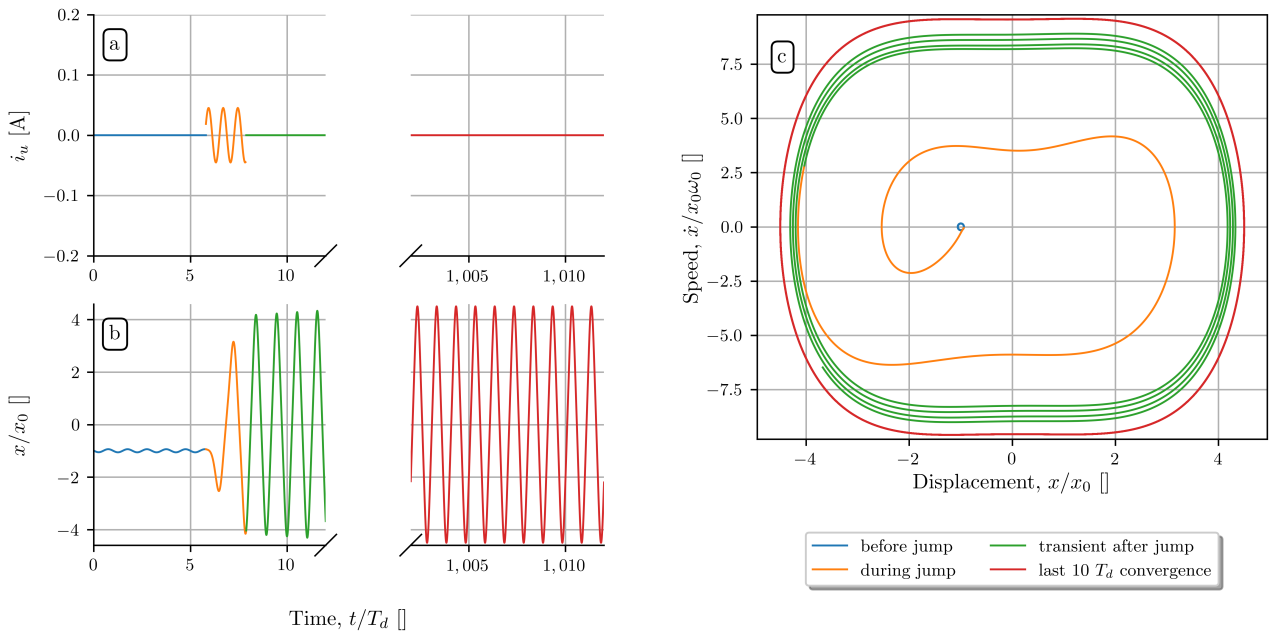

Figure 6: (a) Sinusoidal injected current (3) as a function of time with optimal parameter values $(k_{t_0}^{\text{opt}}, k_{\Delta t}^{\text{opt}}, I_e^{\text{opt}}, \psi_e^{\text{opt}}, \omega_e^{\text{opt}}) = (0.80, 2.08, 0.04, 2.49, 415.34)$. (b) Displacement as a function of time for $f_d = 50$ Hz before (H1L in blue), during (in orange) and after (in green and red) the optimized orbit jump. (c) Trajectory in the dimensionless phase plane $(x/x_0, \dot{x}/x_0\omega_0)$.

Figure 7 shows the optimal invested energy required to jump from the lowest existing orbit to H1H (resp. SH3H) as a function of the vibration frequency. Note that there are few values of the invested energy required for jumping on the two targeted orbits (H1H and SH3H) for vibration frequencies below 25 Hz because there is almost only H1H in this vibration frequency range. Figure 7 shows that the invested energy increases with the vibration frequency². Moreover, this orbit jump strategy makes it possible to reach H1H from the lowest existing orbit until its cutoff frequency at 67 Hz. Note that, the optimal amplitude I_e^{opt} necessarily increases with the vibration frequency and the energy level of the targeted orbit.

²Indeed, the displacement of H1H becomes larger with the vibration frequency, which explains why the energy gap between H1H and H1L becomes wider [9].

Initial orbit \ Targeted orbit	SH3L	SH5H	SH3H	H1H
H1L	5.10^{-3}	1.10^{-2}	$3.7.10^{-2}$	2.54
SH3L	0	7.10^{-3}	$1.8.10^{-2}$	2.06
SH5H	/	0	3.10^{-2}	2.08
SH3H	/	/	0	1.75

Table 1: Optimal invested energy (4) (mJ) required to jump from an initial orbit (left column) to a targeted orbit (top row) for $f_d = 47$ Hz. Invested energy values for jumping from H1L to H1H with 4 intermediates jumps are colored in red while the invested energy for jumping from H1L to H1H in one time is colored in blue.

Figure 7: Evolution of the optimal invested energy required to jump from the lowest existing orbit to H1H (in blue) and those to jump from the lowest existing orbit to SH3H (in red) as a function of the vibration frequency.

Conclusion

In the present paper, we proposed a mathematical framework in order to analyze and evaluate electrically-induced orbit jump strategies. From this framework, we studied an orbit jump approach based on a sinusoidal injected current. By means of an evolutionary algorithm, the optimal set of parameters of this orbit jump approach has been determined. Among results of this analysis is that the optimal injection current that minimizes the injected energy is relatively short and stopped when the VEH is in the neighbourhood of the basin of attraction of the targeted orbit. Another insights is that, for some frequencies, the injected current consumes less energy to jump from a low energy orbit to a high energy orbit with multiple small jumps instead of a single large jump. In the future, the proposed framework could be used to find the optimal orbit jump strategy with a generic current waveform with many additional degrees of freedom.

Degradation at transition zones in railway tracks: 1-D and 2-D model comparison

Andrei B. Fărăgău*, Andrei V. Metrikine*, Karel N. van Dalen*

*Faculty of Civil Engineering and Geosciences, Delft University of Technology, Delft, the Netherlands

Summary. Transition zones in railway tracks are areas with considerable variation of track properties (i.e., foundation stiffness) encountered near structures such as bridges. Due to strong amplification of the railway track's response, transition zones are prone to rapid degradation. To study this degradation, researchers and engineers have developed models ranging from simple 1-D models (e.g., beam on Winkler foundation) to complex 3-D models with accurate geometry and material behaviour. This study compares a 1-D model to a 2-D one with the aim of assessing if the degradation patterns predicted by the more simplistic model are accurate. We choose a very simple geometry for the 2-D model such that the comparison is restricted to (mainly) the influence of the soil layer (present in the 2-D model) on the predicted degradation at transition zones; incorporating the soil layer makes the response of the supporting structure frequency and wavenumber dependent as well as non-local, characteristics which are not usually incorporated in 1-D models. Preliminary results show that the degradation predicted by the 1-D model is significantly larger than the one in the 2-D model.

Introduction

Transition zones in railway tracks are areas with significant variation of track properties (e.g., stiffness, mass, etc.) encountered near man-made structures such as bridges, tunnels or culverts. These zones require more frequent maintenance than the regular parts of the railway track, leading to high costs and reduced availability of the track. A substantial part of the maintenance performed in transition zones is concerned with restoring the vertical position of the track, which changes over time due to soil and ballast settlement.

To understand the settlement mechanisms at transition zones, researchers have developed a multitude of computational models. They range from 1-D models (e.g., beam on Winkler foundation) to 3-D finite element models (FEM) models with accurate geometry of the real scenario. For predictive purposes, the models with more accurate geometry are preferred; these predictive models are important and show reasonable agreement to measurements, especially due to their accurate geometry representation and material behaviour. However, their complexity makes it difficult to investigate specific mechanisms due to the multitude of phenomena simultaneously at play. That is why, for research focusing on individual mechanisms, the simpler models (e.g., 1-D models) are preferred. Nonetheless, the simplistic models may overlook important features that can render their results incorrect.

This study compares two such models, namely a 1-D and a 2-D model, in terms of degradation (after one load passage) with the purpose of judging if the results obtained with the simplified model are trustworthy. The 1-D model is composed of a beam on nonlinear and inhomogeneous Kelvin foundation and is described in [1] while the 2-D model consists of an infinite beam and a viscoelastic-continuum layer (i.e., soil) connected through a layer of nonlinear and inhomogeneous springs and dashpots (Figure 1). The layer of springs-dashpots represents the effective contribution of all components between the rail and soil (i.e., railpads, ballast and sub-ballast). In both models, the nonlinearity and inhomogeneity are located in the layer of springs-dashpots; the nonlinear behaviour of the springs models the compaction of ballast (Figure 1), while the inhomogeneity represents the transition zone. The 2-D model has a simple geometry such that the comparison is restricted to (mainly) the influence of the soil layer on the results; incorporating the soil layer makes the response of the supporting structure frequency and wavenumber dependent as well as non-local, characteristics which are not usually incorporated in 1-D models.

Figure 1: Model schematics: an infinite beam and an elastic-continuum layer connected through a layer of nonlinear and inhomogeneous springs and dashpots, acted upon by a moving constant load (left panel); Piecewise-linear constitutive law of the ballast (right panel).

Tuning the 1-D model

To compare the two models, the parameters of the 1-D model need to be tuned to the ones of the 2-D model. The tuning is performed for the steady-state response in each of the domains (open track and stiff zone) individually. Advanced algorithms have been developed to make the response of the 1-D model match well that of 2D/3D models (see [2]). However, this study aims to investigate if most of the models used in literature, which do not use a complex tuning technique, can predict a correct degradation pattern. Therefore, the tuning is done in a more standard manner. Firstly, the static track stiffness is matched in the two models. Secondly, the mass of the rail in the 1-D model is chosen such that the critical velocities are matched in the two models. Finally, the damping in the 1-D model is chosen based on engineering judgement; nonetheless, the damping in the 1-D model has been varied and for reasonable values it does not significantly affect the results.

Preliminary results

Figure 2 presents the degradation predicted by the two models after one load passage. For the 2-D model, there are two cases presented depending on how the nonlinear constitutive model is defined. Firstly, case A considers that the degradation is governed by the differential displacement between the beam and the top surface of the soil since the nonlinear constitutive model is only for ballast; this represents a realistic case. Secondly, case B assumes the degradation to be governed by the displacement of the beam only; this case is not representative of reality and is considered just for comparison reasons.

Preliminary results show that the degradation in the 1-D model is significantly higher than in the 2-D model (case A). The main reason is that the degradation in the 1-D model is based on the displacement of the beam, while in the 2-D model the degradation is dictated by the differential displacement between the beam and the top surface of the soil. Since the soil is considerably softer than the ballast, the differential settlement between the beam and the top surface of soil is small, leading to reduced degradation. When imposing the degradation to be dictated by the displacement of the beam only (case B), the degradation predicted by the two models becomes comparable in magnitude, although still larger in the 1-D model. This shows that the large difference in degradation (1-D vs 2-D case A) is caused by the springs in the 1-D model being fixed at the bottom while in the 2-D model (case A) the springs lay on a compliant medium.

Figure 2: Degradation predicted by the two models after 1 load passage for a load velocity of 85% the critical velocity; the location of the transition zone is marked by the yellow background.

Conclusions

This study compares two models (1-D and 2-D) representative of railway tracks at transition zones, in terms of the predicted ballast degradation with the purpose of judging if the results obtained with the simplified model are trustworthy. Preliminary results show that the degradation after one load passage predicted by the 1-D model is significantly larger than the one in the 2-D model. This is mainly caused by the springs in the 1-D model being fixed at the bottom while in the 2-D model the springs lay on a compliant medium. The shortcoming of the simplified model considered here could be overcome by adopting a model with two beams connected by the nonlinear and inhomogeneous springs (representative for ballast compaction) and resting on Kelvin foundation. Finally, simplified models (beam on elastic foundation) potentially overestimate the predicted degradation at transition zones.

Summary. Recently, the concept of metamaterials, initially studied for electromagnetic applications has gained interest within a civil engineering context [1, 3]. It has been shown that periodic arrangement of resonators, referred to as unit cells, can provide beneficial properties in vibration absorption, within a specific range of frequencies, the so-called bandgap. In order to take advantage of the full potential these unique structures can offer, a wider breadth of the bandgap is pursued, while additionally shifting the lower bound to lower frequencies renders metamaterials appealing for civil engineering applications. One promising solution to this requirement is the use of nonlinear resonators, which form part of the metamaterial configuration. In the current work, periodic structures consisting of impact damper resonators are investigated, thus introducing a highly nonlinear behaviour. The performance of a single impact damper has already been investigated [4] and its dynamic response has been proven to be advantageous for vibration attenuation. Further exploiting this phenomenon, the current study is extended to multiple degree of freedom (MDOF) systems, which are investigated both numerically and analytically. The MDOF systems occur as concatenation of a finite number of impact damper unit cells. Several characteristics of the proposed configuration are explored as variable parameters for optimization purposes. For the assessment of the system's efficiency, different metrics are being studied, including the frequency response function and the total energy loss as a result of the metastructure contribution. The results confirm the potential of utilization of the metamaterial concept, building on impact phenomena, for vibration attenuation.

Introduction

A significant concern in large-scale civil structures lies in response under dynamic loading, e.g. earthquakes. For this reason, the research community has been constantly working on designing systems, which are able to ensure structural safety, by minimizing the effects of the excitation on the structure. Recently, a novel idea has begun to draw attention in civil engineering applications, building on the concept of metamaterials or metastructures. These are structures characterized by extraordinary filtering properties, attained as a result of diversified mechanisms, such as their microscopic geometry, periodic arrangement, etc [5]. When the frequency of the incoming excitation lies within the constructed filter limits, the propagation of motion is arrested, thus forming a “bandgap”. The challenge that arises, however, lies in the range of the bandgap as well as in the proper adjustment of the lower frequency threshold, which is essential in many engineering applications. In the current work, strong nonlinearities, in the form of impacts, are introduced, in order to address this challenge. Nonlinear attachments to the primary system are generally termed as nonlinear energy sinks (NES). There is extended research and literature in the field of NES, as for reference in the work of Vakakis et al. [4], which also investigates impact dampers as a nonlinear attachment from the non-smooth events point of view. Moreover, in the work of Ibrahim et al [2], analytical approximations of the dynamic behaviour of impacts are provided. Important is the contribution of Masri and colleagues on impact dampers, regarding their general motion [6], their stability analysis [7], as well as their dynamic response to random excitation [8]. Furthermore, the concept of impact dampers is closely associated with particle dampers. In fact, a lattice of several impact dampers can be considered to be a single particle damper. A detailed investigation on the latter, under random excitation, is provided in the work of Lu et al. [9].

Meta-impactor

The idea of the meta-impactor is inspired by the beneficial effect that a single impact damper can have on a structure, under dynamic loading [4]. The attempt is to protect a specific mass with the metamaterial configuration. The concept of the current work is based on the consecutive arrangement of impact damper unit cells (Figure 1). The unit cells consist of a rigid container, containing a laterally unconstrained mass, free to impact on the respective bounds. Furthermore, the resonators are connected elastically to each other, as well as to the protected mass on one end, and to a fixed support on the other. In the current study, the response of the system is investigated under input of a harmonic force F .

Figure 1: Metamaterial lattice configuration

Analysis

The response of the system is studied both numerically and analytically. As for the first part, every impact is analyzed as a non-smooth event, while the equations of motion are affected by a discontinuity. This approach provides results, which are directly linked to the specified parameters of each system (mass, stiffness, damping, etc.) and are restricted to discrete combinations of those parameters. Multiple analyses with varying parameters are carried out for optimization purposes, an example of which is shown in Figure 2. In order to better assess the behaviour of the metamaterial, an analytic parametric approach is pursued. For this reason, the non-smooth interaction between the container and the inner mass is approximated by a continuous highly-nonlinear function. In this setting, the analysis can be carried out parametrically, taking into consideration the variability of the system's characteristics.

Figure 2: Percentage of energy absorption of the total input energy at 1 Hz for a 2 unit cell lattice and varying masses/stiffness ratios

Conclusions

The purpose of this study is to evaluate the performance of metamaterial lattices, consisting of impact damper unit cells, for vibration mitigation. The assessment of the performance is determined, depending on the frequency response function of the system, as well as on the calculation of the total energy absorption. Furthermore, the results of the numerical and analytical procedures are compared, revealing consistency of the analytical approximation. This is particularly helpful for further simulations and subsequent analyses of the resulting dynamics. The concept of metamaterials is proven effective, given a proper design and optimization process, and is suited for shielding of structures from vibrations.

Dynamics of Piecewise Linear Mathieu Equation with Non-Zero Offset

K. R. Jayaprakash* and Yuli Starosvetsky**

*Discipline of Mechanical Engineering, Indian Institute of Technology Gandhinagar, Gujarat, India

**Faculty of Mechanical Engineering, Israel Institute of Technology-Technion, Haifa, Israel

Summary. The current work considers a piecewise linear Mathieu equation with the point of asymmetry being non-zero. The considered oscillator is essentially nonlinear and the primary objective of this study is to explore the regions of instabilities as a function of the excitation amplitude, frequency and interestingly the initial energy imposed on the oscillator. In this study we invoke energy-angle variables and the method of averaging to analytically describe the interesting energy dependent instability zones. We explore the instability zones in the vicinity of 1:1 parametric resonance. We show that the derived analytical model provides a fairly good first order approximation to the unstable regions emerging in the vicinity of 1:1 resonances and it is expected that the analytical method described is applicable to higher order resonances as well.

Introduction

Many computational and analytical attempts have been devoted to understanding of the complex dynamics of a 1DOF piecewise linear oscillator (PWLO) model subject to various types of excitations such as external and parametric forcing. Shaw and Holmes [1] have analysed semi-analytically the harmonically forced PWLO for the periodic orbits and their bifurcations. This study has been followed by Thompson et. al [2] who analysed numerically the subharmonic resonances, bifurcations and chaotic regimes of forced PWLO. Natsiavas [3] has considered the forced response of PWLO with bi-linear damping and successfully derived the relatively simple, semi-analytic solution for n-periodic orbits and analysed their stability. Using a similar approach, author has analysed the n-periodic response including stability analysis of PWLO incorporating the Van-der-Pol type damping [4]. Other works by Natsiavas et al. [5, 6] present the parametric excitation of piecewise linear oscillator as a typical model of gear backlash and asymmetric stiffness. A computational study by Chatterjee et al. [7] was performed on the model proposed by Natsiavas et al. [5] exploring the regions of instability. The current study dwells on the analytical description of these instability regions using asymptotic analysis. The resulting modulation equation provides a first order approximation of these instability boundaries in this class of systems and the approximations obtained by the considered method are found to be good in the case of sufficiently low excitation level.

Model and Analysis

Let us consider a piecewise linear (PWL) oscillator with a non-zero offset ($a > 0$) subject to a parametric excitation,

$$\ddot{q} + f(q) + \varepsilon P \cos(\Omega_e t) q = 0 \quad (1a)$$

$$f(q) = \begin{cases} q, & q < a \\ \delta^2 q + (1 - \delta^2)a, & q \geq a \end{cases} \quad (1b)$$

The above equation is scaled such that the stiffness coefficient is unity for $q < a$, whereas the corresponding coefficient is $\delta \geq 1$ for $q \geq a$. In what follows δ will be referred to as the ‘asymmetry parameter’ and a as the ‘offset parameter’. In fact, Eq. (1) or its different variants have been previously considered in several theoretical works for the two important limiting cases.

Unlike the linear Mathieu equation, its PWL counterpart with a non-zero offset, possesses the energy dependent parametric instability zones. To illustrate this fact, we plot the energy ($E(t)$) corresponding to Eq. (1) assuming the parametric excitation in the vicinity of 1:1 resonance with the fixed level of excitation amplitude (P) and frequency for the two different initial energy levels ($E(0)$). As is clear from the results of Figure 1, formation of unbounded response strongly depends on initial energy. The main objective of the present study is to characterize analytically these energy dependent instability zones. This is done by reformulating the system in terms of the action (I) - angle (θ) (A-A) variables ($q(I, \theta)$), transforming to energy (E)-angle variables ($q(E, \theta)$) and averaging in the vicinity of (1:n) resonance. Subsequent analysis of the averaged equations reveals the formation of quite interesting, energy dependent instability regions for a general resonance condition (1:n). We end up with the following averaged flow,

$$\dot{E}_{Avg} = \frac{\varepsilon n P}{2\lambda} \{ \alpha \sin(v) + \beta \cos(v) \} \quad (2a)$$

$$\dot{v} = \frac{n}{\lambda} \left\{ 1 + \frac{\varepsilon P}{2} \{ \alpha' \cos(v) - \beta' \sin(v) \} \right\} - \Omega_e \quad (2b)$$

Where E_{Avg} – stands for the averaged energy, v – resonance phase, $\lambda = dE/dI$, $\alpha(E), \beta(E)$ are the real and imaginary part of the Fourier coefficient $f_n(E)$ corresponding to $q^2(\theta, E)$ and α', β' are the corresponding derivatives with respect to energy. In Figure 3 (Left panel) we illustrate the phase plane of the averaged flow Eq. (2), while in Figure 3 (Right panel) we plot the transition curves on the force - energy plane corresponding to the saddle point of the averaged flow.

Figure 1: Energy as a function of time corresponding to 1:1 resonance for $a = 0.3, P = 3, \delta = 4$ (Left panel) initial energy lower than the threshold ($E(0) < 1.858, \nu(0) = 3.71$) (Right panel) initial energy higher than the threshold ($E(0) > 1.858, \nu(0) = 3.71$). (refer to the phase contour in the right panel of Figure 2)

Figure 2: (Left panel) Transition force - energy curves (Right panel) Phase plane of the averaged flow corresponding to $P = 3, a = 0.3$ both correspond to $\delta = 4$

As is clear from the phase portrait of the averaged flow, the change in the initial phase will lead to a change in the critical value of initial energy above which the system will exhibit the unbounded response. This behavior is illustrated in Figure 2. One can observe a fixed point (saddle) corresponding to Eq. (2) and the phase plane is split into stable region (A) and unstable regions (B, C, D) delimited by the separatrix. If the initial conditions are picked in the region A, the oscillator will exhibit a bounded response. Whereas, the oscillator exhibits unbounded response for any initial excitation in the other three regions. The correspondence between the analytical approximation and the true model is found to be extremely good for the lower values of the excitation amplitude.

Conclusions

The current analytical and numerical study is devoted to the analysis of the response of piecewise linear Mathieu equation with non-zero offset. To obtain some relatively simple analytical description of the instability zones of a PWL Mathieu equation, we introduce the action-angle variables and apply the method of averaging to deduce a slow-flow model corresponding to a specific resonance case. The study of the slow-flow model provides a clear description of the instability zones. As we have already shown above, these boundaries are not only dependent on the excitation amplitude but also on the initial conditions. The numerical simulations of the full model match extremely well with the deduced slow-flow model for the lower values of the amplitude of parametric excitation. However, the presented analytical model is not devoid of its drawbacks in the sense that it fails to predict the instability boundaries for the higher values of the forcing amplitude. As we have already noted above, in that case the mechanism which leads to unbounded response for essentially low values of energy, is strongly chaotic and cannot be described by the constructed averaged flow.

Estimation of downhole and bit-rock interaction parameters in real-time using an adaptive observer for drilling processes

Shanti Swaroop Kandala*, and Roman Shor*

*Department of Chemical and Petroleum Engineering, University of Calgary, Calgary, Alberta, Canada

Summary. Understanding the happenings at the downhole is extremely important for developing a fully automated drilling system. Towards achieving the same, in this work, an adaptive model-based observer is developed for the real-time estimation of the downhole parameters along with the bit-rock interaction parameters. The bit-rock interaction parameters in real-time will help us in understanding any formation changes along with the occurrence of other unwanted dynamics at the bit-rock interface. In this work, the off-bottom field dynamics model is combined with the bit-rock interaction law and is validated against the field data for wells drilled in North America. The results obtained were satisfactory and highlight the adaptive nature of the soft sensor.

Abstract

Obtaining real-time estimates of the bit-rock interaction (BRI) parameters and real-time formation pose significant challenges in developing an automated closed-loop geo-steering system for drilling operations. A major challenge for the same is the prohibitively expensive high bitrate and low latency downhole telemetry systems. Drilling dynamics can be broadly divided into off-bottom and on-bottom dynamics. Recent results have successfully captured the significant dynamics for off-bottom dynamics and have been validated against the field data [1]. However, developing an on-bottom dynamics field validated model is faced with significant challenges in accurately estimating the bit-rock interaction parameters, which in turn aid in estimating formation detection in real-time. A simulation-validated on-bottom dynamics model was recently proposed by Auriol et al. [2]. The model was developed based on the understanding of bit-rock interaction as proposed by Detournay and Defourny [3]. The BRI law, proposed by Detournay and Defourny, is dependent on friction coefficient at the rock contact, bit constant, depth of cut, intrinsic specific energy of the rock, drilling strength, and weight-on-bit (WOB). Auriol et al. [2] modified the BRI law by simplifying the model whose BRI parameters are dependent on WOB and depth of cut. The variations in the BRI parameters give insights into the happenings of drilling at the interface of the drillstring. Any formation change is reflected in the form of changes in these parameters that give a clear understanding of the drilling environment.

The off-bottom dynamics field validated model is based on the distributed drillstring model and uses only the surface parameters, RPM, and torque. In the proposed on-bottom dynamics model, the modified BRI law proposed by Auriol et al. is combined with the field-validated off-bottom dynamics model. Coupled with the surface RPM and surface torque, the proposed model uses additional surface measurements, weight-on-bit, differential pressure, flow rate to estimate the downhole RPM, downhole torque, and the BRI parameters. The proposed model assumes the torsional motion of the drill string to be the dominating dynamics behavior, a constant rate-of-penetration (ROP) and therefore a steady axial velocity of the bit, no distributed axial dynamics, and the friction coefficients along the drillstring are known. The proposed model is field validated against the field data obtained for an unconventional well drilled in North America.

Figure 1: Schematic indicating the distributed drill string of length L lying in deviated borehole

For brevity, the mathematical model used in this work is described here. The distributed model used in this work is based on the works of Aarsnes and van de Wouw [4], however, only torsional dynamics have been considered. Figure 1 shows the angular velocity ($\omega(t,x)$) and torque ($\tau(t,x)$) with time ($0 < t < T$) and length ($0 \leq x \leq L$), representing the angular motion of the drillstring of length L for a time T and torque obtained using the shear strain that is given as twist per unit length. With J and G as the polar moment of inertia and shear modulus, ($\tau(t,x)$) as torque, and ϕ as the angular displacement in the string, the angular motion of the drillstring is given by
$$\frac{\partial \tau(t,x)}{\partial t} + JG \frac{\partial \omega(t,x)}{\partial x} = 0, J\rho \frac{\partial \omega(t,x)}{\partial t} + JG \frac{\partial \tau(t,x)}{\partial x} = S(t,x),$$
 with ρ being the density.

$S(t, x)$ is the source term due to frictional contact with the borehole and is modeled as $S(t, x) = -k_t \rho J \omega(t, x) - F(\omega, t, x)$, with $F(\omega, t, x)$ being the differential inclusion that represents the Coulomb friction between the drillstring and the borehole. This off-bottom dynamics model cannot estimate the bit torque. To calculate the bit-torque, the BRI law as given by Detournay and Defourny [3] is included to the off-bottom dynamics as $\tau_b = a_1 * WOB + a_2 * \frac{ROP}{RPM}$. The on-bottom dynamics model is essentially developed by the inclusion of the BRI law to the off-bottom dynamics model.

The soft sensor developed in this work is the extension of the same developed for the off-bottom dynamics field validated model that provides estimates for downhole torque and the BRI parameters along with the downhole RPM by using only the surface measurements. The model is initiated with the off-bottom dynamics and initially estimates the friction coefficients (static and kinetic), and the BRI is not activated. With initial guess values for the friction coefficients, the model is initiated and the same are obtained till the bit is fully engaged with the bottom, where the model switches from off-bottom dynamics to on-bottom dynamics. Before the model switches to on-bottom, the convergence criterion is enforced for the friction coefficients. For each depth, the values of friction coefficients are different and those values around which the friction coefficients remain stable for a minimum of 20 seconds are considered as the converged values. Once the bit tags the bottom with the onset of the axial motion, the estimation of the friction coefficients is stopped and the BRI parameters along with the downhole torque are estimated. The main reason behind adopting such an approach is that the observer used in the model cannot distinguish between friction coefficients and the bit-rock interaction parameters. By using such an approach, the friction coefficients and the BRI parameters are estimated separately, without the need for any further complex mathematical model.

Figure 2 shows the normalized well profile of one of the wells for which the field data was used to validate the bit-rock interaction law implemented in the work along with the soft sensor. Figure 3 shows the profiles of the real and estimate of the surface torque along with the estimate for the downhole torque. The bit tags the bottom at about 120 seconds, When the bit tags the bottom, the downhole torque is a combination of the surface torque and the motor torque. The downhole torque presented in figure 3 is the difference between the total torque available at the bit and the mud motor torque. The downhole torque shown in figure 3 is essentially the difference in the surface torque with the bit off-bottom and on-bottom. It should be noted here that the difference between the off-bottom and on-bottom surface torque is very small, and the model has been able to capture the same.

Figure 2: Normalized well profile

Figure 3: Surface and downhole torques profiles

The estimates provided by the proposed soft sensor were found to be robust to poor initial estimates. The vital feature of the observer is its ability of adaptive estimation. Convergence of the friction parameters is aided by the adaptive estimation nature of the soft sensor, which otherwise is computationally expensive using other techniques that include the industry-standard friction tests where the pipe is raised and then lowered. The model used in this work is computationally efficient, which is a result of its simplistic nature. This makes the proposed model an appealing candidate for online, real-time sensing systems for drilling applications.

Analysis of an hydraulic switching converter with analog hysteresis feedback control

Philipp Zagar* and Rudolf Scheidl*

*Institute of machine design and hydraulic drives, Johannes Kepler University Linz, Austria

Summary. Hydraulic switching converters control a hydraulic state, such as pressure or flow rate, by the frequent switching of on-off valves in combination with some hydraulic inductance element and means to flatten pulsation due to switching. In nearly all modern versions of such converters the switching is provoked by electrically actuated valves. The historically first of such converters, Montgolfier's hydraulic ram, used a hydraulic feedback mechanism, because of lacking electrically controlled valves in his time. To make use of the significant cost advantage of pure hydraulic control, authors studied a concept for a buck converter for pressure control based on a specific feedback mechanism. In a theoretical analysis it turned out that this system exhibits a clustering of switching activities in certain operation domains which causes a bad pressure control performance. This paper analyses the essential inner mechanisms responsible for the operational performance and shows how to efficiently calculate approximate stability bounds in state space by using reduction methods.

Introduction

Fig. 1a shows the schematic of the hydraulically controlled buck converter as presented in [1]. An hydraulic inductance pipe L_H is actively switched to system pressure line p_S by a hydraulically piloted 2-2 way on-off valve. During off-phases a fast check valve opens due to oil inertia and the pipe is connected to pressure line p_T . The hydraulic capacitance C_{HC} flattens pressure and flow pulsation at the convert's output. The control principle employs feedback of a low-passed filtered version of p_1 via a feedback circuit (orifice Q_{NoFN} , capacitance C_{FB}) which counteracts as force $p_{FB}A_{FB}$ against the control force $p_C A_C$. This mechanism targets controlling the time mean of pressure p_1 at the pipe entrance which is expected to approximate the mean system output pressure p_2 . In order to assure a fast switching, when p_{FB} exceeds or falls below the threshold values, a hysteretic force F_{hyst} is realized by a special element. A feasible hydraulic design as well as the investigation of a detailed numerical model is presented in [1].

An impression of the converter's control performance and dynamical properties for different operating conditions is given by the diagrams in Fig. 1b. The response on the left hand side meets the main expectations and the desired output pressure $p_2 = p_C$ is reached after a rise time of approx. 0.1 seconds. The right hand side case with a low demanded pressure and a small flow rate, however, show an unacceptable behavior in form of clustered switching which leads to a bad control performance. The understanding of this behavior, i.e. of the essential inner mechanisms and the influence of the main system parameters, is the objective of this paper. This is achieved by model reduction and using the averaging method.

Modelling

The study of the dynamical properties is based on a simple model which incorporates pressure build-up equations in the hydraulic capacitances in node 1, FB and 2, oil inertia an the corresponding change in flow through the hydraulic inductance pipe, as well as orifice equations through the 2-2 way valve, the check valve and the throttle in the feedback circuit, resulting in a system of equations in nondimensionalized form

$$\frac{d}{dt} \begin{pmatrix} \psi_{FB} \\ \psi_1 \\ \psi_2 \\ q_1 \end{pmatrix} = \begin{pmatrix} \sqrt{\psi_1 - \psi_{FB}} \\ a_{NV} [q_{NT} H(\psi_T - \psi_1) \sqrt{\psi_T - \psi_1} + y_{Vrel} \sqrt{1 - \psi_1} - q_1] \\ a_{HL}(q_1 - q_L) \\ -r_H q_1 + \frac{1}{l_H}(\psi_1 - \psi_2) \end{pmatrix}. \quad (1)$$

(a) Comparison between full and reduced system.

 (b) Convergent set of full and reduced system (left). Convergent set of red. system for different values q_L (right).

Figure 2: Simulation results

The main valve and check valve dynamics are disregarded and infinite fast switching is assumed. This is already considered for the check valve in the orifice equation by introducing the heaviside function $H(\cdot)$ in the pressure built-up equation for ψ_1 . The discrete state dynamics of the main valve is modeled by the variable $y_{Vrel} \in \{0, 1\}$ which changes infinitely fast from $0 \rightarrow 1$ and from $1 \rightarrow 0$ when $\psi_{FB} \geq \psi_C \pm \psi_{hyst}/2$.

Eq. (1) describes a non-linear switched system with dynamics on two different time scales, one is the switching of the valve which introduces high-frequency components and the other is the system's internal dynamics. Interestingly, this system is unstable for certain initial conditions, i.e. for a certain parameter set the locally stable system can get unstable if the initial conditions are chosen badly. Solving system (1) for various different combinations of parameters and initial conditions gets inefficient as one has to initialize the solver whenever the state of y_{Vrel} which depend on the fast time scale changes. Therefore, a smooth approximation for the system was derived.

First, the size of the capacitance at node 1 which corresponds to the inverse of parameter a_{NV} is assumed to be very small. This results in a singular perturbed equation as $1/a_{NV}\dot{\psi}_1 \rightarrow 0$, which gives a quadratic expression for ψ_1 for both states of y_{Vrel} . Secondly, the equation for the feedback pressure ψ_{FB} has approximately triangular waveform and so the state-dependent duty cycle $\alpha = fT_{on}$ and the state-dependent pulse-width modulation frequency f can be calculated. The remaining two-dimensional system of equations can be further approximated by using the method of averaging [2]. By introducing the time transformation $t = \epsilon\tau$ one obtains the two-dimensional system in standard form $\dot{x} = \epsilon f(x, t) + \epsilon^2 f^{[2]}(x, \epsilon)$ which can be approximated by a two-dimensional averaged system

$$\frac{d}{dt} \begin{pmatrix} \bar{\psi}_2 \\ \bar{q}_1 \end{pmatrix} = \begin{pmatrix} a_{HL}(\bar{q}_1 - \bar{q}_L) \\ -r_H \bar{q}_1 + \frac{1}{l_H}(\psi_T - \frac{\bar{q}_1^2}{q_{NT}} + \alpha(\bar{q}_1)(1 - \bar{q}_1^2 - \psi_T + \frac{\bar{q}_1^2}{q_{NT}}) - \bar{\psi}_2) \end{pmatrix}. \quad (2)$$

with only four remaining parameters and a smooth right-hand side. This system is used to calculate approximate convergent sets. A physical explanation for the system to get unstable is a oil flow from the output in the backwards direction. Such a flow immediately increases the pressure ψ_1 in node 1 as its capacitance is very small. This pressure is fed back to the main valve demanding for the valve to close. Since only a positive oil flow q_1 (which opens the check valve to the tank) can decrease pressure ψ_1 the controller does not exhibit the intended behavior. The backwards oil flow is due to the system's internal dynamics (long time scale) which is approximated by the reduced two dimensional system reasonably well. For the complete system the condition for getting unstable is $q_1 < 0$. To the averaged system \bar{q}_1 to approximate the minimum of q_1 an expression for the ripple must be subtracted. The first order approximation of the ripple is $\Delta_q = T_1(1 - \bar{q}_1^2 - \psi_C)/l_H$. Fig. 2a shows a solution of the complete and the approximated system. The diagrams in Fig. 2b show true and approximate bounds of a convergent set of initial conditions and the such a converging set for different loading q_L which was calculated by using the reduced system.

Conclusions

A hydraulic buck converter was modeled by a nonlinear switched system. It shows to have bounded regions in state space which are locally stable. To efficiently compute the bounds for different parameters a reduced system with smooth right-hand side was derived and approximations of the stable regions were calculated.

A Reduced Order Model for Steady State Response of Joint Assemblies by Hyper-Reduction and Model-Driven Sampling

Ahmed Morsy, Mariella Kast and Paolo Tiso

Institute for Mechanical Systems, ETH Zürich, Zürich, Switzerland

Summary. The dynamic behavior of jointed assemblies exhibiting friction nonlinearities features amplitude-dependent dissipation and stiffness. To develop numerical simulations for predictive and design purposes, macro-scale High Fidelity Models (HFMs) of the contact interfaces are required. However, the high computational cost of such HFMs impedes the feasibility and efficiency of the simulations. To this end, we propose a model-driven method for constructing hyper-reduced order models of such assemblies. Focusing on steady-state analysis, we use the Multi-Harmonic Balance Method (MHBM) to formulate the equations of motion in frequency domain. Next, the reduction basis is constructed through solving a set of vibration problems corresponding to fictitious interface conditions. Subsequently, a Galerkin projection reduces the order of the model. Nonetheless, the necessary fineness of the mesh of nonlinear elements on contact interfaces represents a bottleneck for achieving high speedups. Thus, we implement an adapted Energy Conserving Weighing and Sampling (ECSW) technique for Hyper Reduction (HR) for joint problems, thereby allowing significant speedups for meshes of arbitrary fineness. This feature is particularly advantageous since analysts typically encounter a trade-off between accuracy and computational cost when deciding on the mesh size, whose estimation is particularly challenging for problems of this type. Finally, the accuracy and efficiency of the method are demonstrated through a case study.

Introduction

Friction along the interfaces of jointed assemblies, which are commonly found in mechanical and aerospace engineering applications, results in a significant dissipation of energy under dynamic loading. One contact model used to model friction contact in HFMs consists of a Jenkins element with a unilateral spring in the normal direction [1], assigned to each mating node pair on the contact interface. This formulation is capable of reproducing states of sticking, slipping, and separation, locally on the interface.

Projection-based ROM techniques reduce the size of the dynamical system by projecting it on a suitable low-dimensional subspace, thus providing accurate and efficient solutions. Recently, Gastaldi et al. [2] presented the Jacobian-Projection (JP) method, where the reduction basis is constructed in the frequency-domain in a multi-harmonic context, taking into account the harmonic coupling induced by the nonlinear forces. Additionally, we augment the JP basis using vectors representing forced responses of linear systems, which are essential for a high accuracy on forces. Since the evaluation of the non-smooth nonlinear forces across the interface impedes significant speedups, we employ an energy-conserving sampling and weighing (ECSW) hyper reduction strategy [3], adapted to the MHBM context of our problem, with training that does not require any HF simulations.

Method

Problem Formulation

For a Finite Element (FE) discretization of the mechanical system, we assume the equation of motion to be written in the form

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{C}\dot{\mathbf{u}} + \mathbf{K}\mathbf{u} + \mathbf{f}(\mathbf{u}) = \mathbf{p}_{\text{ext}}(t), \quad \mathbf{p}_{\text{ext}}(t) = \mathbf{p}_0 + \mathbf{p}_E(\Omega t), \quad (1)$$

where \mathbf{M} is the mass matrix, \mathbf{C} is the damping matrix, \mathbf{K} is the stiffness matrix, $\mathbf{f}(\mathbf{u})$ is the vector of nonlinear forces, \mathbf{p}_0 is a vector representing the static loads (e.g. preclamp forces), and $\mathbf{p}_E(\Omega t)$ is the periodic force acting on the system with a time period $T = 2\pi/\Omega$. We use the Multi-Harmonic Balance Method (MHBM) to formulate our Ansatz of the displacements steady-state response in the frequency domain as

$$\mathbf{u}_h(t) = \mathbf{U}_0 + \sum_{j=1}^H (\mathbf{U}_j^c \cos(j\Omega t) + \mathbf{U}_j^s \sin(j\Omega t)) \quad (2)$$

where \mathbf{U}_0 collects the coefficients of the 0-th harmonic, while $\mathbf{U}_j^{c/s}$ represents the cosine/sine components of the j -th harmonic.

Augmented JP Method

We extend the JP projection method proposed in [2] by not only considering the free vibration modes arising from linearization at different fictitious contact forces, but also including the corresponding linearized forced response in the basis. The fictitious contact forces (and related Jacobians) are obtained by imposing the linear steady-state solution at different scaling factors. For each scaling factor, we thereby solve an eigenvalue problem, and a linear forced response problem:

$$(\mathbf{J}^k - \lambda_i^k \overline{\mathbf{M}}) \phi_i^k = \mathbf{0}, \quad \mathbf{Z}^k \mathbf{U}_{\text{lin}}^k = \mathbf{P}_{\text{ext}} \quad (3)$$

where \mathbf{J}^k is the multi-harmonic stiffness of the structure incorporating the Jacobian of the nonlinear forces corresponding to the k -th system, $\bar{\mathbf{M}}$ is the multi-harmonic mass matrix, λ_i^k is an eigenvalue, ϕ_i^k is the corresponding eigenvector, \mathbf{Z}^k is the dynamic stiffness matrix involving the multi-harmonic mass, damping, and stiffness matrices, and $\mathbf{U}_{\text{lin}}^k$ is the linear dynamic response of the k -th system. After computing, and normalizing the vectors ϕ and \mathbf{U}_{lin} , the harmonic components of the vectors are partitioned. Finally, a Singular Value Decomposition (SVD) procedure is applied to the collected vectors to form a well-conditioned basis for each harmonic component. The steady-state solution is thus approximated by

$$\mathbf{u}_h(t) = \mathbf{U}_0 + \sum_{j=1}^H (\mathbf{U}_j^c \cos(j\Omega t) + \mathbf{U}_j^s \sin(j\Omega t)) \approx \mathbf{V}_0 \mathbf{Q}_0 + \sum_{j=1}^H (\mathbf{V}_j^c \mathbf{Q}_j^c \cos(j\Omega t) + \mathbf{V}_j^s \mathbf{Q}_j^s \sin(j\Omega t)). \quad (4)$$

where \mathbf{V}_0 , \mathbf{Q}_0 are the reduced basis and the reduced coordinates for the 0-th harmonic component, and $\mathbf{V}_j^{c/s}$, $\mathbf{Q}_j^{c/s}$ are the reduced basis and reduced coordinates of the cosine/sine components of the j -th harmonic, respectively. Next, we perform a Galerkin-projection of the forces of the system to obtain the reduced system

$$\tilde{\mathbf{Z}} \mathbf{Q} + \tilde{\mathbf{F}}(\mathbf{W} \mathbf{Q}) = \tilde{\mathbf{P}}_{\text{ext}}, \quad (5)$$

where $\tilde{\mathbf{Z}}$ is the reduced dynamic stiffness matrix, \mathbf{Q} is a vector collecting the reduced degrees of freedom of the system, \mathbf{W} is the block-diagonal reduction basis, $\tilde{\mathbf{F}}(\mathbf{W} \mathbf{Q})$ is the projected nonlinear force vector, and $\tilde{\mathbf{P}}_{\text{ext}}$ is the projected external force vector.

ECSW Hyper Reduction

The idea of the ECSW method is to approximate the nonlinear force vector through attributing weights only to a subset of the nonlinear elements of the mesh in such a way that it approximates an energy-like quantity within a specified tolerance

$$\tilde{\mathbf{F}} = \sum_{e=1}^{n_e} \mathbf{W}_e^T \mathbf{F}_e(\mathbf{W}_e \mathbf{Q}) \approx \sum_{e \in E} \xi_e \mathbf{W}_e^T \mathbf{F}_e(\mathbf{W}_e \mathbf{Q}) = \tilde{\mathbf{F}}_{\text{HR}} \quad (6)$$

where n_e is the number of nonlinear elements, and E represents only a subset of elements for which the weights ξ_e are computed such that the following inequality is satisfied with the least amount of non-zero elements:

$$\|\mathbf{G}\xi - \mathbf{b}\|_2 \leq \tau \|\mathbf{b}\|_2, \quad (7)$$

where \mathbf{G} is a matrix that stores the element-wise contributions to the training snapshots, which in our case are snapshots of the nonlinear forces readily available from the Alternating-Frequency Time (AFT) scheme involved in the construction of the reduced basis. The entries of vector \mathbf{b} represent the assembly of the energy-like quantity from all the elements for the different training snapshots, and τ is set tolerance.

Numerical Results

We apply the proposed method to study the frequency response (FR) of a forced jointed beam. A sketch of the structure is shown in the top left portion of Fig. 1. The Ansatz consists of 5 harmonics. The plot in Fig. 1 features the FR curves for 4 different amplitudes driving the structure at a frequency close to the first bending mode. As demonstrated in the figure, the HR model reproduces the HF results with high accuracy.

The model whose response is shown Fig. 1 has a mesh of 121 nonlinear elements along the contact interface. This model is denoted by Model (1). Table 1 shows that speedups for Model (1) ranging from 5.5 to 7, demonstrating the efficiency of the method. Another model, Model (2), was created to test the convergence of the model with respect to the number of nonlinear elements. This latter has a mesh of 241 nonlinear elements. The FR curves obtained were identical to those shown in Fig.1. This made it possible to conclude that the coarser mesh was sufficient. The speedups of Model (2) are also shown in table 1. They now range from 9.5 to 42.8. It can be noted that also that the HR wall-clock time for Model (2) is only marginally higher than that of Model (1), thanks to the limited number of elements picked by ECSW. In other words, the proposed procedure could alleviate tedious mesh convergence studies, as one could efficiently reduce larger than optimal models.

Conclusion

We presented a hyper-reduced order modelling method for analyzing the steady-state frequency response of jointed structures. The accuracy of the method was shown to be satisfactory for the case studied, and the associated speedups have been presented. A particularly advantageous feature of the proposed method is that the speedups improve as the HF mesh increases in size, thanks to the sparsity of the hyper-reduction scheme.

Figure 1: A sketch of the structure is shown in the top left. The plot shows the FR curves for $F = 0.1\text{N}, 2\text{N}, 5\text{N}, 10\text{N}$ for the 1st bending mode of the structure using 5 harmonics. The results of the HFM and the HR ROM are denoted by HF and HR, along with the relative forcing. The properties of the structure are: $E = 189\text{ GPa}$, $A = 6.25\text{e-4 m}^2$, $L = 0.42\text{ m}$, $\rho = 7820\text{ Kg/ m}^3$, $x_F = 0.24\text{ m}$, $L_c = 0.12\text{ m}$, bolt load = 1.25 KN , $\mu = 0.4$, $k_t = 7.5\text{e9 N/m}$, $k_n = 10\text{e10 N/m}$

	Mesh (1)			Mesh (2)			
Force [N]	HR [s]	HF [s]	Speedups	HR [s]	HF[s]	Speedups	Ratio of Speedups
0.1 N	29.5	206.4	7.0	57.7	550.7	9.5	1.4
2 N	68.7	404.2	5.9	100.9	1864	18.5	3.1
5 N	85.7	473.5	5.5	115.7	3217.6	27.8	5.0
10 N	95.1	520.4	5.5	129.7	5547.8	42.8	7.8

Table 1: Online computational cost of constructing the FRF curves and associated speedups. Model (1) and Model (2) refer to meshes with 121 and 241 nonlinear elements at the contact interface, respectively. The costs of the bases constructions are respectively 28.4s for Mesh (1) and 97.5s for Mesh(2). The total HR training time for each of the models is less than 1s.

Summary. Burgers' equation is a nonlinear scalar partial differential equation, commonly used as a testbed for many newly developed model order reduction techniques and error estimates. Model order reduction of the parameterized Burgers' equation is commonly done by the Reduced Basis (RB) method. In this method, an error estimate plays a crucial role in accelerating the offline phase (when the reduced model is built) and also in quantifying the error induced after reduction in the online phase (when the reduced model is used to find fast solutions). In this study, we introduce two new estimates for this reduction error. The first error estimate is based on the Lur'e-type model formulation of the system obtained after the full-discretization of Burgers' equation. The second error estimate is built upon snapshots generated in the offline phase of the RB method. The second error estimate is applicable to a wider range of systems compared to the first error estimate. Results reveal that when conditions for the error estimates are satisfied, the error estimates are accurate and work efficiently in terms of computational effort.

Problem description

One of the simplest and yet fundamental nonlinear equations describing a conservative system is Burgers' equation, which is sometimes referred to as the scalar version of the Navier-Stokes equations [1]. This equation is defined in the infinite- and finite- dimensional setting, obtained after Finite Volume (FV) discretization, as follows:

$$\frac{\partial u}{\partial t} + \frac{\partial}{\partial x} (f(u)) = 0, \quad t \in [0, T], \quad x \in [0, L] \quad \xrightarrow{\text{FV}} \quad \begin{cases} \Sigma_{lin} : \begin{cases} U^{n+1} = L_{lin} U^n + B U_0^n - \frac{\Delta t}{4\Delta x} L_{nl} U_{nl}^n + \frac{\Delta t}{2\Delta x} B (U_0^n)^2, \\ y^n = C_y U^n, \\ z^n = U^n, \end{cases} \\ \Sigma_{nl} : U_{nl}^n = g(z^n) := (z^n)^2. \end{cases} \quad (1)$$

where $u := u(t, x; \mu)$ is the conservative variable of the system, U^n is the vector of the conservative variables computed at the grid cells at time index n , U_0^n is the boundary input at time index n , y^n is the output of interest specified by matrix C_y , and finally $f(u) := u^2/2$ is the flux function associated with Burgers' equation. Here, t represents time and T is the time horizon of the simulation. In addition, x denotes the spatial coordinate and L is the length of the spatial domain. Finally, $\mu \in \mathcal{D}$ is a vector of parameters used in (1) that varies in the multi-query analysis within the parameter domain $\mathcal{D} \in \mathbb{R}^R$, with $R > 0$ the number of varying parameters. We assume that the initial condition and the boundary condition are represented by the varying parameters. For the initial condition, we assume $u(0, x; \mu) = \mu_1$, which is constant over the spatial domain. For the boundary condition at $x = 0$, we assume

$$u(t, 0; \mu) = \begin{cases} \mu_1, & t = 0, \\ \mu_2, & t > 0. \end{cases} \quad (2)$$

Therefore, in this study, we have $\mu = [\mu_1, \mu_2]$.

The fully discretized system $(\Sigma_{lin}, \Sigma_{nl})$ as in (1) usually has a large dimension. Therefore, real-time simulations cannot be achieved unless powerful computational resources are available. Moreover, control design for such a complex system is generally infeasible. Hence, model order reduction should be applied.

We reduce the dimension of the full-order model (1) by using the RB method [2] and denote the RB solution obtained by using N RB functions with \hat{U}_N^n (similarly \hat{y}_N^n). We are interested in the computation of reliable error estimates and denote the difference between the FV and RB solution by $e^n := U^n - \hat{U}_N^n$ (similarly $e_y^n = y^n - \hat{y}_N^n$).

Error estimates for the reduced model

Following the idea introduced in [3] for linear systems and assuming L_{lin} in Σ_{lin} being a Schur matrix, an error bound on the ℓ_2 -norm of the error signal is constructed as follows:

$$\|e_y\|_{\ell_2} \leq \gamma^{e_y \mathcal{R}} \|\mathcal{R}\|_{\ell_2} + \gamma^{e_y e_{U_{nl}}} \|e_{U_{nl}}\|_{\ell_2}, \quad (3)$$

where $\mathcal{R}^n := \hat{U}_N^{n+1} - \left(L_{lin} \hat{U}_N^n + B U_0^n - \frac{\Delta t}{4\Delta x} L_{nl} \hat{U}_{nl}^n + \frac{\Delta t}{2\Delta x} B (U_0^n)^2 \right)$ is the residual obtained after reduction, $e_{U_{nl}}$ is the approximation error of the nonlinear term U_{nl} , and $\|\mathcal{R}\|_{\ell_2} := \sqrt{\sum_{n=0}^{\infty} \|\mathcal{R}^n\|^2}$ (similarly for $\|e_y\|_{\ell_2}$ and $\|e_{U_{nl}}\|_{\ell_2}$).

Figure 1: (a) Maximum error in the discrete parameter domain during the offline phase, (b) Error evolution by increasing the number of RB functions in the online phase.

Moreover, $\gamma^{e_y \mathcal{R}}$ represents the ℓ_2 -norm of the dynamical error system (obtained after subtracting the lifted reduced-order model from system (1)) from input \mathcal{R} to the output e_y (similarly for $\gamma^{e_y e_{U_{nl}}}$). This ℓ_2 -norm is equal to the \mathcal{H}_∞ -norm of the linear part of the dynamical error system with respect to the same input and output, which is computed as described in [3].

A second error estimate is defined following the idea presented by [4]. Assume that we have the reduced solution with two different levels of accuracy, one using N RB functions, the other one with $N' (> N)$ RB functions and we are interested in the error analysis for the case with N RB functions. We can relate the error of the two reduced models as follows:

$$\|y - \hat{y}_{N'}\|_{\ell_2} \leq \eta_N^{N'} \|y - \hat{y}_N\|_{\ell_2}. \quad (4)$$

Here, y is the actual output computed from (1) and \hat{y}_N is obtained from the reduced model with N RB functions. In the so-called offline phase, N' is increased until the empirically obtained $\eta_N^{N'}$ becomes smaller than 1 for all parameters whose corresponding full-solution is available. Therefore, for any N , we can find N' such that $\eta_N^{N'} < 1$. This condition bears similarities with the small-gain condition mentioned in [3]. Now, in the offline phase, corresponding to each N , the value of N' and the value of $\eta_N^{N'}$ are known.

In the so-called online phase, two reduced solutions with N and N' RB functions should be solved. After obtaining these two computationally cheap solutions, we have:

$$\left. \begin{aligned} \zeta_N^{N'} &= \|\hat{y}_{N'} - \hat{y}_N\|_{\ell_2} \\ \|y - \hat{y}_N\|_{\ell_2} &\leq \|y - \hat{y}_{N'}\|_{\ell_2} + \|\hat{y}_{N'} - \hat{y}_N\|_{\ell_2} \end{aligned} \right\} \xrightarrow{(4)} \|y - \hat{y}_N\|_{\ell_2} \leq \frac{\zeta_N^{N'}}{1 - \eta_N^{N'}}. \quad (5)$$

The reason for having the empirical factor $\eta_N^{N'} < 1$ shows itself here to have finite and positive error estimate.

The evolution of the error estimates and the actual error during the offline and online phase is shown in Figure 1. In general, the ℓ_2 -gain estimate is sharper than the empirical one, but the latter one is faster with a larger applicability region.

Conclusions

In this work, a new error estimate based on the Lur'e type formulation of the nonlinear Burgers' equation is defined. This estimate is rigorous, accurate and effective, but has limited applicability. To circumvent this issue, hinged on the snapshots generated in the offline phase, an empirical error estimate is introduced. Both error estimates work efficiently in terms of computational effort and accuracy. However, the empirical error estimate is faster and also applicable on a wider range of problems compared to the error estimate proposed on the basis of ℓ_2 -gain notion.

Summary. Tracking parameter variations in mechanical systems is a common and demanding challenge due to various reasons. Conventional approaches leverage measurement of time series signals to remodel the mechanical system to mitigate the impact from parameter variations. However, the effectiveness highly depends on the quality of the measured signals which are affected by the modulation of signals and is prone to noise. Additionally, such methods can exhibit further degraded performance when multiple parameters change simultaneously. With this motivation, we propose a novel adaptive modeling method in this paper. The proposed method aims to explore the possibility of combining both the Science-based Modeling (SBM) and Data-based Modeling (DBM) to develop a hybrid adaptive modeling framework to achieve a higher level of accuracy and broader adaptability. We use two coupled Duffing oscillators as the target model and identify the coupling parameter when it varies. Firstly, the perturbation method is applied to develop a science-based model and obtain the asymptotic solutions of the target system. Based on the asymptotic solutions, the system is parametrized and a series of frequency response plots are obtained corresponding to various coupling parameters. Secondly, the dynamical characteristics of the system like the jump phenomenon can be captured in the series of frequency response plots and extracted as features. Finally, an Artificial Neural Network (ANN) is developed, trained and fine-tuned using the features to identify the changing coupling parameter. The results compared with a baseline grey box model demonstrate the effectiveness of the proposed method in increasing the accuracy and robustness of adaptive modeling.

Background Introduction

A model is a abstracted description of a real - often complex - dynamic system. The accuracy and adaptability of a model is critical for understanding of observed phenomena, predictions of system behaviors as well as design, optimization, diagnostics and control. We call the classical approach of modeling, Science Based Modeling (SBM), that used the traditional mathematical models and the associated computer codes have certainly developed reasonable verisimilitude with real behaviors. Generally, the SBM method uses physics or established rules, which are capable of capturing some observed effects qualitatively and provide useful insights into the underlying causalities. However, the limitation of SBM is derived from the fact that many of the practical physical systems are becoming increasingly more complex than can be modeled accurately with the physics we know. On the other hand, due to accelerating development of machine learning, sensor technology, computer hardware and big data, the uncertainties and variations of the systems are more reflected in the collected data. Therefore, these inspire a novel approach of modeling physical systems, namely, Data Based Modeling (DBM). Typically, the DBM method establishes a pattern from the observed data to predict the system response for future inputs. DBM highly depends on the quality and quantity of collected data and the nature of the system, so obtaining more effective data is key to enhance the performance of DBM method. However, the inherent limitation of DBM comes from the fact that it cannot be easily parameterized, or extended to situations that the model has not been exposed to. Any tiny changes of the system can compromise the validity of data-based models such as system degradation, environmental changes and operational condition alterations, all of which are inevitable in practice. Therefore, it is of significant importance to develop adaptive modeling techniques that can adapt to changes and are applicable to real complex systems [1].

Target system

In this paper, we develop an adaptive modeling method and demonstrate it by applying to a set of two coupled duffing oscillators[2, 3], the governing equations of the system are shown in Eq. (1).

$$\begin{aligned} x'' + k_1^*x + d_1^*x' + k_2^*x^3 + k_3^*(x - y) &= 0 \\ y'' + k_1^*x + d_1^*y' + k_2^*y^3 + k_3^*(y - x) &= 0 \end{aligned} \quad (1)$$

We select such a system because it is a low-order baseline system which is nevertheless complex from the point of view of nonlinearity. Moreover, such a model is the candidate for description of various mechanical and electro-mechanical systems. The coupling coefficient of real connected systems is one of the most variable and least predictable coefficients particularly in higher order systems. Therefore, in our target system, it is set to be an unknown parameter and requires identification under varying conditions to evaluate the effectiveness and generality of the proposed method. The analysis is also conducted with different parameters set of damping and nonlinearity to verify the generality of the method. As the external force can vary due to uncontrollable loads of the system, we randomly change the amplitude of excitation within a fixed range.

Methodology

The overview of the hybrid adaptive modeling framework is shown in Fig. 1. Assuming the physical system is perfectly modeled, the governing equations are obtained at time t_1 . At time t_2 , the coupling coefficient of the system may change

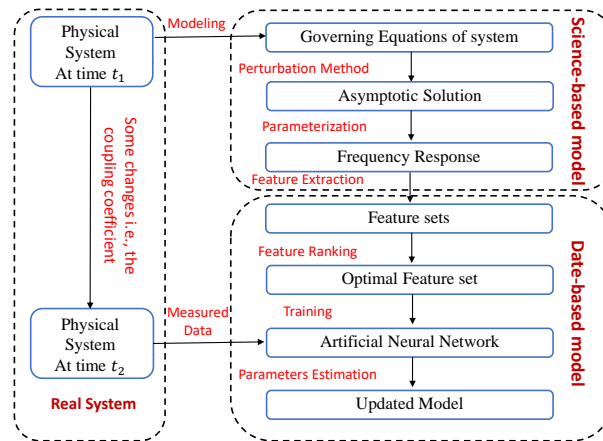

Figure 1: Overview of proposed approach for predicting coupling coefficient

due to wear, fatigue or other operating conditions. Note that t_1 and t_2 are orders of magnitude larger than system dynamic response times. To retain the accuracy of the model, it is necessary to track the variations of the coupling coefficient to update the previous model. We use a perturbation method to analytically solve the governing equations and obtain the frequency response by changing the frequency of excitation. Subsequently, the frequency response corresponding to different coupling coefficients are considered. The nonlinear dynamical characteristics like jump phenomenon and bifurcation points are extracted as appropriate features to describe the changes of frequency responses with the variations of the coupling coefficient. In order to prevent the interference of other parameters like nonlinear stiffness and damping, the mutual information [4] between features and other parameters are also determined. The features which are more sensitive to the changes of the coupling coefficient and less sensitive to other parameters are chosen as an appropriate feature set. Subsequently, an artificial neural network (ANN) with one hidden layer and twenty nodes is developed and trained by selected features in which the architecture of the ANN is determined by grid search, and the performance is optimized by regularization and cross validation. Finally, the frequency response of the real physical system at time t_2 is measured which is more noise-resistant than time series signals. The trained ANN takes the features of measured frequency response signal as input to predict the changed coupling coefficient with 99.8% accuracy.

Conclusions

This paper proposes a hybrid adaptive modeling to identify the changing coupling coefficient in two coupled Duffing oscillators. The features extracted from the Science Based Model are more efficient to capture the nonlinear dynamical characteristics of the real system and help improve the prediction from the Data Based Model. The application of mutual information and feature ranking improves the robustness of extracted features. The ANN developed and trained by the optimal feature set demonstrates better ability to identify the changed coupling coefficient with much higher regression than the classical grey box model.

Summary. This abstract presents a model reduction approach for systems of hyperbolic partial differential equations (PDEs) with nonlinear boundary conditions for drilling applications. These systems can be decomposed into a feedback interconnection of a linear hyperbolic PDE subsystem and a static nonlinear mapping. We show that the linear PDE subsystem can effectively be approximated by a cascaded system of continuous time difference equations (CTDEs) and ordinary differential equations (ODEs). The performance of the proposed technique is investigated by application to a model for managed pressure drilling (MPD).

Introduction

Hyperbolic partial differential equations (PDEs) govern a variety of physical phenomena such as fluid mechanics. These models have in recent years gained much attention in the design of model-based control systems [1]. However, the complexity of these models currently handicaps the design of controllers that can meet advanced performance criteria. To enable controller synthesis for such performance criteria, it is common practice to approximate the hyperbolic system by finite-dimensional models in terms of ordinary differential equations (ODEs). However, this type of approximation exhibits a low accuracy in capturing the wave propagation effect in hyperbolic systems. By contrast, it is known that the boundary behaviour of hyperbolic systems without coupling source terms can exactly be described by low-order continuous-time difference equations (CTDEs). These facts motivate us to investigate a combination of ODEs and CTDEs for the approximating hyperbolic models.

In this study, we consider a special class of systems consisting of two sets of linear isothermal Euler equations with coupling source terms and nonlinear boundary conditions. This particular class of hydraulic models is used in a variety of engineering applications, such as in managed pressure drilling (MPD) automation [2]. We show that these models can effectively be approximated by a series connection of low-order models in terms of CTDEs and ODEs. The CTDE part is employed to embed the advective nature of the system and the ODE part is used to approximate in-domain coupling effects between system variables due to source terms. Because the wave propagation effect is already captured through the CTDE model, the ODE part no longer needs to be of high order. Finally, we apply the proposed model reduction technique to single-phase flow MPD-controlled drilling systems, and present simulation results to illustrate the effectiveness of this method for such MPD applications.

Problem statement

Consider a system of balance laws, consisting of two isothermal Euler equations

$$\frac{\partial Q}{\partial t} + \Psi_c \frac{\partial Q}{\partial \xi} + F_c Q = 0, \quad \Psi_c = \begin{bmatrix} \Psi & 0 \\ 0 & \Psi \end{bmatrix}, \Psi = \begin{bmatrix} 0 & 1 \\ c^2 & 0 \end{bmatrix}, F_c = \begin{bmatrix} F_1 & 0 \\ 0 & F_2 \end{bmatrix}, \quad (1)$$

where $\xi \in [0, l]$ and $t \geq 0$ are the spatial and temporal variables, $Q(t, \xi) \in \mathbb{R}^4$ is the vector of variables, and c [m/s] and l [m] are the speed of sound and length of the spatial domain, respectively. Moreover, $F_1, F_2 \in \mathbb{R}^{2 \times 2}$ characterise the source terms. We assume a zero initial condition $Q(0, \xi) = 0$ and consider boundary conditions of the form

$$\Pi_1 \begin{bmatrix} Q(t, 0) \\ Q(t, l) \end{bmatrix} - \Pi_2 \psi \left(\Gamma \begin{bmatrix} Q(t, 0) \\ Q(t, l) \end{bmatrix}, u(t) \right) = 0, \quad \Pi_1 \in \mathbb{R}^{4 \times 8}, \Pi_2 \in \mathbb{R}^{4 \times n_l}, \Gamma \in \mathbb{R}^{r \times 8}, \quad (2)$$

where $u(t) \in \mathbb{R}^p$ is the input vector and the nonlinear function $\psi(\cdot, \cdot)$ is due to nonlinearities in the boundary conditions. Furthermore, we assume that the output is given by $y(t) = H\Gamma[Q^T(t, 0), Q^T(t, l)]^T$, with $H \in \mathbb{R}^{m \times r}$.

Given the model in (1) and (2), the objective is to approximate the input-output behaviour of this system from the input u to the output y with a model of lower complexity, which allows for faster yet accurate time-domain simulations. Moreover, this model should possess a structure that potentially facilitates the design of high-performance controllers.

The system described by (1) and (2) can be cast into a feedback interconnection of an infinite-dimensional linear system Σ and a static nonlinear mapping $\psi(\cdot, \cdot)$ of the following forms:

$$\Sigma : \begin{cases} \frac{\partial Q}{\partial t} + \Psi_c \frac{\partial Q}{\partial \xi} + F_c Q = 0, Q(\xi, 0) = 0, \\ \Pi_1 \begin{bmatrix} Q(t, 0) \\ Q(t, l) \end{bmatrix} = \Pi_2 v(t), w(t) = \Gamma \begin{bmatrix} Q(t, 0) \\ Q(t, l) \end{bmatrix}, y(t) = Hw(t), \end{cases} \quad (3)$$

$$v(t) = \psi(w(t), u(t)), \quad (4)$$

where $w(t) \in \mathbb{R}^r$ is the output of Σ and $v(t) \in \mathbb{R}^{n_l}$ is its input. This decomposition enables us to reduce the complexity of this model by only reducing the complexity of the linear PDE part and leave the nonlinearities untouched.

Model reduction

In the absence of source terms, Σ can be modelled by a system of CTDEs, which represent the transport phenomenon in the system. However, the source terms lead to distributed in-domain couplings among the travelling waves. Our observations show that these interactions in particular affect the low-frequency behaviour of the system Σ . We can also show that the transfer function of Σ converges to a periodic behaviour (in terms of the frequency variable) of a period of $2\pi c/l$ at high frequencies. This periodic behaviour in the transfer function is a manifestation of the advective nature of the system. Thus, we conclude that in the presence of these source terms, the system behaviour is composed of two dominating aspects: 1) advection and 2) dynamics governing the shape of advective waves. As said before, the (advection-induced) transport aspects can be modelled by CTDEs. This is the dominating aspect at high frequencies. Given that the second aspect is mostly dominant at low frequencies, we compensate for that by a system of ODEs. This explanation motivates us to consider for $\hat{\Sigma}$, the approximate of Σ , a structure which consists of an interconnection of a CTDE model Σ_c and an ODE model Σ_o . Here, we adapt a series interconnection between Σ_c and Σ_o , and refer to it as the cascaded system. We propose the following realizations for Σ_c and Σ_o :

$$\Sigma_c : \begin{cases} E_1 \dot{x}_1(t) = -A_1 x_1(t - \tau) + B_1 \hat{v}(t), \\ z(t) = C_1 x_1(t), \end{cases}, \quad \Sigma_o : \begin{cases} E_2 \dot{x}_2(t) = A_2 x_2(t) + B_2 z(t), \\ \hat{w}(t) = C_2 x_2(t) + D_2 z(t), \end{cases} \quad (5)$$

where $x_1(t) \in \mathbb{R}^{n_1}$ and $x_2(t) \in \mathbb{R}^{n_2}$ are the state vectors, $\hat{v}(t)$ and $\hat{w}(t)$ are approximates of $v(t)$ and $w(t)$, respectively, and $z(t) \in \mathbb{R}^m$ is the output of Σ_c and the input to Σ_o . Moreover, $\tau = l/c$ is the delay and $E_1, E_2, A_1, A_2, C_1, C_2, B_1, B_2$ and D_2 are system matrices of appropriate dimensions. To construct Σ_c and Σ_o , the data-based method in [3] is used. Namely, Σ_c is designed such that its transfer function matches the transfer function of Σ at interpolation points chosen at high frequencies. By contrast, the ODE part Σ_o is designed such that it compensates for the error between Σ and Σ_c at interpolation points in the low-frequency range.

Simulations

In this section, we apply the presented model reduction technique to a model for MPD [2]. Fig. 1 shows the response of the downhole pressure in the annulus to step changes in the input u , consisting of the choke opening and pump flow. As can be observed, the nonlinear cascaded approximation yields an accurate approximation of the original system response, obtained from a discretization, especially in capturing the staircase pressure profile induced by wave propagation effects characteristic to the PDE model.

Figure 1: (Left) A simplified schematic of a drilling system with MPD equipment, (right) comparison between the time-domain response of the reduced nonlinear model and the original model for the bottom-hole pressure (pressure in the annulus at $\xi = 0$).

Conclusions

This abstract presented a model reduction technique for systems of hyperbolic partial differential equations with nonlinear boundary conditions. The reduction is achieved by, first, decomposing the model into a feedback interconnection of a linear infinite-dimensional subsystem and a nonlinear mapping and, second, approximating the linear part by a series connection of a system of delay difference equations and a system of ordinary differential equations. The high accuracy of the approximation has been verified by application to a model for managed pressure drilling.

Summary. In engineering dynamics, model updating is typically applied to minimize the mismatch between a physical system and its digital twin. This paper proposes to use inverse mapping models, based on Gaussian Processes (GPs). The latter are trained offline using simulated data, enabling fast online updating of physically interpretable parameter values in first-principles-based nonlinear dynamics models. The GPs infer parameter values based on time-domain features measured on the real system. Additionally, GPs enables uncertainty quantification of the inferred parameter values. A nonlinear multibody model is used to illustrate the capability of this method to update parameter values, with high computational efficiency, and extract corresponding uncertainty measures.

Introduction

Digital twins allow engineers to optimize the design and performance of a (controlled) physical system, and monitor systems in real-time. Since, a model (i.e., a digital twin) is, not an exact representation of the physical system, fruitful employment of the digital twin is hindered. Model updating is therefore used to minimize the mismatch between the model and the measured system. In this research, we focus on updating parameter values of first-principles models with fixed model structures. To make model updating generally applicable in an online, digital twin context, the updating method should be: 1) computationally fast, 2) applicable to nonlinear models, 3) physically interpretable, and 4) able to quantify the uncertainty in the parameter estimates. The method introduced here uses inverse mapping models, based on Gaussian Processes (GPs): a set of measured features is mapped to a set of corresponding parameter values. Additionally, the GPs yield a quantification of the uncertainty in the estimated parameter values. Although this method has previously been applied to linear systems [3], here, we extend its application to nonlinear systems by using time-domain features.

Methodology

Inverse models are used to, online, rapidly map a set of measured time-domain output features to a set of physically interpretable parameter values of a first-principles (or forward) model, see Figure 1. Parameterizing the forward model with the inferred parameter values, results in an updated model that, when used in a simulation, yields a set of output features close in similarity to the original, measured features. In this research, the output features are defined as samples of the output signals at equidistant moments in time. In contrast to earlier work of the authors [2], in which a neural network is used to define the inverse mapping model, here, GPs are used. Due to the use of GPs, in addition to inferred parameter values, a quantification of the uncertainty in each inferred parameter value is obtained in the form of a standard deviation. For each updating parameter, a separate GP is trained offline using training data. These data are obtained by simulating the forward model and extracting features from the simulated output signals for a number of distinct combinations of updating parameter values, distributed in some admissible updating parameter space \mathbb{P} . Note that the excitation signals and initial conditions used to obtain the training data should be identical to those used for the real measurements as these are implicitly learned by the GPs. Furthermore, the forward model structure is assumed sufficiently accurate.

Figure 1: Schematic representation of in- and outputs to first-principles models and inverse models for model updating.

Case study: a nonlinear multibody system

The GP-based updating method is applied to a two-degrees-of-freedom nonlinear multibody system consisting of two connected rigid beams of mass m_1 and m_2 , respectively, see Figure 2. The $n_p = 4$ updating parameters are: damping constants d_y , d_θ , and spring constants k_y , and k_θ , where we assume that their values lie between the bounds of the parameter set $\mathbb{P} \subset \mathbb{R}^{n_p \times 1}$, specified in Table 1. The system is simulated for 5 seconds with the static equilibrium position of the system, parameterized with parameter values in the center of \mathbb{P} , as initial condition. For the output features, 100 equidistant time samples, of both the $y(t)$ and $\theta(t)$ output signals, are used per sample. To mimic real measurements, these output signals are contaminated by output noise (zero mean, $\sigma_y = 5 \times 10^{-5}$ m, $\sigma_\theta = 0.015$ rad). The system is excited by an impulse-like excitation force $F(t)$ and moment $M(t)$:

$$F(t) = \begin{cases} 5 & \text{N} & \text{if } 0.2 \leq t \leq 0.25 \\ 0 & \text{N} & \text{else} \end{cases}, \quad (1) \quad M(t) = \begin{cases} 0.075 & \text{N} \cdot \text{m} & \text{if } 0.2 \leq t \leq 0.25 \\ 0 & \text{N} \cdot \text{m} & \text{else} \end{cases}. \quad (2)$$

Figure 2: Demonstrator model with non-updating parameter values. The location of the Center Of Mass (COM) is indicated by $y_{COM,2}$ and $z_{COM,2}$. Furthermore, g represents the gravitational acceleration and $I_{COM,2}$ the mass moment of inertia about the COM.

Figure 3: Inferred standard deviation of parameter value estimates for d_y in the subspace of \mathbb{P} spanned by k_y and k_θ .

Table 1: Updating parameters and their lower and upper bound of \mathbb{P} , bias, standard deviation, and mean absolute relative error.

Parameter	Lower bound	Upper bound	μ_ϵ [%]	σ_ϵ [%]	$\mu_{ \epsilon }$ [%]
d_y	0.9 N·s/m	1.1 N·s/m	0.1063	0.9374	0.7412
d_θ	1.75×10^{-4} N·m·s/rad	2.25×10^{-4} N·m·s/rad	-0.0991	1.3673	1.0880
k_y	5 N/m	15 N/m	-0.0004	0.3117	0.2128
k_θ	0.027 N·m/rad	0.045 N·m/rad	-0.0356	0.2581	0.2026

All n_p GPs are trained using the same 250 training samples, generated for as many combinations of updating parameter values, sampled using a Latin hypercube from \mathbb{P} . The squared exponential kernel is used in combination with a Gaussian likelihood and a constant valued mean function, of which the hyperparameters are optimized by minimizing the negative log marginal likelihood. For more information about these settings, the reader is referred to [1].

To demonstrate the proof of principle of the proposed method, output features of $n_t = 500$ test samples are simulated for distinct parameter values $\mathbf{p}(i) \in \mathbb{P}$ (where i indicates the sample), using equivalent settings for the simulation as for the training data generation. Here, all instances of $\mathbf{p}(i)$ are randomly distributed (uniformly) in \mathbb{P} . Then, the trained GPs are used to infer parameter values $\hat{\mathbf{p}}(i) \in \mathbb{P}$ from the simulated output features. To assess accuracy and precision of these inferred parameter values, the relative estimation error is calculated:

$$\epsilon_{\text{rel}}(i) = (\hat{\mathbf{p}}(i) - \mathbf{p}(i)) \oslash \mathbf{p}(i), \quad (3)$$

and used to determine the bias and standard deviation of the relative error, and the mean absolute relative error:

$$\mu_\epsilon = \frac{1}{n_t} \sum_{i=1}^{n_t} \epsilon_{\text{rel}}(i), \quad \sigma_\epsilon = \sqrt{\frac{1}{n_t - 1} \sum_{i=1}^{n_t} (\epsilon_{\text{rel}}(i) - \mu_\epsilon) \otimes (\epsilon_{\text{rel}}(i) - \mu_\epsilon)}, \quad \mu_{|\epsilon|} = \frac{1}{n_t} \sum_{i=1}^{n_t} |\epsilon_{\text{rel}}(i)|. \quad (4)$$

In (3) and (4), \oslash and \otimes denote the entrywise division and multiplication operators, respectively. In Table 1, these error metrics are listed for all updating parameters. As displayed by the low error metrics, these parameters are inferred accurately (low bias) and precisely (low standard deviation). Furthermore, Figure 3 shows the inferred standard deviation in d_y , representing the quantification of the uncertainty in the estimated parameter values, as obtained by the GP, for all test samples in the subspace of \mathbb{P} spanned by k_y and k_θ . Note that the largest inferred standard deviations are located at the edges of \mathbb{P} (especially the edge where $k_y \approx 5$ N/m). The time required to infer all parameter values and their inferred standard deviations is only 13 ms, enabling fast, credible parameter value updating.

Conclusions and future work

In this work, Gaussian Processes are used as inverse mapping models to efficiently update physically interpretable parameter values of a nonlinear multibody model using time-domain features. Additionally, inferred standard deviations, provided by the GPs, provide a quantification of the uncertainty in the updated parameter values. However, costwise, GPs scale poorly with an increasing number of training samples [1]. Consequently, applications to updating problems with many updating parameters may become infeasible. Therefore, in future work, we will investigate Bayesian neural networks as an alternative for inverse mapping models. Furthermore, to improve the sensitivity of the inverse mapping model, optimal excitation design, feature extraction, and feature selection techniques should be explored further.

Nonlinear Modal Testing of Structures with Nonlinear Dissipation

Maren Scheel* and Malte Krack*
 *University of Stuttgart, Stuttgart, Germany

Summary. The dynamics of many technical structures are characterized by both conservative and non-conservative nonlinear forces, which are often challenging to model. Alternatively, a nonlinear model can be identified from experimental data, yielding amplitude-dependent modal properties, which can also serve for model validation or model updating purposes. In this contribution, we present a nonlinear modal testing approach that allows for extracting modal properties for systems with nonlinear damping caused by various types of nonlinearities. Models based on these modal properties describe well the systems' steady-state dynamics around an isolated resonance.

Introduction

Technical structures are usually assembled by several parts, connected through joints. These joints are a common source of nonlinear, dissipative forces due to dry friction. To accurately predict vibrations of such structures, the nonlinear force-deflection relations have to be modeled. In particular, physical processes causing damping are in many cases inherently nonlinear and are properly described only by nonlinear hysteresis models. Therefore, experiments are crucial in order to estimate parameters for the purpose of model updating or to validate numerical models. To this end, experimental methods are needed, which are suited for structures under the influence of conservative and non-conservative nonlinear restoring forces. Different approaches for nonlinear system identification have been suggested in the last years [1]. One approach is to employ the concept of nonlinear vibration modes. If nonlinear forces play a significant role, one set of linear modal properties is of limited use, and nonlinear, i.e. amplitude-dependent, modal properties are needed. These can, for example, be extracted by analyzing the freely decaying response. If the structure is subjected to high damping, e.g. due to joints, the motion decays quickly, which is challenging from a signal analysis perspective. In such cases, using force appropriation to excite steady-state motion is preferable because it allows for a fine frequency resolution and straight-forward signal analysis. Force appropriation can be ensured using controlled excitation, for example with a phase-locked loop [2, 3] or control-based continuation [4]. In this contribution, we successfully apply a nonlinear modal testing method that utilizes steady-state force appropriation to experimentally extract amplitude-dependent modal properties of structures with nonlinear dissipation. The proposed approach is robust against noise and time efficient, which reduces the risk of damaging the specimen. Moreover, the method does not require any prior knowledge on the type or location of the nonlinearity. Using controlled excitation or a control-free alternative, the method overcomes problems related to stability loss of periodic responses, such as jumps, which often hamper the applicability of common frequency response testing (frequency stepping or sweeping). Once the modal properties are identified, it is no longer necessary to measure the frequency response around a resonance, since this can be accurately predicted by assuming that the vibration energy is confined to a single nonlinear mode. The applicability of the nonlinear modal oscillator is, however, limited to single-frequency, near-resonant forcing.

Nonlinear Modal Testing Method

The proposed nonlinear modal testing method is based on the extended periodic motion concept [5], which was introduced to study periodic motion of damped systems, close to a primary resonance. A nonlinear mode according to this concept is a periodic motion of an autonomous system. Periodicity is enforced by an artificial negative damping term that compensates the dissipated energy over one cycle of vibration. In the absence of strong modal interactions, a single nonlinear mode according to this definition accurately describes the steady-state forced response near resonance.

In an experiment, the negative damping term can be approximated by external forcing. We have shown that applying a force at only one location is sufficient for many structures. The excitation force must be in local phase resonance with respect to the fundamental harmonic of the response [6], which is ensured using a phase-locked loop controller, adapting the excitation frequency until local phase resonance is achieved. Alternatively, the system's velocity is scaled and fed back as excitation signal [7]. Varying the excitation amplitude, the amplitude-dependent resonance frequency (i.e. the backbone) is measured. From the Fourier transform of the measured steady-state time signals, the resonance frequency as well as the deflection shapes are extracted, and the modal damping ratio is obtained with a power balance [6].

Experimental Nonlinear Modal Analysis of a Strongly Friction-Damped Beam

The proposed nonlinear modal testing method has been applied to specimens with different sources of nonlinear dissipation such as bolted joints but also systems with nonlinear stiffness such as hardening behavior due to geometric nonlinearities or opponent magnets. Another test case is a cantilevered beam called RubBeR, which is strongly damped by dry friction [8]. This test rig is challenging due to the large increase in damping and frequency shift as well as a significant local mode shape change. The friction is caused by relative motion between the beam and fixed steel plates. The preload at the contact interface is set such that both full-stick and macro-slip is observed in the excitation range of the used shaker. The first bending mode's resonance frequency with full-stick contact is about 111.3 Hz, identified at

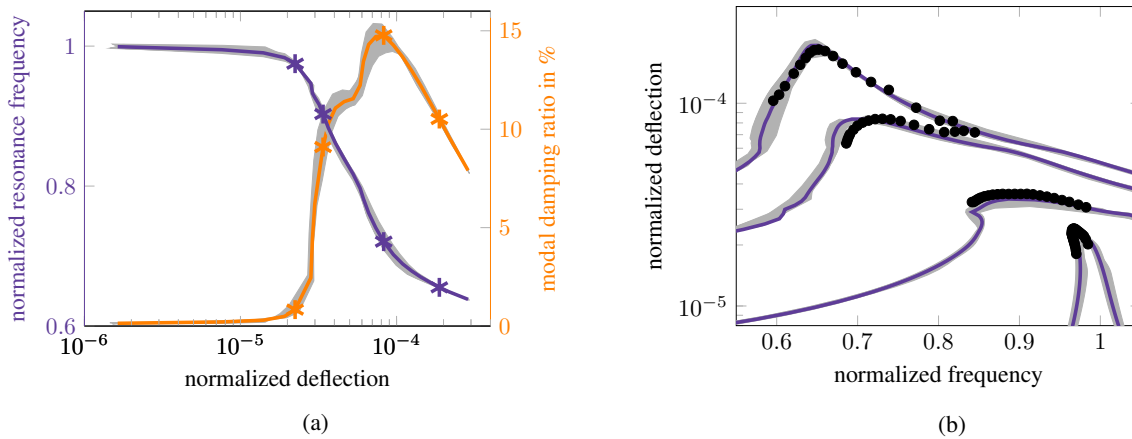

Figure 1: (a) Amplitude-dependent resonance frequency and modal damping ratio and (b) predicted (solid lines) and measured (dots) frequency responses of a friction-damped beam.

low excitation levels. The amplitude-dependent resonance frequencies and modal damping ratios are shown in Fig. 1a. The resonance frequency is normalized with the full-stick frequency, and the deflection amplitude is the amplitude at the beam's tip normalized with the beam's length. The well-known characteristics for friction-damped systems are observed: For low amplitudes, the resonance frequency is constant, but decreases with increasing vibration amplitude, here for normalized deflections above $2 \cdot 10^{-5}$. At the same time, the modal damping ratio increases drastically and decreases again for large amplitudes. For this specimen, the decrease in frequency is about 36 % and the modal damping ratio increases from about 0.1 % to about 15 %. By measuring backbones several times (not modifying the setup), the deviation of the modal properties due to the variance inherent to the test rig is assessed. The measurements are very well repeatable, leading to only a small spread of the extracted modal properties (gray-shaded areas in Fig. 1a with the average plotted with solid lines).

Assuming that the vibration energy is confined to a single nonlinear mode, the system behaves like a single degree-of-freedom oscillator. To assess the usefulness of the extracted properties, the oscillator is set up with the identified amplitude-dependent modal properties [6] and harmonically forced at four different excitation levels. The predicted frequency responses are plotted with solid lines in Fig. 1b and the predictions' spread based on the nonlinear modal properties' spread is indicated with the gray-shaded area. The reference frequency responses (black dots) were obtained with controlled stepped sine measurements. The deviation between predictions and reference measurements is small in comparison with the repeatability band. The very good agreement indicates that the nonlinear-modal oscillator with the properties shown in Fig. 1a is capable of describing frequency responses close to an isolated resonance.

Conclusions

In the absence of strong modal interactions, the proposed nonlinear modal testing method allows for extracting amplitude-dependent modal properties, i.e. resonance frequency, modal damping ratio and deflection shape, for systems with nonlinear dissipation. For all tested specimens, the single nonlinear-mode oscillator based on the identified modal properties describes well the steady-state dynamics around an isolated resonance. Therefore, a simplified single-point excitation mechanism with phase control of the fundamental harmonic or feeding back a scaled velocity signal is sufficient to extract accurate modal properties of structures with nonlinear dissipation. The concept of local phase resonance is, however, applicable only to structures with a diagonal dominant mass matrix (e.g. slender structures). Using single-point excitation for velocity feedback can cause gyroscopic forces that deteriorate the mode isolation quality.

Finite-time tracking control of a nonlinear string to reference dynamics

Marc Wijnand¹, Thomas Hélie² and David Roze²

S3AM team, STMS Lab (IRCAM – ²CNRS – ¹Sorbonne Université), Paris, France

marc.wijnand@ircam.fr

Summary. This paper is concerned with the active control of a string. A nonlinear Kirchhoff-Carrier model of the transverse vibration of a string is considered (presenting a pitch glide at high excitation levels), controlled by a force in its domain. A finite-time tracking controller is designed for a point force, that controls one mode of the string to reference dynamics corresponding to a string with other physical parameters. We illustrate in a simulation how the controller can be used to modify the damping, resonance frequency or the presence of a pitch glide for the selected mode of vibration of the string.

A preliminary version of this work has appeared in [1, Ch. 8].

Introduction

Active vibration control

In a lot of engineering applications, vibration is unwanted as it leads to negative side-effects such as increased wear of components or time and quality loss in production processes. Therefore, numerous *active vibration control* methods have been developed [2, 3], that aim at reducing parasitic vibration.

If a system representation based on the vibration modes is considered, the term *modal control* is used.

Active control of musical instruments

Active control of musical instruments consists in adding a control loop to an existing acoustic musical instrument that is being played by a musician. The terms *augmented* or *hybrid musical instruments* are also used. In some cases, communication to other devices is included, and the term *smart instruments* is used [4].

In terms of the actuator type, two classes of active vibration control are distinguished. In the case of *acoustical active control*, the control acts on a fluid medium. An example is the use of a loudspeaker to create destructive interference in order to cancel sound. In the case of *structural acoustical control*, the control acts on a solid. One can for example attach an actuator to the soundboard of a violin.

In most cases of active control of musical instruments, the goal is not to reduce vibrations as much as possible, but to change frequencies or damping coefficients of the instrument's vibration, enabling the musician to enlarge his sound palette while keeping the ergonomics of the original instrument. One can mention for instance applications to the (xylophone) beam [5], (clarinet) tube [6], (Chinese gong) metal plate [7] and (tom) membrane [8].

Furthermore, active control of musical instruments can be invoked for the study of their dynamical behaviour [9], or for the removal of unwanted phenomena such as the so-called wolf note of the cello [10], or the bad playability of certain notes on the trombone when using a straight mute [11].

Active control of a string

There exists a considerable amount of results concerning the vibration suppression of the string, both in the linear case and using models with different kinds of nonlinearities. The string can be actuated at its boundaries or in its domain, sometimes taking into account ODE dynamics of systems coupled to the string. A broad variety of control design methods have been used, that have been tested in simulation and experimentally.

In particular, tracking control has been used in [12, 13] where a boundary control to a string is designed that lets a mass attached to it follow a reference position. In applications involving axially moving strings, axial velocity tracking has also been used [14].

Active control of a musical string

In a musical context, the goal of active control is to influence the vibration of strings present in violins, pianos, guitars, etc. and that are made of a variety of materials such as nylon and metal. Used string displacement sensors can be electromagnetic [15], piezoelectric [16] or optical (for example [17, 18]). As string actuator, one can use an electromagnetic actuation (for example with the commercially available *EBow* [19] or the alternative [20] in the case of metal strings, or the use of a magnet attached to a nonmagnetic string [17]), or a piezoelectric actuator [21].

Concerning the control of an isolated string, following results have been reported. In [22], the principles of a PID control of a string are discussed, using a collocated sensor and actuator, and enabling to modify resonance frequency and damping. Furthermore, several experimental setups for string control have been considered. In [23], a metal guitar string of length 24 cm tuned to 248 Hz was damped using an optical sensor and an electromagnetic actuator [20]. In [24], the first five modes of a guitar string were damped using a feedback measuring string displacement with a laser, and an electromagnetic actuation. In [21], the setup consisted of a metal guitar string of 50 cm tuned to 220 Hz, an optical string displacement sensor and a piezoelectric actuator at one end of the string. Based on traveling wave control concepts, active damping is achieved, and nonlinearities can be injected, leading to timbral effects.

Active control of other instrument parts coupled to the vibrating string is also possible, such as the violin bridge [25] and the soundboard of a monochord, acoustical guitar and cello [26]. In [27], the construction of a piano with active control is reported, with a piezoelectric sensor on the soundboard and electromagnets over the 88 sets of strings actuators. It is

possible to generate infinite sustain, crescendo on a note and different timbral effects. Finally, an embedded control system using multiple sensors and actuators can be found in some commercially available instruments such as the *Sensus Smart Guitar* (MIND Music Labs, [4]) and the *Smart Acoustic Guitar* (HyVibe, [28]).

Aim and structure of the present paper

This contribution is concerned with the control of a selected mode of the nonlinear Kirchhoff-Carrier string model by a point force for which a finite-time tracking control law is developed. First, the nonlinear string model is recalled, recast as a Port-Hamiltonian System, and projected on the modes of the linearized system. Next, the finite-time tracking controller for a chosen mode is developed, enabling to track a reference trajectory representing a mode with modified physical parameters. Finally, the effect of the control law is illustrated by a simulation.

Nonlinear string model

The Kirchhoff-Carrier string model is recalled. This PDE is subsequently recast as a Port-Hamiltonian system, to which an order reduction by modal projection and truncation is applied. Thus, each mode is represented by a coupled nonlinear ODE.

PDE model

The nonlinear Kirchhoff-Carrier model for the transverse vibrations $w(z, t)$ [m] of a string of length L [m] is considered [29, 30]:

$$\rho A \partial_{tt} w(z, t) + \rho A \mu \partial_t w(z, t) - \left(T_0 + \frac{EA}{2L} \int_{\Omega} (\partial_z w(z, t))^2 dz \right) \partial_{zz} w(z, t) = \frac{1}{L} u(z, t), \quad (1)$$

with ρ [kg/m³] the mass density, A [m²] the circular cross-section, μ [1/s] a positive coefficient representing viscous damping (see [31, §5.3.2]), T_0 [N] the tension, E [Pa] Young's modulus of elasticity and $u(z, t)$ [N] the distributed exciting force defined on $(z, t) \in \Omega \times \mathbb{R}^+$, $\Omega = [0, L]$. The nonlinearity is due to the variation of tension expressed by the integral term $\frac{EA}{2L} \int_{\Omega} (\partial_z w(z, t))^2 dz$ (with $EA \gg T_0$, [32, Ch. 8]), leading to the pitch-glide phenomenon (illustrated in the *Simulation* Section). The string is fixed at its ends (Dirichlet boundary condition) and initially at rest:

$$\begin{aligned} w(z=0, t) &= 0 & w(z=L, t) &= 0 & \forall t \in \mathbb{R}^+ \\ w(z, t=0) &= 0 & \dot{w}(z, t=0) &= 0 & \forall z \in \Omega. \end{aligned}$$

This setup is depicted in Fig. 1.

Figure 1: Setup of the PDE model for a string that is initially at rest ($w(z, t) = 0$) and subjected to a distributed force $u(z, t)$

Port-Hamiltonian system model

Components of an open physical system can (1) exchange energy inside the system; (2) dissipate energy; (3) exchange energy with the exterior of the system through ports. The power balance of the system is satisfied at all time. This is taken into account in the Port-Hamiltonian framework [33].

An infinite-dimensional Port-Hamiltonian system (PHS) can be defined as [34, 35]

$$\begin{cases} \partial_t \mathbf{x} = (\mathcal{J} - \mathcal{R}) \delta_{\mathbf{x}} \mathcal{H}(\mathbf{x}) + \mathcal{G} \mathbf{u} \\ \mathbf{y} = \mathcal{G}^* \delta_{\mathbf{x}} \mathcal{H}(\mathbf{x}), \end{cases}$$

where

- the state \mathbf{x} belongs to the energy state space \mathbb{X} ;
- a scalar product $\langle \cdot, \cdot \rangle_{\mathbb{X}}$ and norm $\| \cdot \|_{\mathbb{X}}$ are defined;
- the Hamiltonian function is defined as $\mathcal{H}(\mathbf{x}) \triangleq \frac{1}{2} \| \mathbf{x} \|_{\mathbb{X}}^2$;
- the operator $\delta_{\mathbf{x}}$ is the variational derivative [35];

- the interconnection operator \mathcal{J} is formally skew-symmetric and the dissipation operator \mathcal{R} is non-negative symmetric, w.r.t. the scalar product;
- the product of the input u and its associated output y represents the power applied to the system via the ports;
- \mathcal{G}^* represents the adjoint operator of the operator \mathcal{G} .

In the finite-dimensional case ($x \in \mathbb{R}^n$), the operators become matrices and δ_x is replaced by the gradient ∇_x [33]. We refer the reader to [36, 37] where the example of a (non)linear mass-spring-damper system is treated.

Next to modeling physical systems, the PHS formalism provides a framework for the development of stable simulation [38] and control [39] methods.

Port-Hamiltonian string model

As shown in [40], the nonlinear string (1) can be recast as an infinite-dimensional Port-Hamiltonian System with state $x^T(z, t) \triangleq [q(z, t) \ p(z, t)] \triangleq [\partial_z w(z, t) \ \partial_t w(z, t)]$, and nonquadratic Hamiltonian function [32, Ch. 8]

$$\mathcal{H}(x(z, t)) = \frac{\rho A}{2} \int_{\Omega} p^2(z, t) dz + \frac{1}{2} \left[T_0 + \frac{EA}{4L} \int_{\Omega} q^2(z, t) dz \right] \int_{\Omega} q^2(z, t) dz, \quad (2)$$

leading to the following infinite-dimensional PHS formulation:

$$\begin{cases} \frac{d}{dt} \begin{bmatrix} q \\ p \end{bmatrix} = \left(\begin{bmatrix} 0 & \frac{1}{\rho A} \partial_z \\ \frac{1}{\rho A} \partial_z & 0 \end{bmatrix} - \begin{bmatrix} 0 & 0 \\ 0 & \frac{1}{\rho A} \mu \end{bmatrix} \right) \begin{bmatrix} \delta_q \mathcal{H} \\ \delta_p \mathcal{H} \end{bmatrix} + \begin{bmatrix} 0 \\ \frac{1}{\rho A L} \end{bmatrix} u \\ y = \begin{bmatrix} 0 & \frac{1}{\rho A L} \end{bmatrix} \begin{bmatrix} \delta_q \mathcal{H} \\ \delta_p \mathcal{H} \end{bmatrix}, \end{cases} \quad (3)$$

with the variational derivative of the Hamiltonian function (2) equal to

$$\delta_x \mathcal{H}(x(z, t)) = \begin{bmatrix} \delta_q \mathcal{H}(x(z, t)) \\ \delta_p \mathcal{H}(x(z, t)) \end{bmatrix} = \begin{bmatrix} \left(T_0 + \frac{EA}{2L} \int_0^L q^2(z, t) dz \right) q(z, t) \\ \rho A p(z, t) \end{bmatrix}.$$

The input $u(z, t)$ being the force applied to the string, and the output $y(z, t) = (1/L) \partial_t w(z, t)$ with $\partial_t w(z, t)$ the transverse velocity, the expression $\int_{\Omega} u(z, t) y(z, t) dz$ [W] represents the instantaneous external power transferred to the string.

Modal projection and order reduction

The infinite-dimensional PHS model (3) is projected on the N first eigenmodes of the linear string (Eq. (1) without the term $\frac{EA}{2L} \int_{\Omega} (\partial_z w(z, t))^2 dz$), that are given by $e_n(z) = \sqrt{\frac{2}{L}} \sin\left(\frac{n\pi}{L} z\right)$, $n > 0$ (Fig. 2):

$$w(z, t) \approx \sum_{n=1}^N e_n(z) W_n(t).$$

Figure 2: First 6 eigenmodes $e_n(z)$ of the linear string of length L . The nodes (stationary points) are indicated by dots.

Then, defining

$$x(z, t) = \begin{bmatrix} \frac{d}{dz} e_1(z) \dots \frac{d}{dz} e_N(z) & \mathbf{O}_{1 \times N} \\ \mathbf{O}_{1 \times N} & e_1(z) \dots e_N(z) \end{bmatrix} \begin{bmatrix} \mathbf{W}(t) \\ \frac{d}{dt} \mathbf{W}(t) \end{bmatrix} = \Phi^\top(z) \mathbf{X}(t), \quad (4)$$

the Hamiltonian function $\mathcal{H}(x(z, t)) = \frac{1}{2} \int_0^1 x^\top(z, t) \mathcal{M}(z, t) x(z, t) dz$ (2) becomes

$$H(\mathbf{X}(t)) = \frac{1}{2} \int_0^1 \mathbf{X}^\top(t) \Phi(z) \mathcal{M}(z, t) \Phi^\top(z) \mathbf{X}(t) dz = \frac{1}{2} \mathbf{X}^\top(t) \mathbf{M}_N(t) \mathbf{X}(t),$$

with

$$\mathbf{M}_N(t) = \begin{bmatrix} \mathbf{D}_N^2 (T_0 + \frac{EA}{4L} \mathbf{X}^\top(t) \mathbf{N}_N \mathbf{X}(t)) & \mathbf{O}_{N \times N} \\ \mathbf{O}_{N \times N} & \rho A \mathbf{I}_{N \times N} \end{bmatrix}, \quad \mathbf{N}_N = \begin{bmatrix} \mathbf{D}_N^2 & \mathbf{O}_{N \times N} \\ \mathbf{O}_{N \times N} & \mathbf{O}_{N \times N} \end{bmatrix}, \quad \mathbf{D}_N^2 = \frac{\pi^2}{L^2} \text{diag}(1, 2^2, \dots, N^2).$$

Next, premultiplying the first equation of the PHS (3) by $\Phi(z)$, integrating it w.r.t. $z \in \Omega$, substituting (4) and using the localized controller setup (7) that will be defined below, one obtains following finite-dimensional PHS:

$$\begin{cases} \frac{d}{dt} \mathbf{X}(t) = \left(\frac{1}{\rho A} \begin{bmatrix} \mathbf{O}_{N \times N} & \mathbf{I}_{N \times N} \\ -\mathbf{I}_{N \times N} & \mathbf{O}_{N \times N} \end{bmatrix} - \frac{\mu}{\rho A} \begin{bmatrix} \mathbf{O}_{N \times N} & \mathbf{O}_{N \times N} \\ \mathbf{O}_{N \times N} & \mathbf{I}_{N \times N} \end{bmatrix} \right) \begin{bmatrix} \mathbf{D}_N^2(T_0 + \frac{EA}{2L} \mathbf{X}^\top(t) \mathbf{N}_N \mathbf{X}(t)) & \mathbf{O}_{N \times N} \\ \mathbf{O}_{N \times N} & \rho A \mathbf{I}_{N \times N} \end{bmatrix} \mathbf{X}(t) \\ \quad + \frac{1}{\rho A L} \begin{bmatrix} \mathbf{O}_{N \times 1} \\ \varphi_1 \\ \vdots \\ \varphi_N \end{bmatrix} U(t) \\ y(z, t) = [0 \quad \frac{1}{L}] \Phi^\top(z) \mathbf{X}(t), \end{cases} \quad (5)$$

with $\varphi_n \triangleq e_n(\ell)$, and ℓ and $U(t)$ will be defined by (7).

The $(N + n)^{\text{th}}$ line of the dynamics for $\mathbf{X}(t)$ gives

$$\ddot{W}_n(t) = -\frac{1}{\rho A} n^2 \frac{\pi^2}{L^2} \left(T_0 + \frac{EA}{2L} \Sigma(t) \right) W_n(t) - \mu \dot{W}_n(t) + \frac{\varphi_n}{\rho A L} U(t), \quad (6)$$

where

$$\Sigma(t) \triangleq \sum_{n=1}^N n^2 \frac{\pi^2}{L^2} W_n^2(t).$$

Each mode n is a nonlinear oscillator with a coupling to the other modes due to the term $\Sigma(t)$, and that is controlled by $U(t)$.

Finite-time tracking control

Hypotheses concerning the control layout are made and the control goal is stated. Then, an existing finite-time control law is applied to obtain the tracking controller that will control one mode of the nonlinear string (5) to chosen reference dynamics.

Controller setup

Following hypotheses are made.

1. (*Point force*) We use a single actuator that is able to deliver a localized force $U(t)$ [N]:

$$u(z, t) \triangleq \delta(z - \ell) U(t), \quad (7)$$

with $\delta(z - \ell)$ the Dirac delta distribution that activates the control law $U(t)$ at the position $z = \ell$ (cf. Fig. 3).

Furthermore, we suppose here that the application of a force at $z = \ell$ does not modify the eigenmodes $e_n(z)$. Then, one can write

$$u(z, t) = \sum_{n=1}^N \langle u(z, t), e_n(z) \rangle \cdot e_n(z) = \sum_{n=1}^N e_n(\ell) U(t) \cdot e_n(z) \triangleq \sum_{n=1}^N \varphi_n U(t) \cdot e_n(z).$$

Because of this hypothesis, the force $\varphi_n U(t)$ is applied to each mode n . Therefore, only one mode can be controlled at a time.

Figure 3: String that is initially at rest, subjected to a point force at $z = \ell$, and with an initial velocity applied at $z = l$ (see *Simulation*)

2. (*Known state*) It is supposed that the entire state $\mathbf{X}(t)$ of the projected PHS model (5) is known from the measured system output¹ $\mathbf{y}_{\text{meas}}(z, t)$, possibly after using an observer.

¹In general, the measured output $\mathbf{y}_{\text{meas}}(z, t)$ differs from the PHS output $\mathbf{y}(z, t)$ defined as the conjugated variables with respect to the system input variables $\mathbf{u}(z, t)$, in the sense that $\int_{\Omega} \mathbf{u}(z, t) \mathbf{y}(z, t) dz$ represents the instantaneous power applied to the PHS.

Control goal

A system $\{\mathcal{S}\}$ described by (5) represents the dynamics of the first N modes of the nonlinear string with physical parameters (ρ, T_0, μ, E) . Following Hypothesis 1, our goal is to construct a controller $\{\mathcal{C}\}$ that lets one mode of the real system $\{\mathcal{S}\}$ track the dynamics of a virtual reference system $\{\mathcal{S}^*\}$ with desired physical parameters $(\rho^*, T_0^*, \mu^*, E^*)$, for an excitation by the same initial conditions (Fig. 4). To this means, a finite-time tracking controller will be designed.

Figure 4: Tracking control layout (i.c.: initial conditions). The dashed arrow represents the reference trajectory $\mathbf{X}^*(t)$ corresponding to the reference system $\{\mathcal{S}^*\}$ that is in reality simulated inside the controller $\{\mathcal{C}\}$.

Finite-time control

Finite-time control [41] is a nonlinear control method enabling to reach an equilibrium point in a finite time. This finite settling time is a stronger property than in the case of asymptotic or exponential control. Finite-time control has useful properties for time-constraint and robust control [42].

Finite-time stability of an ODE with state $\mathbf{x}(t) \in \mathbb{R}^n$ is defined as follows.

Definition 1 (Finite-time stability [42]) Let $\dot{\mathbf{x}} = \mathbf{F}(\mathbf{x})$ represent a closed-loop system, with $\mathbf{F}(\mathbf{x})$ continuous and $\mathbf{F}(\mathbf{0}) = \mathbf{0}$. Let $\Psi^t(\mathbf{x}_0)$ be the time evolution of the state for a given initial state \mathbf{x}_0 .

The origin is a finite-time stable equilibrium if there exists an open neighborhood $U \subset \mathbb{R}^n$ of the origin, where following statements hold:

1. **Finite-time convergence.** There exists a settling-time function $T : U \setminus \{0\} \rightarrow \mathbb{R}_{\geq 0}$ such that for each $\mathbf{x}_0 \in U \setminus \{0\}$, the evolution $\Psi^t(\mathbf{x}_0)$ is defined and unique on $t \in [0, T(\mathbf{x}_0)[$ and $\lim_{t \rightarrow T(\mathbf{x}_0)} \Psi^t(\mathbf{x}_0) = \mathbf{0}$.
2. **Lyapunov stability.** There exists a monotonically increasing function $\delta(\cdot)$, $\delta(0) = 0$, such that for each $\mathbf{x}_0 \in U$, $\|\Psi^t(\mathbf{x}_0)\| \leq \delta(\|\mathbf{x}_0\|)$ for each $t \geq 0$.

Furthermore, if $U = \mathbb{R}^n$, the origin is globally finite-time stable.

Several finite-time control laws have been designed for different kinds of ODE systems. They necessarily are non Lipschitz continuous at the equilibrium point [41]. For ODE systems of dimension $n = 2$, following law can be used.

Lemma 1 (Finite-time stabilisation of the double integrator [43]) The origin of the double integrator

$$\begin{cases} \dot{z}_1(t) = z_2(t) \\ \dot{z}_2(t) = v(t) \end{cases} \quad (8)$$

is finite-time stable for the control law

$$v(t) = -\kappa_1 [z_1(t)]^{\frac{\alpha}{2-\alpha}} - \kappa_2 [z_2(t)]^\alpha,$$

where $\kappa_1, \kappa_2 > 0$, $\alpha \in]0, 1[$ and $[z]^\alpha \triangleq \text{sign}(x)|x|^\alpha$.

No explicit expression for the dependence of the settling-time on the control parameters $(\kappa_1, \kappa_2, \alpha)$ is known. Therefore, these parameters have to be tuned numerically. We refer the reader to [37] for an application of this law to a (non)linear mass-spring-damper system.

Finite-time tracking control applied to the nonlinear string

A finite-time tracking controller is developed for a chosen mode $M \in \llbracket 1, \dots, N \rrbracket$ by imposing the dynamics of (8) to the error

$$e(t) \triangleq W_M(t) - W_M^*(t)$$

between the real modal displacement $W_M(t)$ and the reference modal displacement $W_M^*(t)$ of mode M . A finite-time stabilization of

$$W_M(t) \rightarrow W_M^*(t), \quad \dot{W}_M(t) \rightarrow \dot{W}_M^*(t)$$

is thus obtained for the error dynamics

$$\frac{d}{dt} \begin{bmatrix} e(t) \\ \dot{e}(t) \end{bmatrix} = \begin{bmatrix} \dot{e}(t) \\ -\kappa_1 [e(t)]^{\frac{\alpha}{2-\alpha}} - \kappa_2 [\dot{e}(t)]^\alpha \end{bmatrix}. \quad (9)$$

After substituting the expression (6) for the real ($W_M(t)$) and desired ($W_M^*(t)$) oscillators, one solves (9) for the control law $U(t)$, which corresponds to

$$U(t) = \frac{1}{\varphi_M} \left[-\rho AL \left(\kappa_1 [W_M - W_M^*]^{\frac{\alpha}{2-\alpha}} + \kappa_2 [\dot{W}_M - \dot{W}_M^*]^\alpha \right) + M^2 \frac{\pi^2}{L} \left(T_0 W_M - \frac{\rho}{\rho^*} T_0^* W_M^* + \frac{A}{2L} \left(E \Sigma W_M - \frac{\rho}{\rho^*} E^* \Sigma^* W_M^* \right) \right) + \rho AL \left(\mu \dot{W}_M - \mu^* \dot{W}_M^* \right) \right]. \quad (10)$$

Applying this finite-time tracking control law to the system \mathcal{S} will control its M^{th} mode to the M^{th} mode of the reference system \mathcal{S}^* . As previously mentioned, because of Hypothesis 1, we do not have additional degrees of freedom to act on the other modes $n \neq M$.

The design of the control parameters ($\kappa_1, \kappa_2 > 0, \alpha \in]0, 1[$) present in the tracking controller has to ensure that it has faster dynamics than the dynamics of the nonlinear string (by Tikhonov's theorem, see for instance [44, Theorem A.11]). Their values have to be assessed by a simulation, that is presented in the next session.

Simulation

A system $\{\mathcal{S}\}$ is considered, with physical parameters from [45, Table 1] representing a steel string with fundamental frequency $f = \frac{1}{2L} \sqrt{\frac{T_0}{\rho A}} = 55 \text{ Hz}$:

$$L = 1,8 \text{ m}, \quad A = \pi \cdot (1,5 \text{ mm})^2, \quad \rho = 7800 \frac{\text{kg}}{\text{m}^3}, \quad E = 2 \cdot 10^{11} \text{ Pa}, \quad \mu = 3 \frac{1}{\text{s}}, \quad T_0 = 2161 \text{ N}.$$

The string is excited by an initial velocity localized at $z = l$ (Fig. 3):

$$\dot{w}(z, 0) = V_0 \left[\frac{\text{m}}{\text{s}} \right] \cdot \delta(z - l),$$

whose projection on mode $e_n(z)$ yields the initial conditions $\dot{W}_n(0) = V_0 \sqrt{\frac{2}{L}} \sin\left(\frac{n\pi l}{L}\right)$, $n \in \llbracket 1, \dots, N \rrbracket$.

The controlled system $\{\mathcal{S} \& \mathcal{C}\}$ using control law (10) is simulated for two cases:

- ① a reference system $\{\mathcal{S}^*\}$ where the parameters (T_0, ρ, μ) of the linearized string model are modified for the mode $M = 2$, leading to a change in frequency and damping,
- ② a reference system $\{\mathcal{S}^*\}$ where the parameter E of the nonlinear string model is modified for the mode $M = 1$, leading to a modification of the pitch-glide effect.

The simulations are performed using the backwards Euler method [46] with time step $\delta t = 10^{-5} \text{ s}$, using $N = 10$ modes and initial conditions with $V_0 = 50 \frac{\text{m}}{\text{s}}$. Excitation location l and control location ℓ will be set in function of the shape of the chosen controlled mode M (cf. Fig. 2, and [22, §II.C]).

Example ①: frequency and damping modification

Modifying the tension T_0 and/or mass density ρ , one can change the frequency of the M^{th} mode: $f_M^* = \frac{M}{2L} \sqrt{\frac{T_0^*}{\rho^* A}}$, whereas modifying the damping coefficient μ enables to damp the string quicker (active damping) or less quick (infinite sustain).

We consider the case where the string is excited at $l = \frac{1}{4}L$ and controlled at $\ell = \frac{3}{4}L$. The mode $M = 2$ is controlled to a reference trajectory with $T_0^* = 1.12T_0$ and $\rho^* = 0.88\rho$ (corresponding to $f_2^* = 124 \text{ Hz} > f_2 = 110 \text{ Hz}$), $\mu^* = 1.5\mu$ (increased damping), $E^* = E$ (no pitch-glide modification). Control parameters $\kappa_i = 0.5 \cdot 10^{11}$ and $\alpha = 0.95$ were used. A tracking of the reference signal $W_2^*(t)$ is achieved by $W_2(t)$ under the action of the control law $U(t)$ (Fig. 5). The spectral content of the second mode (Fig. 7) confirms that its frequency was increased to f_2^* , and that the signal is damped more quickly.

One can observe the effects of the control law $U(t)$ on the other modes $n \neq 2$, such as the appearance of low-amplitude harmonics in the higher-order modes, that cannot be influenced in the current control setup. Furthermore, we note that the 4th mode is not excited by the initial conditions nor by the control law $U(t)$, as both are located at a node of this mode ($\dot{W}_4(0) = 0, \varphi_4 = 0$; cf. Fig. 2).

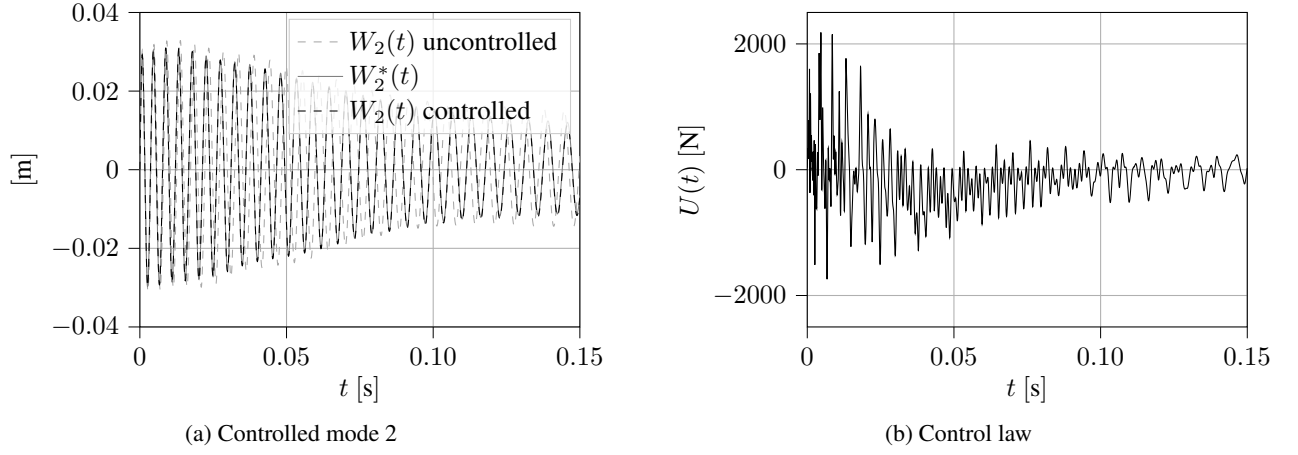

Figure 5: Example ①: controlled mode 2 and control law

Example ②: pitch-glide attenuation

A pitch glide is the nonlinear phenomenon where the frequency increases with increasing amplitude of the transverse vibration $w(z, t)$ of the string, because of the tension modulation expressed by the term

$$\frac{EA}{2L} \int_{\Omega} (\partial_z w(z, t))^2 dz$$

in (1). This phenomenon was visible in Example ① (Fig. 7).

In this second example, we consider the case where the string is excited at $l = 0.4L$ and controlled at $\ell = 0.5L$. The mode $M = 1$ is controlled to a reference trajectory with $T_0^* = T_0$ and $\rho^* = \rho$ (no frequency modification), $\mu^* = \mu$ (no damping modification) and $E^* = 0.3E$ (pitch-glide attenuation²). Control parameters $\kappa_i = 1 \cdot 10^{10}$ and $\alpha = 0.95$ were used.

A tracking of the reference signal $W_1^*(t)$ is achieved by $W_1(t)$ under the action of the control law $U(t)$ (Fig. 6). The spectral content of the first mode (Fig. 8) confirms that the pitch-glide phenomenon is attenuated.

Again, one can observe the effects of the control law $U(t)$ on the other modes $n \neq 1$, that cannot be influenced in the current control setup. In particular, the pitch-glide effect is increased for the second mode (and higher modes, although their amplitude is smaller), and harmonics appear in the higher-order modes.

Figure 6: Example ②: controlled mode 1 and control law

Conclusions and perspectives

A tracking controller was designed, that is able to modify physical model parameters of a chosen mode of a truncated modal model of a nonlinear Kirchhoff-Carrier string taking into account the pitch-glide phenomenon. Two use cases were illustrated in simulation, where frequency, damping and the pitch glide-phenomenon were modified, and the effect on the other modes was observed.

Future works include the consideration of a more realistic sensor and actuator setup taking into account their placement [22, §II.C] and the development of an observer in order to reconstruct the state. Furthermore, robustness of the controller against measurement noise or bad parameter estimation can be assessed.

²A reference stiffness of $E^* = 0$ would correspond to a pitch-glide removal, but requires unrealistic force levels of 30 kN for $U(t)$. This control goal was used in the preliminary simulation shown in [1, §8.4]. An analysis of the required control power as in [22, Appendix B] is not performed here.

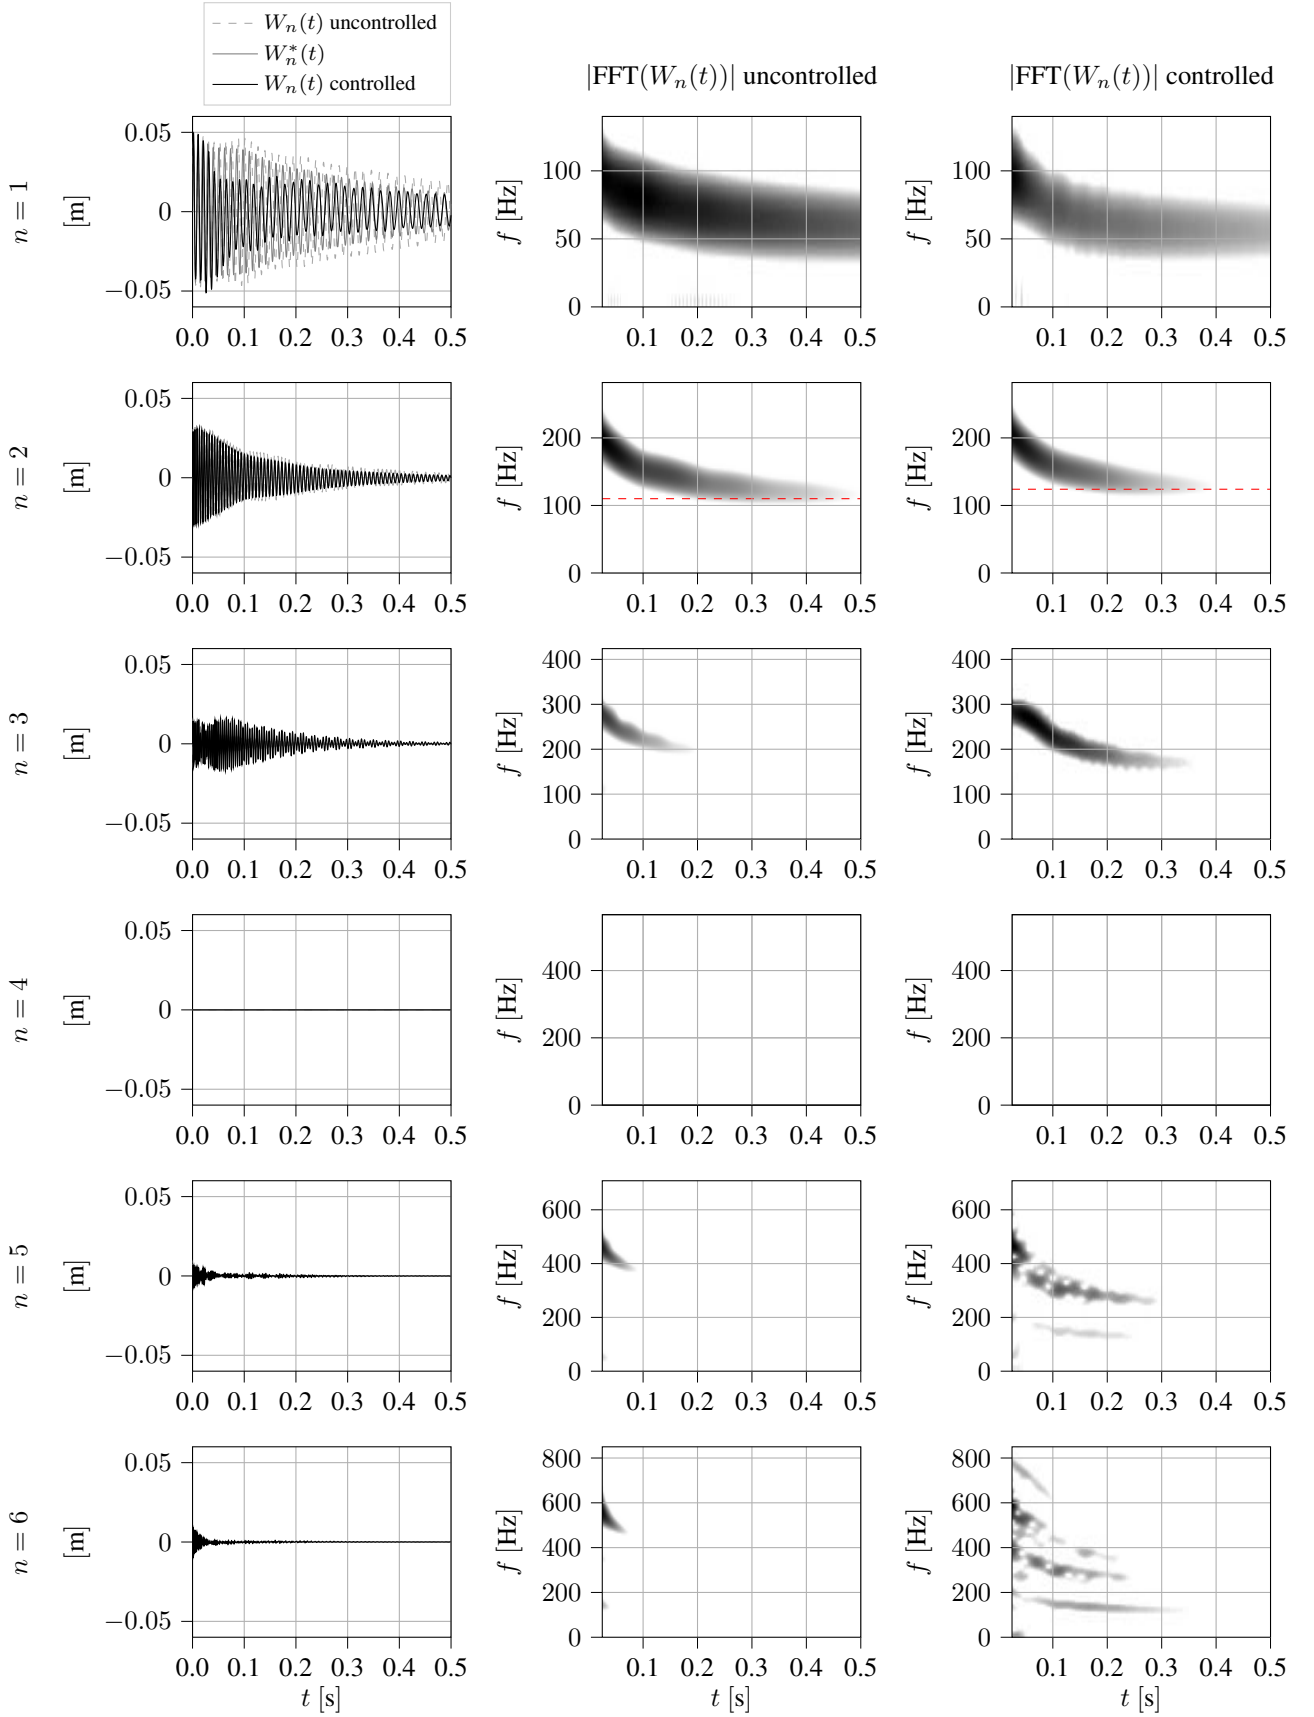

Figure 7: Example ①: time evolution and spectral content of the first 6 modes. The FFT is calculated using a Hann window and the same logarithmic color scale is used for the (un)controlled cases of a given mode. Red dashed lines indicate the asymptotic values of the frequencies (corresponding to the linearized string model) for mode 2 in the (un)controlled cases.

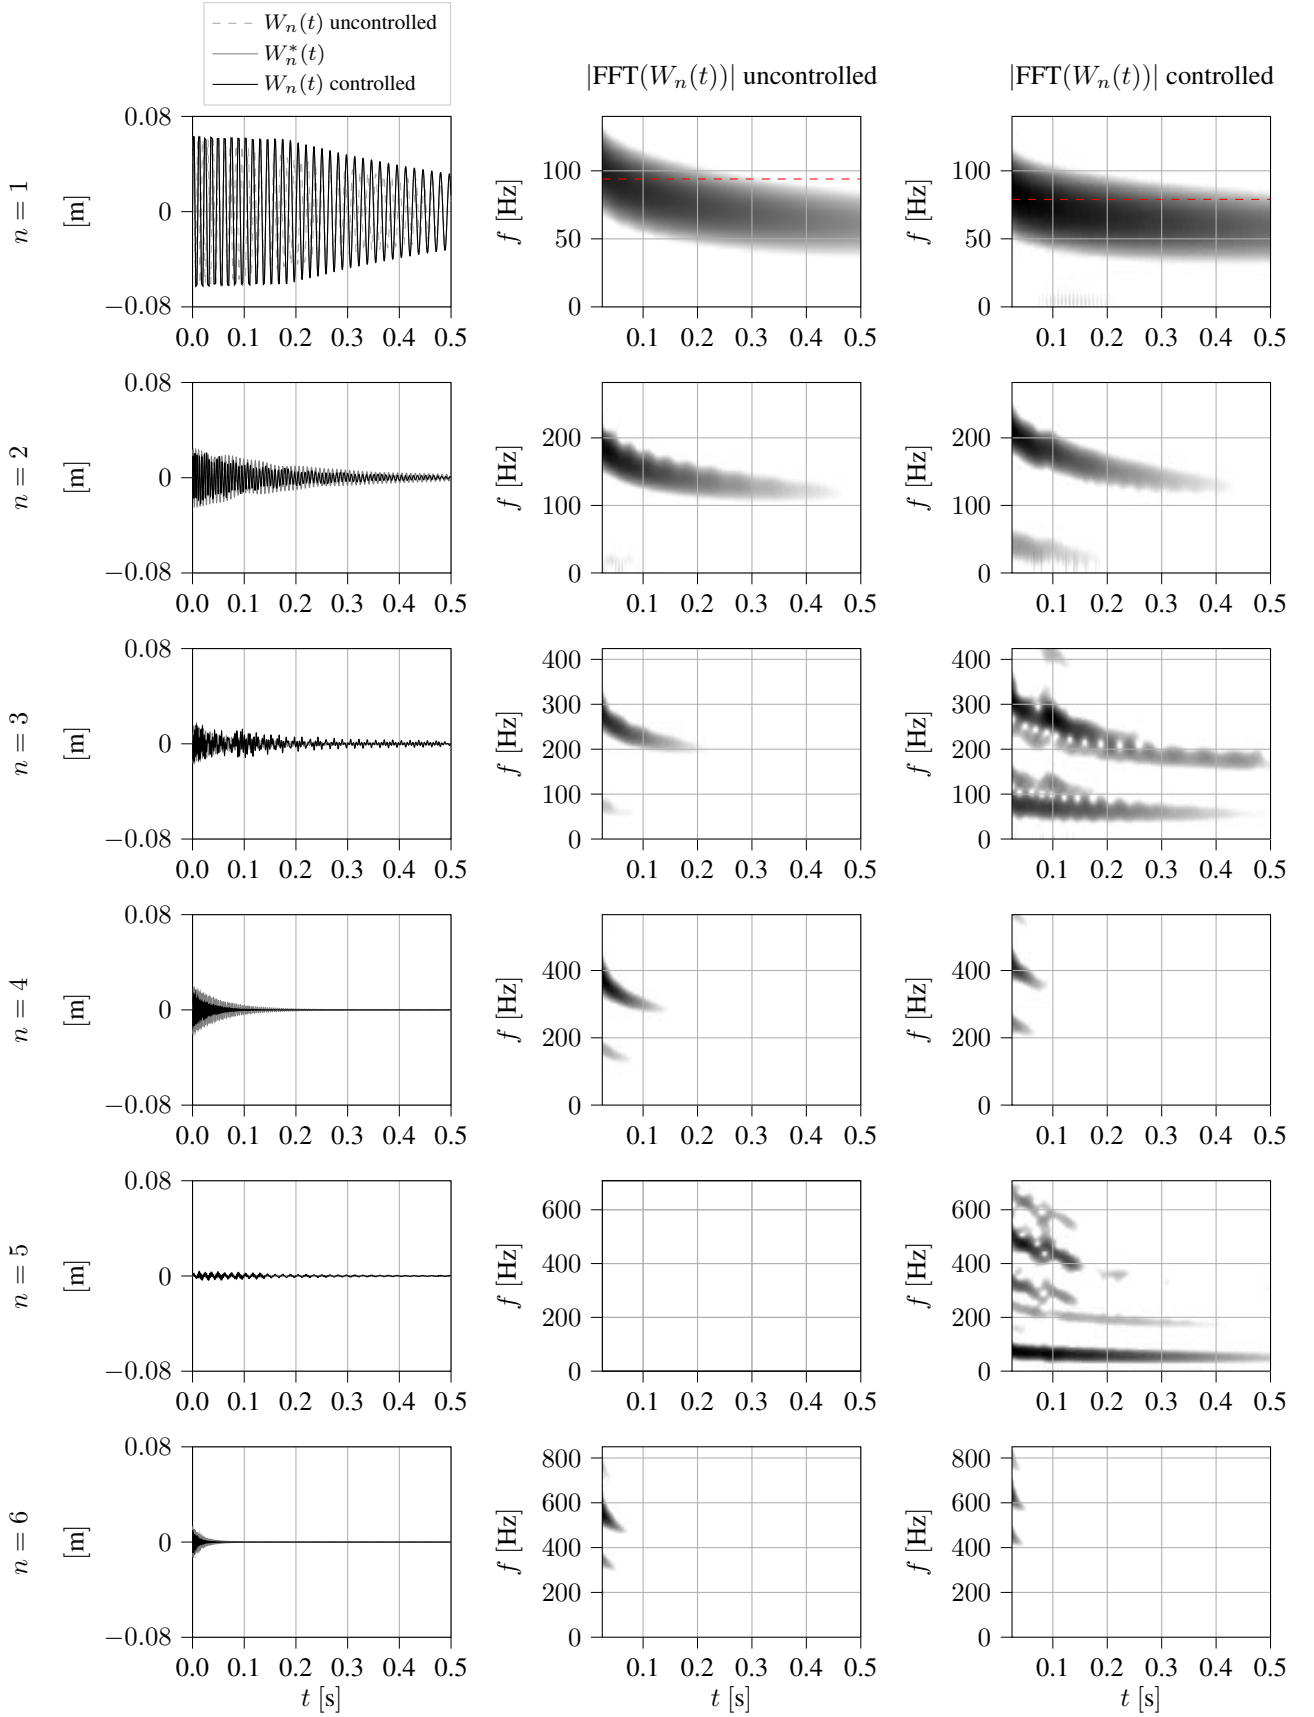

Figure 8: Example ②: time evolution and spectral content of the first 6 modes. The FFT is calculated using a Hann window and the same logarithmic color scale is used for the (un)controlled cases of a given mode. Red dashed lines indicate the starting frequencies of the pitch glide for mode 1 in the (un)controlled cases.

Summary. We investigate the emergence of quasiperiodic sound regimes in a model of flute-like musical instruments. The model itself is a system of delay differential equations of neutral type (NDDEs). We employ advanced numerical continuation methods to compute bifurcation diagrams in the space of relevant playing and making parameters. Our results show the role played by the detuning between the instrument resonance frequencies in the emergence of quasiperiodic regimes.

Self-sustained musical instruments are complex nonlinear dynamical systems and show a wealth of dynamical regimes. This includes equilibrium solutions where no sound is produced and periodic oscillations which most often correspond to the notes produced by the instrument, but also non-periodic oscillation regimes [1]. The existence and stability of these different sound regimes depend sensitively on making parameters which are fixed by the instrument maker and on playing parameters which are continuously tuned by experienced players. In the context of western classical music, non-periodic sound regimes are most of the time avoided and can be considered as a defect of the musical instrument or as a lack of control from the musician. On the other hand, some non periodic sounds, often referred to as *multiphonics*, are often played on purpose in jazz, contemporary or traditional music. Flute-like instruments in particular, show a diversity of non-periodic sound regimes (see Figure 1). This includes *multiphonic sounds* played on purpose in transverse flutes and recorders, *rolling notes* which instrument makers try to avoid, modulated regimes due to wall vibrations [2], but also, e.g., *sonidos rajados*, a highly-modulated sound produced by traditional pan-like flutes from Central Chile [3]. Here we consider a model of flute-like musical instrument, and investigate the physical mechanism responsible for the emergence of non-periodic regimes.

Figure 1: Left: Non periodic sound played by a traditional chilean pan-like flute. Middle: Non periodic simulated sound obtained using the NDDE model of a recorder. Right: Modulus of the input admittance of an alto recorder, for the fingering used to play the note B flat. The admittance is modelled as a sum of 6 resonant modes.

In flute-like musical instruments such as transverse flutes, recorders, quenans and organ pipes, the sound production results from the coupling between an intrinsically unstable air jet blown by the musician and an acoustic resonator which is composed of the air column contained in the pipe of the instrument [4]. Depending on the instrument, the pipe can include several tone holes: different *fingerings*, corresponding to different combinations of open and closed tone holes, are used by the musician to change the properties of the acoustical resonator, including its resonance frequencies and damping factors. More precisely, the air pressure in the musician mouth results in the emergence of an air jet at the output of a channel which is a part of the instrument (for recorders) or formed by the musicians lips (in transverse flutes, pan-like flutes ...). This air jet is intrinsically unstable and oscillates around a sharp edge called *labium*. This oscillation results in an alternate flow injection inside and outside the instrument pipe, which constitutes a dipolar pressure source for the acoustic resonator. The acoustic waves thus created propagate in the acoustic resonator and perturb back the air jet at the channel exit. This perturbation is amplified while convected along the jet, and sustains the air jet oscillation and, as such, the sound production. Importantly, the convection time of the perturbation along the air jet introduces a delay τ in the system, whose value is directly related to the pressure P_m in the musician's mouth, which is one of the main control parameter. Overall, flute-like instruments are modelled by a system of $2n$ delay differential equations of neutral type (NDDE), with n the number of acoustic modes taken into account to model the resonator, as shown in Figure 1 (right).

We focus here on the theoretical investigation of this model, and use advanced numerical methods to perform a bifurcation analysis. Because delay differential equations (DDEs) have an infinite dimensional phase space, they are more complicated to solve numerically than ordinary differential equations (ODEs). In particular, specific numerical methods have to

Figure 2: Bifurcation diagram of the NDDE flute model, showing the frequency along branches of stable (solid lines) and unstable (dotted lines) periodic solutions, with respect to the delay τ . Black dots correspond to torus bifurcation points T, where a periodic solution changes stability, with two complex conjugate Floquet multipliers crossing the unit circle.

be considered for the calculation and continuation of their solutions. We use here the continuation toolbox DDE-Biftool [5, 6]. This allows for the calculation and continuation of equilibrium solutions, periodic solutions and their respective bifurcations in system of DDEs. More precisely, a collocation method is used to compute periodic solutions. This is coupled to a predictor-corrector algorithm to continue the branches of solutions with respect to a parameter of interest of the physical model. Here, these numerical methods have been adapted so that the same calculations are possible for NDDEs [7, 8].

The bifurcation analysis of the NDDE model of flute-like instruments shows that multiple branches of periodic solutions emerge in Hopf bifurcations when the main control parameter P_m increases, which corresponds to a decreasing value of the delay τ (see Figure 2). From a musical point of view, the different branches of periodic solutions correspond to the different *registers* of the instruments, that is to say to periodic regimes associated with the different acoustic modes of the resonator. These periodic regimes have oscillation (*playing*) frequencies close to the resonance frequencies of the instrument, and can be interpreted as the different notes played by a musician for a given fingering. The stability analysis of these periodic solution show that they destabilise through torus bifurcations when the mouth pressure P_m increases further (*i.e.* when τ decreases). These bifurcations can lead to stable quasiperiodic oscillations. We investigate further the emergence of quasiperiodic regimes by performing the numerical continuation of curves of torus bifurcation in the (P_m, ξ) -plane. Here, ξ is an inharmonicity parameter, which models the detuning between the different acoustic resonant modes. The obtained bifurcation set demonstrates the major role played by the resonator inharmonicity on the existence and stability of quasiperiodic regimes.

Overall, our results provide a better understanding of the physical mechanism responsible for the emergence of non periodic sound regimes in flute-like musical instruments. They strongly suggest that experimentally-observed modulated sound regimes can be interpreted as quasiperiodic oscillations on a stable torus, resulting from the loss of stability of one of the *registers* of the instrument. The bifurcation analysis unveils the major role played by the inharmonicity of the acoustic resonator in this process. This paves the way towards a better experimental control of non-periodic sound regimes, which instrument makers and musicians either try to avoid or to enhance depending on the musical and cultural context.

Nonlinear damping laws preserving the eigenstructure of the momentum space for conservative linear PDE problems: a port-Hamiltonian modelling

Thomas Hélie*, Denis Matignon†

*S3AM team, Laboratory of Science and Technology of Music and Sound, IRCAM-CNRS-SU, Paris, France

†University of Toulouse, ISAE-Supaéro, Toulouse, France

Summary. Application to morphing in sound synthesis with the mutation of damping material properties leads us to introduce a class of nonlinear damping models operating on the momentum equation of the Hamiltonian formulation of a conservative mechanical PDE; the modal decomposition of the original linear vibrating structure is useful to analyze the preserved geometric features.

Initial conservative mechanical problem

We consider *linear conservative mechanical* systems, the solutions of which admit an eigen-decomposition. Typically, they can be finite-dimensional (mass-stiff) ODE systems, or infinite-dimensional continuous problems on a *bounded space domain* with *homogeneous boundary conditions*, governed either by the PDE (1) or by Hamiltonian descriptions (2a-2b).

PDE description

The models under consideration have the form

$$M(z)\ddot{w}(z, t) + \mathcal{K}(z)w(z, t) = f(z, t) \text{ for all } (z, t) \in \Omega \times \mathbb{R}_+, \quad (1)$$

with zero initial conditions, where z and t denote the space and time variables, Ω a bounded space domain, w a displacement, f an external force, M a mass matrix and \mathcal{K} a structured differential stiffness operator. Technically, we assume that $M(z)$ is a symmetric uniformly positive definite matrix ($M \in L^\infty(\Omega, S_n^+)$, $\varepsilon \text{Id} \leq M(z) \leq \|M\|_{L^\infty} \text{Id}$), that $\mathcal{K}(z)$ is a symmetric positive differential operator such that $M^{-1}\mathcal{K}$ defines a self-adjoint operator on a Hilbert space \mathbb{H} . In practice, \mathcal{K} can be a spatial operator with classical (e.g. Dirichlet or Neumann) homogeneous boundary conditions (see example).

Hamiltonian description

We also assume that this model admits a Hamiltonian description (including the excitation). The mechanical state $X = [q, p]^\top$ is composed of a configuration variable $q(z, t) := \mathcal{J}_{qp}(z) w(z, t)$ (that typically encodes a geometrical deformation) and the momentum $p(z, t) := M(z) \dot{w}(z, t)$. The Hamiltonian is $H(X = [q, p]^\top) = \frac{1}{2} \int_\Omega (p(z)^\top L_p(z) p(z) + q(z)^\top L_q(z) q(z)) dz$ with $L_p := M^{-1}$ and L_q symmetric and uniformly positive, so that its variational derivative is $\delta_X H(X) = \mathcal{L}X$ with $\mathcal{L} := \text{diag}(L_q, L_p)$. The governing equation is

$$\partial_t X = \mathcal{J} \delta_X H(X) + \begin{bmatrix} 0 \\ 1 \end{bmatrix} f \quad \text{with } \mathcal{J}(z) = \begin{bmatrix} 0 & \mathcal{J}_{qp}(z) \\ -\mathcal{J}_{qp}^*(z) & 0 \end{bmatrix}, \quad (2a)$$

$$v = [0, 1] \delta_X H(X), \quad (2b)$$

where $\mathcal{J} = -\mathcal{J}^*$ is skew-symmetric ($\mathcal{J}_{pq} = -\mathcal{J}_{qp}^*$). The observation equation (2b) produces the power-conjugated variable v of excitation f , and this system is power-balanced: $dH(X(\cdot, t))/dt$ is the sum of the external power $\langle f(\cdot, t), v(\cdot, t) \rangle$ supplied in Ω and that incoming through boundaries (zero for the homogeneous conditions assumed in this paper) [2]. Equation (2a) relates the efforts $e = [e_q, e_p]^\top := \delta_X H = [L_q q, L_p p]^\top$ to the flows $f = [f_q, f_p]^\top := \partial_t X = [\dot{q}, \dot{p}]^\top$. Note that its interpretation on the displacement variable reads

$$f_q = \mathcal{J}_{qp} e_p \quad \longrightarrow \quad (\mathcal{J}_{qp} \dot{w}) = \mathcal{J}_{qp} \dot{w} \quad \text{(kinematic concordance equation)} \quad (3)$$

$$f_p = -\mathcal{J}_{qp}^* e_q + f \quad \longrightarrow \quad (M \ddot{w}) = -\mathcal{J}_{qp}^* L_q \mathcal{J}_{qp} w + f \quad \text{(momentum balance)} \quad (4)$$

and $v = \dot{w}$ (output), so that the momentum balance corresponds to (1) with the meaningful factorization $\mathcal{K} = \mathcal{J}_{qp}^* L_q \mathcal{J}_{qp}$.

Example of a rectangular membrane

Consider a 2D membrane ($z = (x, y) \in \Omega = (0, X) \times (0, Y)$) with transverse displacement w [m], surface mass density $M(z) = \rho(z) > 0$ [Kg/m²], tension tensor $T_{2 \times 2}(z)$ [N/m] and with fixed boundaries so that $\mathcal{K}(z) = -\text{div}(T_{2 \times 2}(z) \text{grad})$ is defined on $\mathcal{D} = \{w \in H^2(\Omega) \text{ s.t. } w|_{\partial\Omega} = 0\}$ in (1).

For a homogeneous membrane with constant parameters $\rho(z) = \rho_0$ and $T_{2 \times 2}(z) = T_0 I_2$, both operators $\mathcal{K}(z) = -T_0 \Delta$ and $M(z)^{-1} \mathcal{K}(z) = -(T_0/\rho_0) \Delta$ involve the standard Laplacian $\Delta := \text{div}(\text{grad}) = \partial_x^2 + \partial_y^2$ defined on domain \mathcal{D} .

In this simple case, $M^{-1}\mathcal{K}$ is a Riesz-spectral operator. Its point spectrum is composed of positive eigenvalues ω_{mn}^2 with $\omega_{mn} = \sqrt{\frac{T_0}{\rho_0} \sqrt{(\frac{m\pi}{X})^2 + (\frac{n\pi}{Y})^2}}$ for integers $m, n \geq 1$. These eigenvalues ω_{mn}^2 are associated with the eigenfunctions $e_{mn}(x, y) = \frac{2}{\sqrt{XY}} \sin(\frac{m\pi x}{X}) \sin(\frac{n\pi y}{Y})$, which are orthonormal in $\mathbb{H} = L^2(\Omega)$. The dynamics $w_{mn}(t) := \langle w(\cdot, t), e_{mn} \rangle_{\mathbb{H}}$ carried by each modal space function e_{mn} is governed by (1) projected on e_{mn} ($\ddot{w}_{mn} + \omega_{mn}^2 w_{mn} = \langle f, e_{mn} \rangle_{\mathbb{H}}$). Each ODE is associated with two poles $\lambda_{mn}^\pm = \pm i\omega_{mn}$ (roots of the characteristic polynomials $\mathcal{P}_{mn}(\lambda) = \lambda^2 + \omega_{mn}^2$).

Figure 1: Spectrograms of signals produced for: (a,b) linear damping for two sets of parameters; (c) a nonlinear damping with behaviour "a" at high energies and "b" at low energies.

A natural Hamiltonian description is obtained by introducing the strain¹ $\vec{q} := \text{grad } w$ (meaning that $\mathcal{J}_{qp} := \text{grad}$ and $\mathcal{J}_{qp}^* = -\text{div}$), the surface momentum $p := \rho_0 \partial_t w$ and the Hamiltonian weighted by $L_p = 1/\rho_0$ and $L_q = T_0 I_2$. Matrix \mathcal{J} is then given by $\mathcal{J}(z) := \begin{bmatrix} 0 & \mathcal{J}_{qp}(z) \\ -\mathcal{J}_{qp}^*(z) & 0 \end{bmatrix} = \begin{bmatrix} 0 & \text{grad} \\ \text{div} & 0 \end{bmatrix}$, and $\mathcal{J} \delta_X H = \mathcal{J} \mathcal{L} = \begin{bmatrix} 0 & \frac{1}{\rho_0} \text{grad} \\ T_0 \text{div} & 0 \end{bmatrix}$ is a Riesz-spectral operator with eigenvalues $\lambda_{mn}^\pm = \pm i \omega_{mn}$ and eigenfunctions $E_{mn}^\pm := [\vec{q}_{mn} := \text{grad } e_{mn}, p_{mn}^\pm := \rho_0 \lambda_{mn}^\pm e_{mn}]^\top$. We now look for damping that preserves the kinematics (3) and the eigenstructure of the p -subspace (modes e_{mn}).

Structured damping class: linear and nonlinear models

Modifying the governing equation (2a) as $\partial_t X = (\mathcal{J} - \mathcal{R}) \delta_X H + [0, 1]^\top f$ introduces some dissipation in the system if $\mathcal{R}(z) = \mathcal{R}(z)^*$ is symmetric positive.

In this paper, inspired by [1] and following previous work in [3, 4], we first propose the linear damping class built on the parameters and the structure of the initial conservative system thanks to a polynomial function \mathbb{P} with positive coefficients:

$$\mathcal{L} \mathcal{R} = \Sigma \mathbb{P}((\mathcal{L} \mathcal{J})^* (\mathcal{L} \mathcal{J})) \quad \text{with } \Sigma = \begin{bmatrix} 0_{qq} & 0_{qp} \\ 0_{pq} & I_{pp} \end{bmatrix}. \quad (5)$$

Theorem: equation (5) defines a damping class that : (i) preserves the kinematics concordance equation (3) of the original problem, between $\partial_t \vec{q}$ and $\delta_p H$; (ii) preserves the eigenstructure of the p -subspace.

The element of the proof are the positivity of operators $(\mathcal{L} \mathcal{J})^* (\mathcal{L} \mathcal{J})$ and of the coefficients of \mathbb{P} for the dissipation, the selection matrix Σ that operates property (i), and the powers of $(\mathcal{L} \mathcal{J})^* (\mathcal{L} \mathcal{J})$ generated by the polynomial \mathbb{P} for (ii). \diamond

Secondly, we generalize the previous class from linear to *nonlinear* dynamics, by making the positive coefficients of the polynomial \mathbb{P} depend on the state $X(t)$ and using the new damping operator $\mathcal{R}(X(t))$ instead of \mathcal{R} : indeed, passivity and properties (i-ii) still stem from the genuine structure (5).

Simulation for the homogeneous membrane

Three simulations of a membrane (see spectrograms of $\partial_t w$ in figure 1a-c) are performed for three damping polynomials $\mathbb{P}_{a,b,c}$ of the operator $(\mathcal{L} \mathcal{J})^* (\mathcal{L} \mathcal{J}) = \frac{T_0}{\rho_0} \text{diag}(-\text{grad div}, -\Delta)$: \mathbb{P}_a of degree 0 (fluid damping) with constant coefficient; (b) \mathbb{P}_b of degree 1 (fluid and structural damping) with constant coefficients; (c) an interpolation $\mathbb{P}_c = f(e)\mathbb{P}_a + (1-f(e))\mathbb{P}_b$ for e.g. the interpolation function $f(e) = \tanh \sqrt{e/e_0}$ driven by the energy signal $e(t) = H(X(t))$. As a result the damping locally behaves like (a) for energies $e \gg e_0$, like (b) for $e \ll e_0$ (including the sound extinction), building a physically-morphed sound in-between that can be interpreted as complex or mutating materials.

Conclusion

The port-Hamiltonian setting proves useful to analyze morphing strategies applied to sound synthesis, since the geometry of the underlying physics can be fully preserved during the transformation involving nonlinear damping models, which are easily parameterized using polynomials.

Summary. This article presents several topics related to the use of nonlinear modes and normal forms to analyse and model the vibratory response of geometrically nonlinear structures. It is first shown that the normal form theory provides a mathematically rigorous and clear framework to exhibit the mathematical form of very reduced order models. Then, this theory is applied to model the nonlinear vibrations of chinese opera gongs, that exhibits particular frequency glides in normal playing conditions, under an impulse forcing at center. It is shown that at low amplitude, a single Duffing like oscillator is sufficient to precisely explain this behaviour, due to the hardening/softening behaviour of the fundamental axisymmetric vibration mode. At larger amplitude, mode coupling are experimentally observed, well recovered by a reduced order model reduced to a few nonlinear modes involved in a 1:2:2 internal resonance.

Figure 1: (left) Photograph of a chinese opera gong and the coil magnet driving system used for experimental identification; (middle) spectrogram of the acceleration signal after a mallet strike, measured by an accelerometer glued on the gong; (right) backbone curves of the fundamental nonlinear mode obtained from the free vibration regime after a mallet strike and from an experimental continuation with a phase locked loop.

Chinese opera gongs take the form of an axisymmetric thin shell, such the one shown in Fig. 1(left). When the gong is hit with a mallet at its center, a very characteristic pitch glide can be heard. This can be related to a change of the instantaneous frequency of vibrations, that can be seen on the vibration spectrogram of Fig. 1(middle) around the natural frequency of the fundamental axisymmetric mode. Then, the same spectrogram also shows that the second harmonics of the vibration signals mixes with a couple of higher modes with companion asymmetric mode shapes. In this article, we show that those two features (the pitch glide and the mode interaction) can be quantitatively recovered by reduced order models, that take the form of a few coupled nonlinear oscillators, justified by the normal form theory applied to a generic nonlinear modal model of the system.

Nonlinear modes and normal form

We consider an elastic structure whose displacement $w(\mathbf{x}, t)$ at time t and position \mathbf{x} is expanded on a family of N eigenmodes of the linearized and undamped model:

$$w(\mathbf{x}, t) = \sum_{k=1}^N \Phi_k(\mathbf{x}) q_k(t), \quad (1)$$

where $(\omega_k, \Phi_k(\mathbf{x}))$ are the k -th natural angular frequency and mode shape. In free undamped vibrations, the modal coordinates $q_k(t)$ satisfy the following set of coupled nonlinear equations, for all $k = 1, \dots, N$:

$$\ddot{q}_k + \omega_k^2 q_k + \sum_{i,j=1}^N \beta_{ij}^k q_i q_j + \sum_{i,j,l=1}^N \gamma_{ijl}^k q_i q_j q_l = 0, \quad (2)$$

where β_{ij}^k and γ_{ijl}^k are nonlinear coefficients stemming from the geometrical nonlinearities. Using normal forms, as introduced in [9], a nonlinear polynomial change of coordinate is introduced, leading to replace model (2) by a new one, function of the new (normal) coordinates $u_k(t)$. This new dynamical system has an important property: it involves only resonant nonlinear terms. This property enables a rigorous and straightforward truncation strategy, divided in two cases.

If there are no internal resonance relation between the oscillations frequencies, the resonant terms are only of cubic order and they do not break the invariance of the oscillators. Consequently, a motion on a single oscillator (the i -th.) is possible and takes the form:

$$u_k = 0 \quad \forall k \neq i, \quad \ddot{u}_i + \omega_i^2 u_i + \Gamma_1 u_i^3 + \Gamma_2 u_i \dot{u}_i^2 = 0, \quad (3)$$

where (Γ_1, Γ_2) are two coefficients depending on the nonlinear coefficients β_{ij}^k and γ_{ijl}^k , that take into account the influence of all linear modes. This particular motion, linked to its invariance property, defines a nonlinear mode, whose dynamics is governed by the single oscillator (3). The values of Γ_1 and Γ_2 defines the hardening or softening feature of the nonlinear mode [9, 8].

If there is an internal resonance between some modes, the corresponding oscillators have to be kept in the dynamics and are coupled by particular nonlinear terms. Their form can be easily deduced from the internal resonance relation. For instance, in the case of a 1:2 internal resonance between modes 1 and 2, their natural frequencies verify the relation $\omega_2 \simeq 2\omega_1$ and the normal form reduced order model is:

$$u_k = 0, \quad \forall k \neq 1, 2, \quad \begin{cases} \ddot{u}_1 + \omega_1^2 u_1 + \alpha_1 u_1 u_2 = 0, \\ \ddot{u}_2 + \omega_2^2 u_2 + \alpha_2 u_1^2 = 0, \end{cases} \quad (4)$$

where (α_1, α_2) are the coefficients of the two quadratic resonant terms [6].

If the damping is small, its influence on the invariant manifolds geometry can be neglected and a modal viscous damping terms of the form $2\xi_k \omega_k \dot{u}_k$, with $\xi_k \ll 1$, can be added in the above models with no loss of accuracy.

Identification

If an accurate model is at hand, the values of the coefficients of the normal forms (3), (4) can be obtained from the ones of the modal model (2) using the formula of [9] or directly from a finite-element model [5]. Another strategy is to rely on experiments to identify those coefficients. At low amplitude and without internal resonance, we can show that the influence of coefficients (Γ_1, Γ_2) on the dynamics can be embedded into a single cubic coefficient, whose sign governs the hardening / softening behaviour of the nonlinear mode. As shown in [1, 3], this coefficient can be efficiently estimated with an experimental backbone curve, that can be measured by experimental continuation based on a Phase-Locked Loop (PLL). As a consequence, it is here proven that an accurate reduced order model for this low amplitude single nonlinear mode motion is a classical Duffing oscillator. This identification procedure can be extended to measure more complex dynamics, such those involving 1:1 internal resonance [2]. In the case of the internal resonance of Eq. (4), coefficients (α_1, α_2) can be estimated by experimental forced responses, as explained in [7, 4].

Acoustics of a chinese gong

The above method can be applied to chinese opera gongs, in order to investigate and explain their particular sound. Considering first their pitch glide, it is possible to extract from a free response in normal playing conditions the relation between the instantaneous frequency of oscillations as a function of the amplitude. It can be shown that it matches exactly the experimental backbone curve (Fig. 1(right)), leading to the conclusion that the characteristic pitch glide of the Chinese opera gongs is an acoustic manifestation of the hardening / softening behaviour of their fundamental nonlinear mode, whose frequency changes as a function of the amplitude because of the geometrical nonlinearities. Then, using a model of the form (4) with an additional cubic term, the 1:2:2 internal resonance of Fig. 1(middle) can also be recovered by proper estimation of coefficients (α_1, α_2) .

Summary. Numerical continuation using the Asymptotic Numerical Method (ANM), together with the Harmonic Balance Method (HBM), allows to follow the periodic solutions of non-linear dynamical systems such as physical models of wind instruments. This has been successfully applied to practical problems such as the categorization of musical instruments from the calculated bifurcation diagrams [2]. Nevertheless, one problem often encountered concerns the uncertainty on some parameters of the model, the values of which are set arbitrarily because too difficult to measure experimentally. In this work we propose a novel approach where constraints based on experimental measurements are added to the system, as well as the uncertain parameters of the model relaxed. This approach allows the continuation of the periodic solution with constraints to be performed, together with the calculation of the variation of the relaxed parameters along the solution branch. A successful application of this technique to a physical model of a trumpet is presented in this paper.

Physical model of the {player-trumpet} system and continuation

We consider a one-dimensional lip model, coupled to the resonator impedance described by a series of complex modes similar to what is proposed in [2]. The coupling between the mechanical oscillator and the acoustic resonator is achieved by a stationary Bernoulli flow equation, considering turbulent mixing in the mouthpiece with no pressure recovery. The mechanical and acoustic equations are given in system 1, where y is the vertical lip position (y_0 is the lip position at rest), ω_l , Q_l , μ_l and b the lip mechanical parameters, s_k and C_k with $k \in [1, N]$ the modal parameters of the N resonances of the acoustic impedance of the instrument, Z_c the characteristic impedance, u the volume flow, p the downstream pressure at the input of the instrument (in the mouthpiece), and p_0 the upstream (mouth) static pressure.

$$\begin{cases} \ddot{y}(t) + \frac{\omega_l}{Q_l} \dot{y}(t) + \omega_l^2 (y(t) - y_0) = \frac{1}{\mu_l} (p_0 - p(t)) \\ \dot{p}_k(t) = Z_c C_k u(t) + s_k p_k(t), \forall k \in [1, N] \end{cases} \quad (1)$$

with $p(t) = 2 \sum_{k=1}^N \Re(p_k(t))$ and $u = \sqrt{\frac{2|p_0 - p|}{\rho}} b \cdot \text{sign}(p_0 - p) \cdot \theta(y)$, where $\theta(y) = \frac{|y| + y}{2}$, b is the lip width and ρ is the air density.

The case of a negative opening of the lips is managed by introducing the function $\theta(y)$ which enforces $u = 0$ if $y < 0$. The modal parameters of the N modes of the impedance are extracted from the measured input impedance using the high resolution method ESPRIT [3]. In this model, the values of the lip parameters are critical but particularly difficult to set, as it is extremely difficult to evaluate them experimentally.

We choose to work with the Asymptotic Numerical Method (ANM) implemented in the software MANLAB [4]. This method is based on the expansion of the solutions under the form of truncated Taylor series, providing analytical formulations of the branch of solution. Recently, this method has been associated to the Harmonic Balance Method (HBM) for the search of periodic solutions of oscillating systems [5].

One requirement of MANLAB relies on the recast of nonlinearities of the model into, at most, quadratic nonlinearities. The complete quadratic dimensionless model can be found in [2].

Continuation with constraints

Two constraints are introduced as follows:

$$\|\tilde{p}\|_{L_2} = S\gamma + I, \quad (2)$$

where $\gamma = p_0/P_M$ is the dimensionless mouth pressure with $P_M = \mu_l \omega_l^2 y_0$, S and I are constant values, and $\|\tilde{p}\|_{L_2} = 2 \left\| \sum_{k=1}^N \Re(\tilde{p}_k) \right\|_{L_2}$.

The second constraint simply writes as follows:

$$f_0 = F, \quad (3)$$

where F is a constant value.

Adding two equations to the system requires two parameters of the model to be relaxed, that is two unknowns to be introduced. We choose to relax Q_L and $\zeta = Z_c b y_0 \sqrt{\frac{2}{\rho P_M}}$ (ζ can be seen as an “embouchure” parameter). This requires to recast the system of equations in order to preserve the quadratic property of the model.

Results and conclusions

Figure 1 shows the result of continuation with constraints applied to the physical model described in previous section. In the bottom plot, the evolution of $\|\tilde{p}\|_{L_2}$ with respect to γ measured on a trumpet player during a slow crescendo-decrescendo maneuver is represented in red. A linear fit of the red curve is applied, which gives S and I (Eq. 2) and defines the constraint on $\|\tilde{p}\|_{L_2}$. The constraint on f_0 is such as it remains constant and equal to the value at the initial calculation point (about the playing frequency of a Bb4).

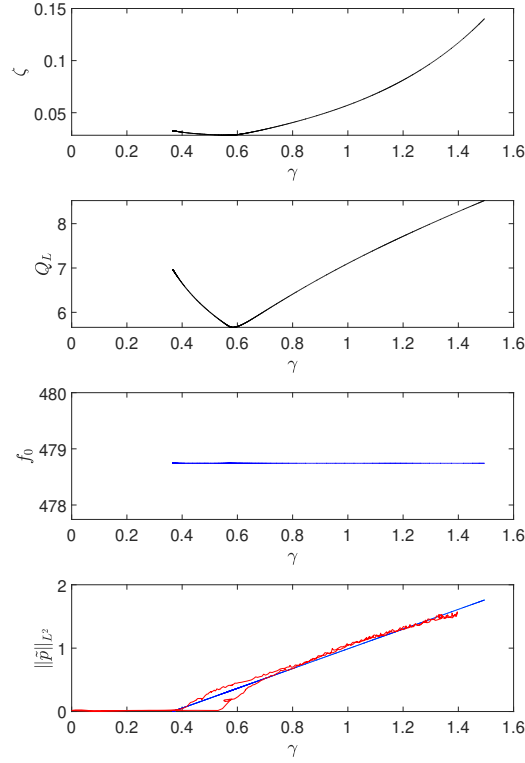

Figure 1: Results from continuation with constraints. Evolution of ζ , Q_L , f_0 and $\|\tilde{p}\|_{L_2}$ with respect to the dimensionless mouth pressure γ . In red is the evolution of $\|\tilde{p}\|_{L_2}$ with respect of γ measured on trumpet player during a slow crescendo-decrescendo maneuver.

It can be seen that the two constraints are well respected: f_0 is constant with respect to γ , and $\|\tilde{p}\|_{L_2}$ evolves linearly with respect to γ (the solution branches, in blue, are superimposed with the target constraint on Fig. 1 bottom plots). The stability of the branch was computed and the branch was found stable across the whole range of γ . The variations of ζ and Q_L are represented on the two top plots. Significant variations of these two variables are observed, showing the importance of adapting these parameters in order to match the constraints.

These results highlight the ability of the ANM to calculate the evolution of some parameters of the model while applying some mathematical constraints to the output of the continuation calculation. By defining these constraints from experimental data, this approach can be seen as an inversion method, allowing to retrieve the parameter values of the model necessary to achieve a given performance (playing a crescendo-decrescendo at completely constant playing frequency). This method then shows great perspectives for the parametrisation of physical models of brass instruments, as well as for objective comparison of brass instruments.

Summary. The current study is motivated by some observations of highly nonlinear dynamical effects in biological auditory systems. We examine the hypothesis that one of the underlying mechanisms responsible for the observed nonlinearity is self-excited oscillation (SEO). According to this hypothesis the detection and processing of input audio signals by biological auditory systems is performed by coupling the input signal with an internal element undergoing SEO. Under appropriate conditions such coupling may result in synchronization between the input signal and the SEO. In this talk I will present some supporting evidence for this hypothesis by showing that some well-known phenomena in musical tonality can be explained by the Hopf model of SEO and the Arnold model of synchronization. Moreover, some mathematical properties of these models are employed as guidelines for the construction of some modulations that can be applied to a given musical composition. The construction of some intriguing patterns of musical harmony is demonstrated by applying these modulations to known musical pieces [1].

Summary. Employing elastic rod theory we study the question which forces and moments measured at the base of a mammal's whisker (tactile sensor) allow for the prediction of the location in 3D space of the point at which the whisker makes contact with an object. We show that, in the case of non-tip contact, the minimum number of independent forces or moments is three but that conserved quantities of the rod equilibrium equations prevent certain triples from giving a unique solution. The existence of these conserved quantities depends on the shape and material properties of the whisker. For tapered or intrinsically curved whiskers there is no obstruction to the prediction of the contact point. Our results explain recent numerical observations in the literature and offer guidance for the design of robotic tactile sensory devices.

Introduction

Mammal whiskers (vibrissae) allow terrestrial animals to obtain information about geometrical and mechanical properties of the environment [1]. Animal whiskers are thin flexible rods grown out of follicles and consist of dead cells; there are no sensors along the length of a whisker. Sensing therefore relies on the detection by mechanoreceptors at the whisker base of forces and moments induced by contact with an external object and transmitted through the elastic medium. Knowledge of how whiskers perform their sensory functions is of interest to engineers designing artificial tactile sensors [2]. To use such artificial whiskers in robotics, it is essential to be able to determine the location, with respect to a reference frame, of the point along the whisker shaft at which contact with an object occurs.

If three forces and three moments (in three independent spatial directions) are measured at the (fixed) whisker base, then a suitable mechanical model of the whisker (e.g., a 1D continuum elastic rod or beam model [3]) allows the entire configuration of the whisker, and hence the contact point, to be determined. These six measurements, however, require an expensive six-axis load cell. It is natural, therefore, to ask whether fewer measurements would suffice to uniquely predict the location of the contact point.

Past studies of this contact problem have mainly focussed on the planar case, where the contact point is specified by two coordinates [4]. Whisker configurations, especially those with intrinsic curvature, may generally be non-planar. The whisker contact problem was numerically studied in 3D in [5]. All 20 possible combinations of triples of base forces and moments were analysed, however no theoretical explanation of the results was given. Here we show that the difference in the predictive ability of triples of forces and moments is mainly caused by the existence of conserved quantities, which arise for whiskers with certain geometrical profiles (curvature, taper, etc.).

Boundary conditions and conserved quantities

The solution of an n th-order ODE, $du/ds = f(u)$, $u \in \mathbb{R}^n$, $s \in [a, b]$, involves n integration constants. In physical problems a unique solution is then usually obtained by imposing n boundary conditions at $s = a$ and/or $s = b$ to fix those integration constants. For a linear ODE it is a rigorous result that a unique solution is obtained if the n boundary conditions are linearly independent. For a nonlinear ODE (or nonlinear boundary conditions) the result is only true locally (i.e., near a given solution) and only 'generically', i.e., away from branching points (bifurcations) for special values of any parameters in the equations or values imposed at the boundary. (In the special case that all boundary conditions are specified at one end, i.e., for an initial-value problem, a unique solution is guaranteed also for a nonlinear ODE.)

A conserved quantity (first integral) of the ODE is a function of the dependent variables u_i ($i = 1, \dots, n$) whose value is constant along solutions of the equation. The presence of such quantities may put constraints on the specification of boundary conditions [6]. For instance, in the simple case that one of the variables itself, say u_k , is a conserved quantity and we choose the boundary condition $u_k(a) = c$, then $u_k(b) = d$ is not a proper boundary condition at the other end: if c and d were unequal there would obviously be no solution, while if c and d were equal there might be infinitely many solutions (depending on the other boundary conditions). In either case the BVP is said to be ill-posed. Another, independent, boundary condition needs to be imposed instead to obtain a locally unique solution (i.e., a solution with no infinitesimally close solutions). It is not always a priori clear that a given ODE has one or several conserved quantities and well-posedness of a nonlinear BVP is generally not straightforward.

Conserved quantities can be viewed as continuous symmetry properties of the ODE. A more obvious example of continuous symmetry is rotational symmetry of the equations, in which case for a well-posed BVP one has to impose boundary conditions that break the symmetry, thereby picking out one of the continuous family of solutions. Besides continuous symmetry a BVP may also have discrete symmetry, for instance, reflection symmetry, in which case the BVP has multiple *isolated* solutions. Each of these will generally be locally unique and the BVP is considered well-posed, with the solution being *globally* non-unique. 'Modes' (i.e., eigenfunctions) in eigenvalue problems, which also occur as isolated solutions, are other examples of globally non-unique solutions. Conserved quantities do not necessarily distinguish between such solutions.

Equilibrium equations for an elastic whisker

We model the whisker-object contact problem by formulating a two-point boundary-value problem using Kirchhoff rod theory [3]. Let $Oxyz$ be an orthogonal laboratory frame fixed at the base of the whisker (Fig. 1). The whisker is taken to be inextensible and unshearable and to have length L . Its centreline is denoted by $\mathbf{r}(s) = (x(s), y(s), z(s))$, where $s \in [0, L]$ is arclength along the whisker, $s = 0$ corresponding to the base O and $s = L$ corresponding to the tip. Under the above assumptions we can introduce an orthonormal material frame $\{\mathbf{d}_1, \mathbf{d}_2, \mathbf{d}_3\}$ with \mathbf{d}_1 tangent to the centreline \mathbf{r} , i.e., $\mathbf{r}' = \mathbf{d}_1$, and \mathbf{d}_2 and \mathbf{d}_3 directed along principal axes of the whisker's cross-section (here and in the following a prime denotes differentiation with respect to s). By orthonormality of the material frame there exists a vector $\boldsymbol{\Omega}$ such that $\mathbf{d}_i' = \boldsymbol{\Omega} \times \mathbf{d}_i$ ($i = 1, 2, 3$). The components of this vector in the material frame, $(\omega_1, \omega_2, \omega_3) =: \boldsymbol{\omega}$, $\omega_i = \boldsymbol{\Omega} \cdot \mathbf{d}_i$, are the strains of the theory, i.e., the curvatures ω_2 and ω_3 , about \mathbf{d}_2 and \mathbf{d}_3 , and the twist ω_1 , about \mathbf{d}_1 [3].

The force and moment balance equations for the whisker are

$$\mathbf{F}' + \boldsymbol{\omega} \times \mathbf{F} = \mathbf{0}, \quad \mathbf{M}' + \boldsymbol{\omega} \times \mathbf{M} + \mathbf{i} \times \mathbf{F} = \mathbf{0}, \quad (1)$$

where $\mathbf{F} = (F_1, F_2, F_3)$ and $\mathbf{M} = (M_1, M_2, M_3)$ are triples of force and moment components in the material frame and $\mathbf{i} = (1, 0, 0)$. We assume the linear constitutive relations: $M_1 = C(s)\omega_1$, $M_2 = B(s)\omega_2$, $M_3 = B(s)(\omega_3 - \omega_{30}(s))$. Here, $B(s)$ and $C(s)$ are the bending and torsional stiffnesses, resp. They are not constant in the particular case of a tapered rod.

The undeformed shape of the whisker is assumed planar but may be curved with intrinsic curvature $\omega_{30}(s)$.

Eqs. (1) imply, respectively, that $\mathbf{F} \cdot \mathbf{F}$ and $\mathbf{F} \cdot \mathbf{M}$ are constant. If $\omega_{30} \equiv 0$, then $M_1 = \text{const}$. The Hamiltonian $H = M_1^2/(2C) + (M_2^2 + M_3^2)/(2B) + M_3\omega_{30} + F_1$ is conserved provided B , C and ω_{30} are constant, i.e. the rod is translationally symmetric in the arclength s [6].

Table 1: Triples \mathbf{P} of measurements that give rise to an **ill-posed** BVP with non-isolated solutions, for various intrinsic shapes of the rod (* stands for any of the other quantities).

rod	cylindrical	tapered
straight ($\omega_{30} = 0$)	$(M_1, *, *)$	
	$(\alpha, \beta, *)$	
	(F_1, M_2, M_3) $(F_1, M_n, *)$	
curved ($\omega_{30} \neq 0$)	-	-

Figure 1: Coordinate systems for a whisker in point contact with an object at $s = s^*$. For frictionless contact the contact force F_n is normal to the whisker.

We assume the whisker to be fixed in both position and orientation at the base ($s = 0$). At the contact point ($s = s^* \leq L$) a normal contact force will act from the surface of the object onto the whisker for a frictionless single-point contact. We therefore consider the following boundary conditions: $\mathbf{r}(0) = \mathbf{0}$, $\mathbf{d}_i(0) = \mathbf{d}_{i,0}$, $\mathbf{P}(0) = \mathbf{P}_0$, $F_1(s^*) = 0$, $\mathbf{M}(s^*) = \mathbf{0}$, where $\mathbf{P} = (P_1, P_2, P_3)$ is the vector of base measurements consisting of three components chosen from the six force and moment components. We also introduce polar representations of the force and moment in the whisker [5]. Thus we write $F_2 = F_n \cos \alpha$, $F_3 = F_n \sin \alpha$, $M_2 = M_n \cos \beta$, $M_3 = M_n \sin \beta$. Here $F_n = \sqrt{F_2^2 + F_3^2}$ and $M_n = \sqrt{M_2^2 + M_3^2}$ are the magnitudes of the normal force and moment components, while α and β are the angles these components make with the material axes.

We note that three base measurements are sufficient for the well-posedness of the tactile sensing BVP. We analyse how this well-posedness depends on the precise choice of measured components P_i .

Summary of results

The results of our analysis are summarised in Table 1, where those combinations of force/moment measurements are listed that are **not appropriate** in the design of an effective set of sensors at the base of a robotic whisker. A tapered whisker may here be interpreted as any whisker whose B or C is not constant.

Influence of mass on horizontal forced oscillations in oscillatory model of a young tree with branches

Summary. In this paper we analysed the influence of mass on amplitudes of horizontal forced oscillations in previously developed model of complex oscillatory system that resembles corymb type of inflorescence. For describing oscillatory behavior of this system under external force influence deflection coefficients were used. The analysis was done for the case of single frequency external excitation for two different values of circular frequencies. For the value 10/s for the external force circular frequency we obtained nonlinear correlation between amplitudes and masses.

Introduction

Plants and trees oscillate under the influence of wind. This is particularly important for young seedlings that can be damaged before the plant is fully rooted in the ground. Oscillations of tree stem of living trees can be studied through different approaches [1, 2], where it is possible to measure the natural frequencies of trees [3]. Type and structure of wood structure (material properties of the system that could be considered as complex oscillatory system) and characteristics of wind (an external force) may contribute to the damage of a tree and cause it to crack or fall. Mechanical stability of trees is thus a very important problem [4]. Young tree seedlings are of particular interest in urban area exposed to the wind. Recently we developed the model of a complex oscillatory systems that was inspired by corymb type of inflorescence [5]. We use this model (Fig1) to study the influence of mass of tree branches on amplitudes of horizontal forced oscillations at the certain points of the tree stem.

Description of the model

The system could be assumed as ideally elastic system consisting of material particles on rigid massless rods with length ℓ_i with the angle β_i to light elastic console with length ℓ . Length of the console corresponds to the tree stem, and length of the massless rods to the tree branches. Material particles at the end of the massless rods correspond to the mass of the branch. The approximations of this system are: connections between rigid massless rods and elastic console are rigid, oscillations of console and system are small, tilts of tangent to elastic axis of banded console are very small and negligible, tilts of console cross-section during console banding according to x and y axis of cross section are very small and negligible. Masses of material particles are equal. System oscillates in horizontal and vertical plane. Bending stiffness of the elastic console is equal in horizontal and vertical plane. For describing oscillatory behavior of this system influence coefficients of deflection were used. Displacement influence coefficients were determined on the basis of equations of elastic line of console load with unit force and unit momentum. Forced oscillations of the system can be described by two independent subsystems of ordinary differential equations in vertical and horizontal plane. Each subsystem of ordinary differential equations consists of four coupled ordinary differential equations of second order in the following form:

Figure 1. Complex oscillatory systems that can be used for studying oscillations of tree with branches. (Taken from ref [1].

Table 1. Resonant values of oscillations of the console for different masses of single material points (branches)

Resonant values $\Omega y(1/s)$	1kg	1.3kg	1.6kg	1.9kg	2.2kg	2.5kg	2.8kg
R1	5.924	5.196	4.724	4.325	4.028	3.771	3.556
R2	3.435	3.013	2.681	2.427	2.301	2.158	1.559
R3	8.074	7.049	6.383	5.837	5.425	5.113	4.837

For oscillations in horizontal plane:

$$x_i = \alpha_{i1} F_{01x} \sin \Omega_x t + \alpha_{i2} (-2m_2 \ddot{x}_2) + \alpha_{i3} (-2m_3 \ddot{x}_3) + \alpha_{i4} (-m_4 \ddot{x}_4) + \delta_{i2} (-2m_2 \ddot{x}_2 \ell_2 \sin \beta_2) + \delta_{i3} (-2m_3 \ddot{x}_3 \ell_3 \sin \beta_3) \quad i = 1 \dots 4 \quad (1)$$

Where α_{ik} and δ_{ik} are influence coefficients of deflection on cross section "i" under unit force $F_k = 1$ and under unit

momentum. $M_k = 1$ respectively, on section 'k'. For calculating the influence coefficients of deflection the bending stiffness of the elastic console is needed and is equal to: $B_x = B_y = EI_x = EI_y = E \frac{r^4 \pi}{4}$ where $I_x = I_y = \frac{r^4 \pi}{4}$ is the axial moment of inertia of the surface of the cross-sectional area for the corresponding central axis passing through the center of the circle. E is Young's module of elasticity, r is half a diameter of the console. We analyze influence of mass of tree branches on amplitudes of horizontal forced oscillations at the certain points of the tree stem. Numerical analysis was done for the following data: $E=10,7 \times 10^9 \text{ Pa}$, $r=0,015 \text{ m}$, $\ell_2 = \ell_3 = 0,55 \text{ m}$, $\ell = 1,5 \text{ m}$, $\beta_2 = \pi/4$, $\beta_3 = \pi/6$; $\Omega_y = 5/s$ and for $\Omega_y = 10/s$, for different masses (from 1-3kg with step 0.3).

Results

Dependences of amplitudes of masses of material particles on their ends (branches) for two values of circular frequency of external force are shown on Fig.2. Graphs were obtained by calculating all the values numerically using Python programming language. Library numpy was used for determinant calculation, while matplotlib was used for graph plotting. In the Table 1. tree resonant values are shown for each mass value for which characteristic local minimum and maximum of amplitudes in certain point of the complex oscillatory model are obtained when circular frequency of the external force is $\Omega_y = 10/s$.

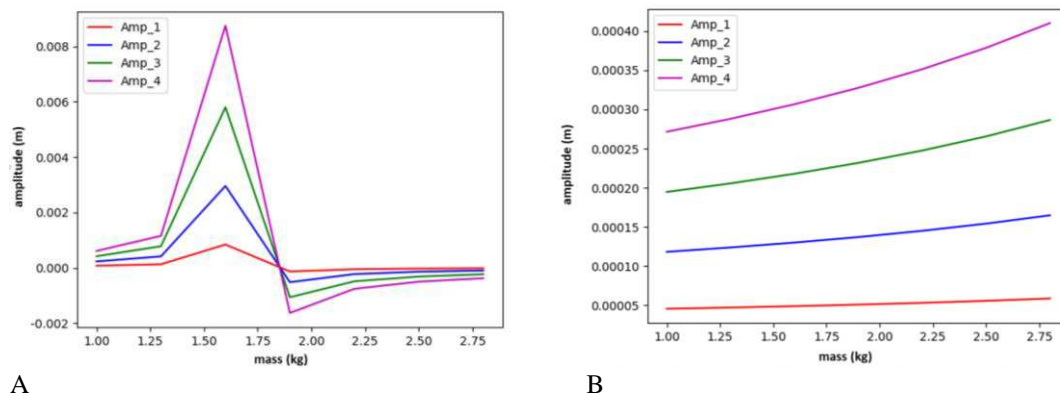

Figure 2. A. Amplitudes of oscillations of four different points for different masses of material particles for $\Omega_y = 10/s$. B. Amplitudes of oscillations of four different points for different masses of material particles for $\Omega_y = 5/s$.

Conclusions

We analysed influence of mass on amplitudes of horizontal oscillations of a complex oscillatory model of young tree with branches under external force with circular frequency of $\Omega_y = 5/s$ and $\Omega_y = 10/s$. When circular frequency of the external force is 5/s, which is around resonant frequencies for most of the selected masses we obtained constantly increasing amplitudes of forced horizontal oscillations of our complex oscillator. For the case when circular frequency of the external force is 10/s, amplitudes of forced horizontal oscillations of our complex oscillator have nonlinear character showing local maximum and minimums. Maximum amplitude for the chosen data systems is for mass 1.6 kg per branch. Absolute minimum of the amplitude is for mass 2.8 kg per branch. Specific combination of the parameters of the system and circular frequency of the external force determine the maximum amplitude of forced oscillations and it has a nonlinear character.

Summary. To analyse the effect of vaccination strategies and the reinfection or temporary acquired immunity of individuals in a population with virus presence as well the social distancing, a variation of the SIR (Susceptible-Infected-Removable) model is proposed. The calculation of the equilibrium points for the stability analysis of the system is performed. Two equilibrium points were found, one disease-free and the other endemic, for which the existence conditions are discussed. The stability of the points was analysed and the results were verified through simulations varying the parameters of vaccination, reinfection and social distancing.

Introduction

Due to technological advances, which used to take time to get from one place to another, today it travels in a matter of hours, facilitating the risk of the appearance of a new virus quickly turning into a pandemic. The interest in studying the modeling of infectious diseases lies in understanding the mechanisms of transmission and thus being able to establish prevention policies. Mathematical modelling is useful to show the dynamics of disease spread and indicate which parameters are relevant to guide control strategies.

One of the ways to study the spread of a disease is to establish models composed of a set of formal mathematical symbols to relate population groups, dividing them into compartments, giving rise to compartmental models [1, 2]. These models are an approximation of the real relationships existing in the object of study [3, 4]. For this matter, differential equations are used that establish dynamic relationships between their states depending on the rate of infection, social isolation, mortality, recovery, and vaccination rate [5].

These models contributed to the study of Covid-19 [6]. A disease that quickly became a serious pandemic, claiming the lives of millions of people around the world [7]. The present work aims to analyse the influence of the vaccination rate, as well as the influence of its effectiveness in reducing the spread of the virus.

For this, it is proposed a modification in the Susceptible - Infected - Removed (SIR) compartment model proposed by Kermack and McKendrick in 1927 [8, 9, 10]. In this new model, social distancing, the effect of the vaccine [11, 12], and its effectiveness in coordinated actions are considered. We want to study the influence of varying the effectiveness of vaccination on the endemic balance [13, 14, 15], as well as the effort needed to ensure its stability.

In addition, it is intended to evaluate the influence of the model parameters on the basic reproduction number of the infection (R_0). Which measures the infectivity of a pathogen in an environment in which no one has acquired immunity to it. With this parameter indicate the effective reproduction number (R_e), exposed to the real conditions of disease evolution and relating to the influence of variations in efficacy on vaccination strategies. The objective of the article is to study the effects of vaccination to prevent the spread of epidemics, to determine the minimum effort of the vaccine as well as the effect of reinfection in the disease control process.

Models Descriptions

The proposed model is a modification of the original SIR model proposed by Kermack and McKendrick [8, 9, 10]. In this model, the susceptible population S is infected at a rate when it comes in contact with an infected individual from I . The effect of social distancing measures in the susceptible individuals is introduced by the parameter θ , and the subject to the condition $0 < \theta < 1$ and ω is the group to which vaccination is given.

The compartment I represents the infectious population in the incubation phase prior to the onset of symptoms and this population can be asymptomatic or symptomatic. The total population is considered constant, the mortality rate is equal for members of all classes, μ is the mortality and birth rate assumed to be equal, β is the recovery rate, and δ is the reinfection rate, as shown in figure 1.

The model assumes the following hypotheses:

- Fixed population;
- The ways to stop being susceptible is if a person becomes infected, if he is immunized by vaccination or by the mortality rate;
- When the person recovers, they receive permanent immunity;
- The probability of infection is not affected by age, sex or social status;

Figure 1: SIR model with vaccine influence, social isolation and reinfection rate.

- The birth and death rate are part of the considerations;
- All births fall into the susceptible class;
- The mortality rate is the same for all compartments and mortality is assumed to be equal to the birth rate.
- The reinfection rate demonstrates the possibility that the individual will be susceptible again.

The model assumes the following notations:

$S(t)$ Number of susceptible individuals at time (t) ; $I(t)$ Number of infected individuals at time (t) ; $R(t)$ Number of individuals recovered at time (t) ; α probability of a susceptible individual becoming infected; β : probability of an infected recovering; θ : social isolation rate; ω vaccination rate of the susceptible; μ mortality rate; δ reinfection rate; N the death is equal for members of all three classes, and it is assumed that the birth and death rates are equal so that the total population is stationary.

Equations

Considering these elements, the model can be described as:

$$\begin{cases} \dot{S} &= \mu N - \frac{\alpha(1-\theta)S(t)I(t)}{N} - \omega S(t) - \mu S(t) + \delta R(t); \\ \dot{I} &= \frac{\alpha(1-\theta)S(t)I(t)}{N} - \beta I(t) - \mu I(t); \\ \dot{R} &= \beta I(t) + \omega S(t) - \mu R(t) - \delta R(t). \end{cases} \quad (1)$$

With constant populations:

$$\dot{S} + \dot{I} + \dot{R} = 0. \quad (2)$$

consequently:

$$S(t) + I(t) + R(t) = N. \quad (3)$$

Taking into account the population density:

$$s = \frac{S}{N}; i = \frac{I}{N}; r = \frac{R}{N}. \quad (4)$$

By substituting (4) in (1):

$$\begin{cases} \dot{s} &= \mu - \alpha(1-\theta)si - \omega s - \mu s + \delta r; \\ \dot{i} &= \alpha(1-\theta)si - \beta i - \mu i; \\ \dot{r} &= \beta i + \omega s - \mu r - \delta r; \end{cases} \quad (5)$$

with the initial conditions $s(0) \geq 0$, $i(0) \geq 0$ and $r(0) \geq 0$.

Here μ is the recruitment and natural death rate, α is the effective contact rate between susceptible and infected individuals, ω is the rate of vaccination, θ is the social isolation and δ is the reinfection rate. All the parameters are positive and for θ the restriction considered $0 < \theta < 1$.

Disease-free and endemic equilibrium points

To investigate the influence of the introduction of feedback from the recovered individuals with no immunity, the equilibrium points from (5) must be determined and their stability must be discussed.

For the proposed model, there are two equilibrium points: one endemic and the other free from infection.

Disease-free equilibrium point:

$$\bullet P_1 (s^*, i^*, r^*) = \left(\frac{\mu + \delta}{\omega + \mu + \delta}, 0, \frac{\omega}{\omega + \mu + \delta} \right);$$

Endemic equilibrium point:

- $P_2 (s^*, i^*, r^*)$ such as:
- $s^* = (\frac{\beta + \mu}{\alpha(1-\theta)});$
- $i^* = (\frac{\mu(\mu + \delta)(\alpha(1-\theta)) + \delta\omega(\beta + \mu) - (\beta + \mu)(\omega + \mu)(\mu + \delta)}{(\alpha(1-\theta))\mu(\beta + \mu + \delta)});$
- $r^* = (\frac{\beta}{\mu + \delta}i^* + \frac{\omega(\beta + \mu)}{(\mu + \delta)(\alpha(1-\theta))});$

Consequently, the existence condition for the endemic equilibrium P_2 is given by

$$\mu(\mu + \delta)(\alpha(1 - \theta)) + \delta\omega(\beta + \mu) > (\beta + \mu)(\omega + \mu)(\mu + \delta). \quad (6)$$

and obtain:

$$\omega < \mu \left(\frac{\alpha(1 - \theta)}{(\beta + \mu)} - 1 \right) \quad (7)$$

From the analysis of the endemic point, it can be seen that to guarantee its existence, it is necessary to respect the condition 7. Analyzing this point, the minimum vaccination effort necessary to reach the point free of infection can be concluded.

Stability analysis

In order to analyse the local stability of the system, the jacobian of the model is calculated at the equilibrium points.

$$J = \begin{bmatrix} -\alpha(1 - \theta)i^* - \omega - \mu & -\alpha(1 - \theta)s^* & \delta \\ \alpha(1 - \theta)i^* & \alpha(1 - \theta)s^* - \beta - \mu & 0 \\ \omega & \beta & -\delta - \mu \end{bmatrix}.$$

Analyzing the Jacobian at point P_1 :

$$J_{P_1} = \begin{bmatrix} -\omega - \mu & -\alpha(1 - \theta)s^* & 0 \\ 0 & \alpha(1 - \theta)s^* - \beta - \mu & 0 \\ \omega & \beta & -\mu \end{bmatrix}.$$

Using the mathematical tool Matlab 2015, the eigenvalues of the resulting Jacobian matrix are calculated, in order to analyze the stability of the equilibrium point.

Eigenvalues P_1 :

$$\lambda_1 = -\mu;$$

$$\lambda_2 = -\omega - \mu - \delta;$$

$$\lambda_3 = \alpha(1 - \theta)s^* - \beta - \mu.$$

The stability analysis for model figure 1 presents the disease free equilibrium point and, considering the existence condition, the eigenvalues are given by: $\lambda_1 = -\mu$, $\lambda_2 = -\omega - \mu - \delta$ and $\lambda_3 = \alpha(1 - \theta)s^* - \beta - \mu$. The third eigenvalue indicates that if $(s^* < \frac{\beta + \mu}{\alpha(1 - \theta)})$ the system is asymptotically stable and if $(s^* > \frac{\beta + \mu}{\alpha(1 - \theta)})$ the system becomes unstable indicating a bifurcation in the parameter space.

substituting the variable s^* for the expression calculated at the disease-free equilibrium point, we obtain:

$$\omega > \frac{(\mu + \delta)(\alpha(1 - \theta))}{\beta + \mu} - \mu - \delta, \quad (8)$$

from 8 we can conclude the minimum necessary effort of the vaccination strategy to eradicate the epidemic.

Numerical experiments

In order to clarify the stability results obtained analytically for points P_1 and P_2 , a series of numerical experiments were carried out.

From the analysis of point P_1 the bifurcation condition 8 is obtained for which the system can behave in a stable or unstable way. To show this behaviour, simulations were performed by varying the values of the system parameters. Figure 2, figure 3 show that for any initial condition, point P_1 it's stable if $\omega > \frac{(\mu + \delta)(\alpha(1 - \theta))}{\beta + \mu} - \mu - \delta$.

On the other hand, when the condition $\omega < \frac{(\mu + \delta)(\alpha(1 - \theta))}{\beta + \mu} - \mu - \delta$ is set, the system always reaches stability at the endemic point P_2 , behaviour that is shown in figures 5, 6 and 7.

Figure 4 shows that starting from an initial condition $(S, I, R) = (0.9, 0.12, 0.08)$, close to the equilibrium point P_1 , and with parameter values $\alpha = 0.6$, $\beta = 0.6$, $\theta = 0.1$, $\delta = 0.2$, $\mu = 0.01$ and $\omega = 0.3$. guaranteeing the stability condition, the P_1 point is reached.

Figure 5 shows that starting from an initial condition $(S, I, R) = (0.3, 0.7, 0.0)$, far to the equilibrium point P_1 , and with parameter values $\alpha = 0.6$, $\beta = 0.6$, $\theta = 0.1$, $\delta = 0.2$, $\mu = 0.01$ and $\omega = 0.3$. guaranteeing the stability condition, the P_1 point is reached.

Figure 2: disease free point.

Figure 3: disease free point.

Figure 4: disease free point phase.

In the figure 6 shows the phase diagram of the system with the combination of parameters so that the existence of a disease-free equilibrium point is guaranteed. Each trajectory represents a possible initial condition of the system variables (Susceptible and Infected) and their evolution over time until reaching the equilibrium point. The arrows indicate the direction of movement of the trajectories.

Figure 7 shows that starting from an initial condition $(S, I, R) = (0.3, 0.7, 0.0)$, close to the equilibrium point P_2 , and with parameter values $\alpha = 0.9, \beta = 0.3, \theta = 0.1, \delta = 0.2, \mu = 0.3$ and $\omega = 0.1$. guaranteeing the stability condition, the P_2 point is reached.

Figure 8 shows that starting from an initial condition $(S, I, R) = (0.8, 0.2, 0.0)$, far from the equilibrium point P_2 , and with parameter values $\alpha = 0.9, \beta = 0.3, \theta = 0.1, \delta = 0.2, \mu = 0.3$ and $\omega = 0.1$. guaranteeing the stability condition, the P_2 point is reached.

In the figure 9 shows the phase diagram of the system with the combination of parameters so that the existence of an endemic equilibrium point is guaranteed. Each trajectory represents a possible initial condition of the system variables (Susceptible and Infected) and their evolution over time until reaching the equilibrium point. The arrows indicate the

Figure 5: Endemic point

Figure 6: Endemic point

Figure 7: Endemic point phase

direction of movement of the trajectories.

The proposed model is intended to show that in a population where the disease has a temporary immunity character, there is a minimum vaccination effort necessary to eradicate the disease. This result can be verified through variations in the change in the parameters of vaccination, reinfection and social distancing.

In order for the disease-free point to be reached, a minimum vaccination effort given by the equation 8. If the vaccination strategy does not follow this regime, the disease will remain in the population indicating endemic characteristics.

Conclusion

This paper presented a modification of the Susceptible-Infected-Removed (SIR) compartmental model proposed by Kermack and McKendrick in 1927. The social distance, the effect of the vaccine, and its effectiveness in coordinated actions were considered. In addition, the influence of variation in vaccination efficacy on the endemic equilibrium, and the effort required to ensure its stability, were studied.

From the analytical and numerical results, it can be said that the model has two equilibrium points, one endemic and the other disease-free, the existence of each being given by a bifurcation condition that depends on the probability of infection, the social distance and the recovery and infection rates. From there it is possible to find the minimum effort necessary to prevent the epidemic from occurring.

As shown above the existence of the endemic or disease-free point depends on the value of the existence condition. The higher the vaccination and social distancing, the faster the disease-free point will be reached.

Dynamics of a self-propelled soft capsule moving in the small intestine

Summary. In this work, we study the dynamics of a vibro-impact soft capsule self-propelling in the small intestine for capsule endoscopy through finite element modelling. Soft coating by using the super-soft silicone rubber was used to reduce the potential damage induced by the rigid capsule on the intestine. Our studies indicate that the dynamics of the capsule becomes complex due to the capsule-intestine interaction, and the coating's elastic modulus and thickness may affect the performance of the capsule significantly. Therefore, a proper selection of these coating parameters is vital for capsule design.

Introduction

The small intestine, an anatomical site previously considered inaccessible to clinicians due to its small diameter and lengthy size, is the part of the gastrointestinal tract between the stomach and the colon as illustrated in Fig. 1(a). Since its introduction into clinical practice twenty years ago, capsule endoscopy [1] has become established as the primary modality for examining the surface lining of the small intestine. However, its reliance on peristalsis for passage through the intestine leads to significant limitations [2], in particular due to the unpredictable and variable locomotion speed. Significant abnormalities, e.g., small-bowel bleeding, may be missed, due to intermittent high transit speeds that lead to incomplete visualisation of the intestinal surface. Furthermore, each case produces up to 100,000 still images, from which video footage is generated, taking 30-90 minutes for the clinician to examine in its entirety. The current procedure is considered both time-consuming and burdensome for clinicians.

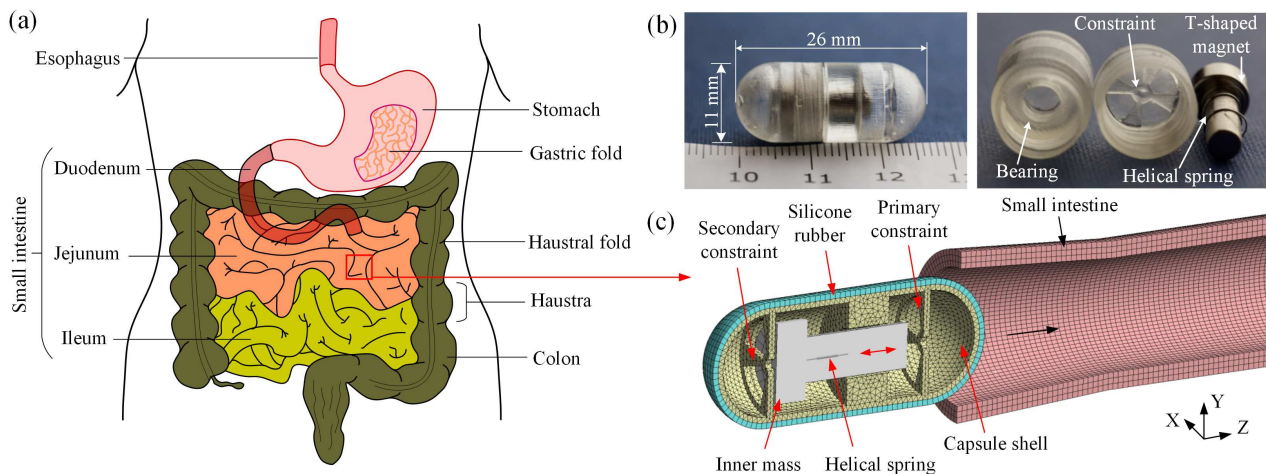

Figure 1: (a) Anatomy of the gastrointestinal tract, (b) external and internal views of the rigid capsule prototype [3] and (c) cross-sectional view of the finite element model, where the coated capsule consists of an inner mass (T-shaped magnet) vibrating and impacting with the primary and the secondary constraints under external magnetic excitation and the interaction of a helical spring.

Building a reliable propulsive mechanism in a capsule (with 26 mm in length and 11 mm diameter) for active endoscopy is a challenging task. Different propulsion methods were proposed in the past few decades for small-intestine diagnosis. The purpose of this work is to study the dynamics of a soft capsule self-propelled in the small intestine through finite element (FE) modelling. The self-propelled capsule developed in the Applied Dynamics and Control Lab at the University of Exeter [3] as shown in Fig. 1(b) can progress either forward or backward driven by its internal vibrations and impacts. Previous FE investigation [4, 5] has focused on studying the capsule-intestine interaction by using a rigid capsule made of polyethylene. However, to reduce the potential damage caused by the rigid shell on the intestine and optimise the capsule's movement, super-soft silicone rubber was used to coat the capsule shell. In this work, we explored the complex dynamics of the coated capsule moving in the lumen of the small intestine as presented in Fig. 1(c) under different coating parameters, such as the coating's elastic modulus and thickness.

Finite element model

FE modelling of the capsule-intestine contact was carried out by using ANSYS WORKBENCH with the consideration of material parameter configuration, geometry, contact settings, meshing, constraints and loads. As can be seen from Fig. 1(c), the polyethylene capsule shell was coated by the super-soft silicone rubber uniformly, and the diameter of the coated capsule was kept as 11 mm. The inner mass made by a T-shaped magnet can move forward and backward under the excitation of an external square-wave magnetic field. The frequency, amplitude and duty cycle ratio of the magnetic

field were the control parameters to be tested, and the capsule was driven within a small intestine with an inner diameter of 10 mm. If the interaction force between the inner mass and the capsule is greater than the intestinal friction, the capsule will move either forward or backward. In the present work, we studied the influence of capsule coating's elastic modulus and thickness on its dynamics and progression speed and compare them with the original capsule without any coating.

Numerical results

Capsule's progression and phase trajectories under different elastic moduli of the coating obtained from the FE model are presented in Fig. 2. Based on our simulation, the capsule has an average speed of 14 mm/s when the elastic modulus of the coating is 8 psi, and the average speed is 21 mm/s when the coating is increased to 10 psi. As the elastic modulus increases to 12, 14 and 16 psi, the capsule oscillates at its original position only without any progression. According to our observation, this was due to the fact that the intestine moved together with the capsule, so no relative movement was generated between the capsule and the intestine. When the capsule has no coating, the average speed of the capsule is 18 mm/s. As can be seen from the phase portraits in Fig. 2, the capsule has periodic motions for all the cases. However, the capsule cannot repeat the exact periodic motion, which is due to the asymmetric capsule-intestine interaction.

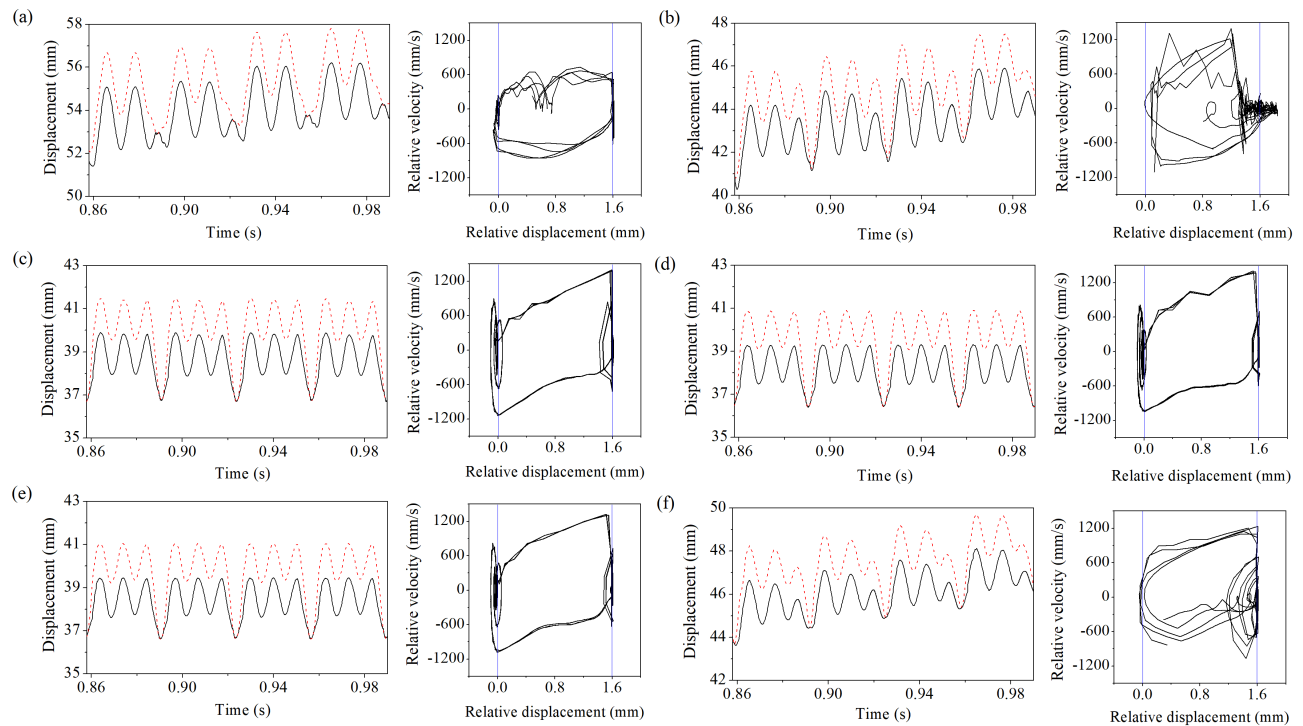

Figure 2: Time histories of displacements of the capsule (black solid lines) and the inner mass (red dashed lines) and their corresponding phase trajectories (relative displacement versus velocity between the inner mass and the capsule) obtained for the elastic moduli of the coating at (a) 8 psi, (b) 10 psi, (c) 12 psi, (d) 14 psi, (e) 16 psi and (f) no coating. The inner mass was driven by a square-wave excitation with the frequency of 30 Hz, the amplitude of 0.3 N and the duty cycle of 80%. Left and right vertical blue lines on the phase portraits indicate the impact boundaries for the secondary and the primary constraints, respectively.

Conclusions

To conclude, the coating of the capsule has a significant influence on the nonlinear motion of the capsule. With a proper selection of elastic modulus and thickness of the coating, an optimum progression of the capsule can be achieved. Our further studies indicate that a harder coating may lead to a greater capsule-intestine contact pressure, while a thicker coating can reduce the contact pressure which can minimise the damage induced by the capsule on the intestine.

Extended abstract

When studying the response of a structure to a dynamic excitation, the modelling of energy dissipation has always been a challenge to the engineers. Different methodologies were set up for different kinds of problems. These include the modelling of friction forces, hysteretic behavior and restitution coefficients for non-linear structures. For linear structures, modelled with finite elements, the general practice is to use either viscous equivalent modal damping or viscous proportional “Rayleigh” damping.

Content overview

The first part of the paper gives a quick overview of the most usual representations of energy dissipation in dynamic analyses, with a particular focus on the use of a proportional Rayleigh damping and its drawbacks when applied to a linear but not linearly supported structure. The second part describes the “ghost” damping methodology set in place to overcome those drawbacks. The third part presents tests case basis on which the “ghost” damping was checked, including simple examples representative of a handling crane, a fuel rack and a seismically isolated building.

PART 1: Representation of energy dissipation in usual engineering practices

Values for modal damping are found in numerous seismic design codes around the world and they constitute the energy dissipation modelling basis for most applications in the industry (see references [1], [2], [3], and [5]). It has become common practice to try to apply these modal damping values to dynamic problems that are not solved on a modal basis. To do so with a finite element model, the most widely applied method consists in building a viscous damping matrix [C] as a linear combination of the mass matrix [M] and the stiffness matrix [K], α and β being referred to as the Rayleigh coefficients. This method is referred to as the Rayleigh method, after the work of Baron Rayleigh in the 1870s (see [6] in the references). It is possible to create a [C] matrix that produces a required given modal damping value, although for only two structural modes at most.

For the case of linear structures, with a non linear supporting system, which will be the main focus of this paper, an unwanted effect of using a Rayleigh damping, even only on the linear part of the model, is that it produces damping forces that will spuriously limit, and ultimately stop the motion of the structure relative to its support basis. Indeed, the $\alpha[M]$ part of the Rayleigh damping matrix is predominantly diagonal. These diagonal terms, when multiplied by the velocity vector, produce damping forces proportional to the velocity of each node relative to the calculation referential, as illustrated by equation (1) for a two mass system, with a single degree of freedom for each node (U_X is the displacement of node X relative to the calculation referential, M_X the mass attached to this node).

$$\{F_{\alpha_damping}\} = \alpha \begin{bmatrix} M_1 & 0 \\ 0 & M_2 \end{bmatrix} \begin{Bmatrix} \dot{U}_1 \\ \dot{U}_2 \end{Bmatrix} = \begin{Bmatrix} \alpha M_1 \dot{U}_1 \\ \alpha M_2 \dot{U}_2 \end{Bmatrix} \quad (1)$$

Any rigid body motion of this two mass system relative to the calculation referential gives rise to non intended resisting damping forces. This phenomenon will be referred to as the “spurious damping of rigid body motions” in this paper.

On the other hand, the $\beta[K]$ part of the Rayleigh damping produces forces that are only proportional to the relative velocities between nodes connected by an element. As an example, if a spring of stiffness K_1 connects the two masses of the simple system described earlier, the resulting damping forces are illustrated by equation (2).

$$\{F_{\beta_damping}\} = \beta \begin{bmatrix} K_1 & -K_1 \\ -K_1 & K_1 \end{bmatrix} \begin{Bmatrix} \dot{U}_1 \\ \dot{U}_2 \end{Bmatrix} = \begin{Bmatrix} \beta K_1 (\dot{U}_1 - \dot{U}_2) \\ \beta K_1 (\dot{U}_2 - \dot{U}_1) \end{Bmatrix} \quad (2)$$

These forces do represent dissipation of energy because of structural deformation, which is generally the objective assigned to Rayleigh damping.

The inadequacy of using the $\alpha[M]$ part of the Rayleigh damping is known and some references can be found in regulatory documentations such as [1] and [2]. As a consequence, cautious engineers will only use the $\beta[K]$ part and therefore lose the ability to properly damp the lower frequency modes of the structures. Such approach invariably results in overly conservative estimations of the structural responses.

PART 2: Description of the ‘GHOST’ damping methodology

The so-called “ghost” damping methodology has been specifically developed for the case of linear structures on a non linear support. Its objective is to overcome the two drawbacks of the Rayleigh proportional damping method identified in Part 1: controlled modal damping value on only two modes and spurious damping of rigid body motions. In the case of non linearly supported linear systems, the non linear support is generally explicitly modelled and is itself a source of energy dissipation, through friction coefficients (case of a handling crane) or modelling of a hysteretic material behaviour (case of a seismically isolated building). The linear part is modelled by linear stiffness and mass matrices, $[K]$ and $[M]$, which remain constant throughout the calculations.

The “ghost” methodology aims at producing damping forces on the linear structure which are only proportional to the structure deformation velocities. This is what happens with the usual Rayleigh damping for purely linear systems. To achieve this goal, the rigid body motion of the linear part of the model is subtracted from its overall movement when constructing the damping forces vectors. The form of these desired damping forces is illustrated in equation (3) for the two-masses-one-stiffness system described earlier.

$$\{F_{\alpha_damping}\} = \begin{Bmatrix} \alpha M_1 (\dot{U}_1 - \dot{U}_{g1}) \\ \alpha M_2 (\dot{U}_2 - \dot{U}_{g2}) \end{Bmatrix} \text{ and } \{F_{\beta_damping}\} = \begin{Bmatrix} \beta K_1 (\dot{U}_1 - \dot{U}_2) \\ \beta K_1 (\dot{U}_2 - \dot{U}_1) \end{Bmatrix} \quad (3)$$

The $\beta[K]$ part is of the same nature as the proportional Rayleigh damping $\beta[K]$ matrix. The $\alpha[M]$ part results in forces proportional to the node velocity minus the rigid body motion velocity at the node location. In this equation, U_{gx} represents the displacement of node X due only to the rigid body motion.

PART 3: Tests cases basis for the “GHOST” damping methodology

Tests cases will be developed in the full article.

Conclusions

Two drawbacks of using a classic proportional Rayleigh damping methodology in the dynamic analysis of non-linearly supported linear structures were highlighted: spurious damping of rigid body motions and under-damping of some major modes located in between the first and the last mode frequencies of interest. These drawbacks are known and the cautious engineer will usually make conservative assumptions to avoid the first one. The present paper describes a methodology to suppress the spurious damping of rigid body motion by using a “ghost” structure within a FE model and generate damping forces proportional to the actual structure velocities relative to its “ghost”. At the same time, different Rayleigh coefficients are used for different directions, in order to bring the equivalent modal damping values of the linear part of the model closer to the targets in each direction, often defined in the codes.

Basins of attraction for the model of rotating hub with two pendulums

Zofia Szmit*, Nemanja Andonovski[†], Stefano Lenci[†] and Jerzy Warmański*

*Department of Applied Mechanics, Faculty of Mechanical Engineering, Lublin University of Technology, Lublin, Poland

Summary. The goal of this paper is to study nonlinear dynamics of the system consisting of two pendulums attached to a hub rotating in the horizontal plane. Equations of motion are derived from Lagrange equations of the second kind. Next, the equations are transformed to the system of six first-order ordinary differential equations. Based on the set of first-order differential equations of motion basins of attraction are calculated. Moreover, the synchronisation phenomenon is studied in case of symmetric and nonsymmetric pendulums.

Introduction

Rotating structures have many applications in mechanical and aerospace engineering, like for example arms of industrial robots, wind turbines, helicopter rotors and jet engines. Additionally, pendulums are very well known as dampers for instance in high buildings and helicopter rotor dampers. There are many publications, which are concentrated on pendulums, like a paper about a model consisting of chains of nonlinear coupled pendulums subjected to harmonic excitations [1]. Authors studied nonlinear dynamics and synchronisation phenomenon for that theoretical model, they examined an influence of initial conditions as well as an influence of horizontal excitation on motion of the chain system. Most of the paper about dynamics of pendulums are focused on pendulums rotating only in a vertical plane, while a different approach is presented in [2]. Authors presented numerical results for a model of a hub with pendulums rotating in the horizontal plane, they proved that the model is strongly nonlinear and even chaotic motion may appear. Authors linearised the problem and solved such equations analytically for small oscillations. Whereas, analysis of basin of attraction are very useful, specially in case of strongly nonlinear systems. They consist regions of all the initial conditions that converge to associated attractors forward in time. Analyzing the basins of attraction we can inspect the impact of initial conditions on the global behaviour of a dynamical system [3].

The aim of this paper is to study the dynamics and synchronisation phenomenon in a system composed of a rotating hub with two pendulums. Basins of attractions are calculated to study excited vibrations of the system. Additionally, the synchronisation phenomenon in a case of symmetric and nonsymmetric system and bifurcation scenario is study as well.

Model and equations of motion

The analyzed model consists of the two pendulums attached to a rigid hub rotating in the horizontal plane. Mathematical pendulums are connected to the hub by joints treated as a flapping hinge with nonlinear Duffing's type spring and a linear viscous damper.

Figure 1: Model of the hub with two pendulums rotating in the horizontal plane; top view

The hub is described by radius R_0 and mass moment of inertia J_0 , while m_j and l_j are mass and length of the pendulums, c_j is a viscous damping coefficient and k_j , k_j^* , k and k^* are the nonlinear spring coefficients, where $j = 1, 2$. Two types of nonlinear springs, first type in the hinges and second type spring connecting the hub with background are used in the model. Additionally we assume that, the hub may oscillate or rotate in the horizontal plane, while pendulums may oscillate and also rotate around the hinge in their relative motion. The gravity force does not influence the dynamics of the system, because of the hub rotation in a horizontal plane. Motion of the hub is represented by angle of rotation ψ , while variables φ_j are coordinates of relative motion of the pendulum with respect to the hub.

The differential equations of motion are derived on the basis of Lagrange equations of the second kind and written in the dimensionless form as shown below:

$$\begin{aligned}
 & (1 + \gamma_1 + \gamma_2) \ddot{\psi} + \zeta_h \dot{\psi} + 2 \frac{\gamma_1}{\delta_1} \dot{\delta}_1 \dot{\psi} + 2 \frac{\gamma_2}{\delta_2} \dot{\delta}_2 \dot{\psi} + \frac{\gamma_1}{\delta_1} \cos \beta_1 \ddot{\varphi}_1 + \frac{\gamma_2}{\delta_2} \cos \beta_2 \ddot{\varphi}_2 \\
 & + \frac{\gamma_1}{\delta_1^2} \cos \beta_1 \dot{\delta}_1 \dot{\varphi}_1 + \frac{\gamma_2}{\delta_2^2} \cos \beta_2 \dot{\delta}_2 \dot{\varphi}_2 + \frac{\gamma_1}{\delta_1} \frac{d}{d\tau} (\cos \beta_1) \dot{\varphi}_1 + \frac{\gamma_2}{\delta_2} \frac{d}{d\tau} (\cos \beta_2) \dot{\varphi}_2 + \kappa_h \psi + \kappa_h \psi^3 = \mu \\
 & \ddot{\varphi}_1 + \delta_1 \cos \beta_1 \ddot{\psi} + \delta_1 \frac{d}{d\tau} (\cos \beta_1) \dot{\psi} + \cos \beta_1 \dot{\delta}_1 \dot{\psi} - \delta_1 \frac{d\delta_1}{d\varphi_1} \dot{\psi}^2 \\
 & - \cos \beta_1 \dot{\delta}_1 \dot{\psi} - \delta_1 \frac{d}{d\tau} (\cos \beta_1) \dot{\psi} + \zeta_1 \dot{\varphi}_1 + \omega_{01}^2 \varphi_1 + \kappa_1 \omega_{01}^2 \varphi_1^3 = 0 \\
 & \ddot{\varphi}_2 + \delta_2 \cos \beta_2 \ddot{\psi} + \delta_2 \frac{d}{d\tau} (\cos \beta_2) \dot{\psi} + \cos \beta_2 \dot{\delta}_2 \dot{\psi} - \delta_2 \frac{d\delta_2}{d\varphi_2} \dot{\psi}^2 \\
 & - \cos \beta_2 \dot{\delta}_2 \dot{\psi} - \delta_2 \frac{d}{d\tau} (\cos \beta_2) \dot{\psi} + \zeta_2 \dot{\varphi}_2 + \omega_{02}^2 \varphi_2 + \kappa_2 \omega_{02}^2 \varphi_2^3 = 0,
 \end{aligned} \tag{1}$$

where μ is external harmonic torque supplied to the hub, defined as: $\mu = \rho \cos(\omega\tau)$. The equations of motion (1) are strongly nonlinear and coupled by inertia and nonlinear geometric terms. First equation describes the motion of the hub, while two other equations represent the motion of each pendulum.

Results

The set of equations have been transformed to the system of six first-order ordinary differential equations and the following relations have been introduced: $\psi = y_0, \dot{\psi} = y_1, \varphi_1 = y_2, \dot{\varphi}_1 = y_3, \varphi_2 = y_4$ and $\dot{\varphi}_2 = y_5$. In the numerical calculation it is assumed that the pendulum No. 1 is slightly shorter than second pendulum. Firstly, the resonance curves and trajectories of the system attractors are computed. Next, basins of attraction are obtained, which is very time consuming numerical procedure.

Figure 2: Basin cross-section of the hub, segment with $y_{2-5} = 0.075$ for the excitation frequency a) $\omega = 1.4$, b) $\omega = 1.5$ and c) $\omega = 1.6$

In Fig. 2 we are able to see basin cross-section for the hub, where initial states of pendulums are close to zero. For the frequency $\omega = 1.4$ the gray basin takes most of the area, for higher values of ω the blue basin increases significantly. Furthermore, results on Fig. 2 shows that the motion of the hub in most of the cases converge to gray and blue attractors, while purple attractor has impact motion of pendulums. Blue, purple and gray attractors are corresponding to periodic motion.

Final remarks

The strongly nonlinear model of the hub rotating in the horizontal plane with two pendulums is studied. The resonance curves and trajectories of the system attractors are computed as well as basins of attraction. The obtained results give us more accurate understanding of the dynamics of the analyzed model.

Abstract

High speed rotor systems mounted on gas foil bearings present bifurcations which change the quality of stability, and may compromise the operability of rotating systems, or increase noise level when response amplitude drastically increases. The paper identifies the dissipating work in the gas film to be the source of self-excited motions driving the rotor whirling close to bearing's surface. The energy flow among the components of the system is evaluated for various design sets of bump foil properties, rotor stiffness and unbalance magnitude. The paper presents a methodology to retain the dissipating work at positive values during the periodic limit cycle motions caused by unbalance. An optimization technique is embedded in the pseudo arc length continuation of limit cycles, those evaluated (when exist) utilizing an orthogonal collocation method. The optimization scheme considers the bump foil stiffness and damping as the variables for which bifurcations do not appear in a certain speed range. It is found that Neimark-Sacker bifurcations, which trigger large limit cycle motions, do not exist in the unbalanced rotors when bump foil properties follow the optimization pattern. Period doubling bifurcations are possible to occur, without driving the rotor in high response amplitude. Different design sets of rotor stiffness and unbalance magnitude are investigated for the efficiency of the method to eliminate bifurcations. The quality of the optimization pattern allows optimization in real time, and bearing properties shift values during operation, eliminating bifurcations and allowing operation in higher speed margins.

Introduction

Gas Foil Bearings (GFBs) are part of a promising oil-free technology in modern high-speed rotating machinery, distinguished for their reliability, simplicity, and environmentally friendly characteristics. Relying on a thin gas film building up an aerodynamic, load-carrying lubrication wedge, such bearings are self-acting and do not require any external pressurization. Most notably, due to the absence of solid-to-solid contact between the airborne rotor journal and the bearing sleeve, excessively low wear and power loss can be achieved. Several types of GFBs have been introduced in the past, with the most common and efficient being the bump type foil bearing. The major difference detected in comparison with the conventional oil bearings is the presence of a thin gas film as a lubricant, which results to building up an aerodynamic, load-carrying lubrication wedge and eliminates the need for external pressurization [1-4].

During the last few decades, the potential of GFBs has been widely confirmed by a great number of successful applications in air cycle machines of commercial aircraft [5]. Lately, in particular as a result of insurmountable speed, temperature, and weight limitations of conventional rolling-element bearings, novel concepts of oil-free turbochargers [6], oil-free rotorcraft propulsion engines [7], and micro gas turbines [8] are gaining increasing interest. Gas foil bearings have been successfully used in high-speed turbomachines, and they present a remarkable reliability. As the stiffness of the foils is much smaller than that of the fluid film, the foil bearings can adapt to various working conditions through foil deformations. Owing to these advantages, foil bearings are identified as a potential alternative for oil bearings. If properly designed and operated, foil bearings would incur very slight wear and have a long service life [7].

The design of a GFB is a multi-physical problem, and the research work on GFBs follows generically scientific objectives which have to couple each other at most times; these are mainly a) the material development (super alloys) for use in the GFB components [3], b) the fluid-structure interaction including the aerodynamic lubrication problem (compressible flow) and the structural problem predicting the bump foil structure dynamic properties and dynamic behaviour [9-12], c) the nonlinear dynamics of simple or complex rotors mounted on GFBs [13-19], d) the development of alternative GFB configurations including also adjustable configurations and control schemes [20].

Nonlinear dynamics of rotor-GFB systems, and its study with tools like continuation methods, is relatively new object. Continuation methods have been applied on the nonlinear dynamics of rotor systems on oil bearings of several types [21,22], and recently in GFB rotor systems as well [23]. Bifurcations of Hopf type have been investigated at both bearing types (with oil and gas) [24]. The strongly nonlinear aerodynamic forces render a variety of motions and stability quality in the system, including periodic, quasi periodic and chaotic motions. Further to that, the system has the potential of totally different motions even at the same operating speed, according to initial conditions and operating parameters, such unbalance magnitude. Dynamic systems present stable and unstable solution branches and respective bifurcation sets, and this is the case in rotor-GFB systems too. Nonlinear dynamics of rotor-GFB systems were mostly used to correlate the quality of response of the system with advances in top/bump foil structure simulation, or alternative models in the aerodynamic simulation.

Further to the aerodynamic modelling and, the bump type foil modelling has been investigated during the last decades as its properties are directly correlated to the aerodynamic performance of the bearing. Heshmat et al. [1] introduced the so-called simple elastic foundation model, consisting of linear elastic uncoupled springs. No viscous damping was taken

into account until Peng and Carpino [9] and Ku and Heshmat [26] took into consideration the top-to-bump foil and bump-to-housing Coulomb friction damping. Later on, Peng and Carpino [27] introduced a 2D foil model structure characterized by linear stiffness and damping coefficients, while considering the elastic behaviour of the bump foil. Alternative approaches have been published by Lez et al. [25] and other researchers [23], where the foil bumps and their interaction are modelled by multi-degree freedom systems. Baum et al. [12] introduced another foil structure, consisting of rigid, massless, beam-like elements with one finite dimension in axial direction and no coupling of the elements in the circumferential one, where each bump foil is modelled by a non-linear spring and a linear damper.

This paper aims to the insight of the local instability mechanisms, which trigger bifurcations, and drive the response of the system far from its elastic response (self-excited vibrations), usually close to the bearing clearance in journal positions and the rotor-stator clearance along the rotor. In this paper, it is found that the dissipating energy in the gas film should be directly correlated to the first (at lower speed) bifurcation detected in such a system, this being a Neimark-Sacker bifurcation in the unbalanced system, at most cases, or a period-doubling (flip) bifurcation in some others. Specifically, this paper benefits from the well-known lemma that self-excited motions are triggered when negative damping is included in the system; similar notification was made in [28] for rotors on oil bearings, under linear harmonic analysis. The energy flow is evaluated in this system for various design sets and this is used to an optimization scheme to avoid bifurcations in a certain speed range. The paper is organized as follows:

The dynamic system of consisting of an elastic Jeffcott rotor mounted on two GFBs is composed for the autonomous and the non-autonomous case. The composition of the system renders a set of ordinary differential equations of 1st order (ODE set). The aerodynamic lubrication model and the bump foil structural model follow existing literature [12,14]. The authors program the pseudo arc length continuation method [29-31] with embedded orthogonal collocation method to provide the potential periodic solutions of the ODE set with unbalance excitation.

Moreover, the quality of motions developed in such system is discussed evaluating the bifurcation sets, the time-frequency decomposition of the response and Floquet multipliers, for some design scenarios and at a certain speed range. The energy flow is evaluated in the system during the respective periodic motions, with primary interest on the dissipative work of gas forces. An optimization scheme of successive polls for the two GFB design variables is implemented from the literature [32] and retains the dissipative work in the gas film positive in the respective speed range; Neimark-Sacker bifurcations are found to be eliminated in the respective speed range. However, period doubling bifurcations still exist at some cases, without these to drive the response at high amplitudes though. Different rotor stiffness and unbalance magnitude are considered in the results. The paper concludes that maximizing the dissipative work in the gas film does not trigger self-excited motions of the system, in a certain operating speed range, approximately two times wider than the respective without optimization of the GFB properties.

Modelling and Formulation of the Nonlinear Dynamic System

The physical model of the flexible rotor and of the gas foil bearings is presented in Fig. 1 where the symmetric rotor model considers the well-known Jeffcott rotor. The analytical dynamic model includes 4 DoFs for the rotor (due to symmetry), and the unique parameter of rotor design included in the model is the rotor's lateral stiffness \bar{k}_s . The gas foil bearing model [2] considers linear spring and damping properties in the bump foil in the radial direction, and the key parameters of the gas bearing design consider the bump foil compliance $\bar{\alpha}_f$, and the pump foil damping coefficient c_f as a function of the loss factor η .

Figure 1: a) representation of an elastic Jeffcott rotor model with two journal masses at its ends, mounted on two gas-foil bearings;
b) representation of the gas foil bearing configuration

Analytical model of the gas bearing

The assumptions introduced in the elastoaerodynamic lubrication problem are: a) isothermal gas film, b) laminar flow of the gas, c) no-slip boundary conditions, d) continuum flow, e) negligible fluid inertia, f) ideal isothermal gas law ($p/\rho = \text{constant}$), g) negligible entrance and exit effects, and h) negligible curvature ($R \approx R + c_r$). The Reynolds

equation for compressible gas flow under these assumptions is given in Eq. (1) [12], and it is an implicit function of time and of journal and top foil kinematics.

$$\frac{\partial}{\partial \bar{x}} \left(\bar{p} \bar{h}^3 \frac{\partial \bar{p}}{\partial \bar{x}} \right) + \kappa^2 \frac{\partial}{\partial \bar{z}} \left(\bar{p} \bar{h}^3 \frac{\partial \bar{p}}{\partial \bar{z}} \right) = \bar{\Omega} \frac{\partial}{\partial \bar{x}} (\bar{p} \bar{h}) + 2 \frac{\partial}{\partial \tau} (\bar{p} \bar{h}) \quad (1)$$

Analytical solution for Eq. (1) cannot be defined; a common approach to evaluate the pressure distribution is the FDM. The pressure domain is converted into a grid of $i=1, \dots, N_x+1$ and $j=1, \dots, N_z+1$ points, where i and j are the indexes in the circumferential and axial direction respectively, see Fig. 3a.

The Reynolds equation is first rewritten defining the first time derivative of the pressure in Eq. (2a) and after some math in Eq. (2b). Then, the discrete Reynolds equation is defined in the grid points expressing the partial derivatives with finite differences.

$$\frac{\partial}{\partial \tau} (\bar{p} \bar{h}) = \frac{1}{2} \frac{\partial}{\partial \bar{x}} \left(\bar{p} \bar{h}^3 \frac{\partial \bar{p}}{\partial \bar{x}} \right) + \frac{\kappa^2}{2} \frac{\partial}{\partial \bar{z}} \left(\bar{p} \bar{h}^3 \frac{\partial \bar{p}}{\partial \bar{z}} \right) - \frac{\bar{\Omega}}{2} \frac{\partial}{\partial \bar{x}} (\bar{p} \bar{h}) \quad (2a)$$

$$\dot{\bar{p}} = \frac{1}{2\bar{h}} \frac{\partial}{\partial \bar{x}} \left(\bar{p} \bar{h}^3 \frac{\partial \bar{p}}{\partial \bar{x}} \right) + \frac{\kappa^2}{2\bar{h}} \frac{\partial}{\partial \bar{z}} \left(\bar{p} \bar{h}^3 \frac{\partial \bar{p}}{\partial \bar{z}} \right) - \frac{\bar{\Omega}}{2\bar{h}} \frac{\partial}{\partial \bar{x}} (\bar{p} \bar{h}) - \frac{\dot{\bar{p}} \bar{h}}{\bar{h}} \quad (2b)$$

Figure 2a: Finite difference grid $N_x \times N_z$ used for the evaluation of pressure distribution

Figure 2b: Definition of the mean pressure p_m applied over bearing length L_b , and of gas force F_b with respective indexes.

Figure 2c: Representation of the physical model; bump foil is modelled by linear springs and dampers.

The dimensionless parameters of gas pressure \bar{p} , gas film thickness \bar{h} , spatial coordinates (circumferential and axial respectively) θ and \bar{z} , time τ , rotating speed $\bar{\Omega}$, and ratio $\kappa = R/L_b$ are included in the elastoaerodynamic lubrication problem of Eq. (1). The gas film thickness function is defined in Eq. (3) for the continuous and the discrete pressure domain (finite difference grid) where $\bar{q} = \bar{q}(\theta)$ (or $\bar{q}_i = \bar{q}(\theta_i)$ in the discrete pressure domain) is the foil deformation in radial direction, see also Fig. 2a and Fig. 3b.

$$\bar{h} = 1 - \bar{x}_j \cos \theta - \bar{y}_j \sin \theta + \bar{q}, \quad \bar{h}_i = 1 - \bar{x}_j \cos \theta_i - \bar{y}_j \sin \theta_i + \bar{q}_i \quad (3)$$

Boundary and initial conditions of the problem are defined in continue. Ambient pressure is assumed at the starting and ending angle of the foil (periodic boundary condition) in Eq. (4), in the continuous and the discrete pressure domain respectively.

$$\bar{p}(\tau, \theta_0, \bar{z}) = \bar{p}(\tau, \theta_0 + 2\pi, \bar{z}) = 1, \quad \bar{p}_{1,j} = \bar{p}_{N_x+1,j} = 1 \quad (4)$$

Taking into account the symmetry of the lubrication problem, instead of assuming the gas pressure equal to the ambient p_o at the axial ends, $\bar{p}(\bar{z}=0) = \bar{p}(\bar{z}=1) = 1$, the boundary condition can be written in Eq. (5) (for the continuous and the discrete pressure domain). In this way the lubrication problem is solved in the half domain, reducing the evaluation cost severely.

$$\left. \frac{\partial \bar{p}}{\partial \bar{z}} \right|_{\bar{z}=1/2} = 0, \quad \frac{\bar{p}_{i,N_z/2} - \bar{p}_{i,N_z/2-1}}{\Delta \bar{z}} = 0 \quad (5)$$

Last, the initial conditions for the dimensionless form of the problem are defined in Eq. (6) (in the continuous and the discrete pressure domain).

$$\bar{p}(\tau=0, \theta, \bar{z}) = 1, \quad \bar{p}_{i,j} = 1 \quad \text{and} \quad \bar{q}(\tau=0, \theta) = 0, \quad \bar{q}_i = 0 \quad (6)$$

After evaluating gas pressure \bar{p} (as $\bar{p}_{i,j}$), the nonlinear gas forces are determined in Eq. (7), where $\Delta\bar{x} = 2\pi / N_x$ and $\Delta\bar{z} = 1 / N_z$.

$$\bar{F}_{B,X} = - \int_0^{2\pi} \int_0^1 (\bar{p}-1) \cos \theta d\bar{z} d\theta = - \sum_{i=2}^{N_x} \sum_{j=2}^{N_z} ((\bar{p}_{i,j}-1) \cos \theta_i \Delta\bar{x} \Delta\bar{z}) \quad (7a)$$

$$\bar{F}_{B,Y} = - \int_0^{2\pi} \int_0^1 (\bar{p}-1) \sin \theta d\bar{z} d\theta = - \sum_{i=2}^{N_x} \sum_{j=2}^{N_z} ((\bar{p}_{i,j}-1) \sin \theta_i \Delta\bar{x} \Delta\bar{z}) \quad (7b)$$

In this way the aerodynamic problem renders $N_x \cdot N_z$ ODEs of 1st order with respect to the time derivative of the point pressure in Eq. (8)

$$\dot{\bar{\mathbf{p}}} = \left\{ \dot{\bar{p}}_{i,j} \right\} = \mathbf{f}_B(\bar{\mathbf{p}}, \bar{\mathbf{x}}, \dot{\bar{\mathbf{x}}}, \bar{\mathbf{q}}, \dot{\bar{\mathbf{q}}}) \quad (8)$$

The vectors $\bar{\mathbf{x}}$ and $\bar{\mathbf{q}}$ may be perceived as $\bar{\mathbf{x}} = \{x_j \quad y_j \quad x_d \quad y_d\}^T$ representing the journal motion (coupled to the disc motion through the rotor's equations of motion) and $\bar{\mathbf{q}} = \{\bar{q}_1 \quad \bar{q}_1 \quad \dots \quad \bar{q}_{N_x}\}^T$ representing the foil motion (coupled to the journal motion through the Reynolds equation due to the gas film thickness function).

It is important to mention that it is quite common that sub-ambient pressure arises in GFBs. The sub-ambient pressure can cause the top foil to separate from the bumps into a position in which the pressure on both sides of the pad is equalized. Heshmat et al. [1] introduced a set of boundary conditions accounting for this separation effect. More specifically, a simple Gumbel boundary condition is imposed, meaning that sub-ambient pressures are discarded when integrating the pressure in Eq. (7) to obtain the bearing force components $\bar{F}_{B,X}$, $\bar{F}_{B,Y}$ essentially leaving the sub-ambient regions ineffective. In terms of numerical calculations, the assumption made by Heshmat [1] can be simply explained as following: in case fluid pressure p is lower than the ambient p_0 , then the former should be considered equal to p_0 and the foil deformation at these points will be zero ($\bar{q}_i = 0$ for $\bar{p}_i < 1$).

The simplified model for the bump foil structure is depicted at Fig. 2b. The structure consists of $N_x - 2$ linear massless elements of stiffness \bar{k}_f (compliance $\bar{a}_f = 1 / \bar{k}_f$) and damping \bar{c}_f . The springs and dampers mount the corresponding $N_x - 1$ top foil stripes of area $\Delta x \cdot L_b$ (or dimensionless area $\Delta\bar{x} \cdot 1$), see Fig. 3b. The top foil of the bearing is not covering a complete cylinder; a single gap can be found at $\theta = \theta_0$, see Fig. 2a, where the top foil is clamped to the bearing housing. Therefore, the moving top foil stripes are $N_x - 1$, see Fig. 3b. The top foil stripes are assumed to remain parallel to the bearing longitudinal axis during their lateral motion, therefore no axial coordinate is required for the top foil motion. The geometry of the foil structure and its properties, shown in Figs. 2a and 3b, render the dimensionless compliance $\bar{\alpha}_f = 2p_0(l_0/t_b)^3(1-v^2)s_0/(c_f E)$ [14]. The motion of each of the top foil stripe is excited by the mean gas pressure $\bar{p}_{m,i}$ acting on the top of it, creating the gas force $\bar{F}_B(i)$, see Figs. 2b and 3b. The mean gas pressure $\bar{p}_{m,i}$ is defined in Eq. (9) (in the continuous and discrete pressure domain respectively), for dimensional and dimensionless form.

$$p_m(\theta) = \frac{1}{L_b} \int_0^{L_b} p(\theta) dz, \quad p_{m,i} = \frac{1}{L_b} \sum_{j=2}^{N_z} (p_{i,j} \Delta z), \quad \bar{p}_{m,i} = \frac{1}{1} \sum_{j=2}^{N_z} (\bar{p}_{i,j} \Delta\bar{z}) = \frac{1}{N_z} \sum_{j=2}^{N_z} (\bar{p}_{i,j}) \quad (9)$$

The foil stiffness and damping coefficient are given as $\bar{k}_f = 1 / \bar{\alpha}_f$ and $\bar{c}_f = \eta \bar{k}_f$ for foil motion synchronous to the excitation. The $N_x - 1$ ODEs that describe the radial displacement \bar{q}_i of the stripe i are defined in Eq. (10).

$$\bar{c}_f \dot{\bar{q}}_i + \bar{k}_f \bar{q}_i = \bar{p}_{m,i}, \quad i = 2, 3, \dots, N_x \quad (10)$$

The ODEs in Eq. (10) may be written as in Eq. (11) to be used in continue.

$$\dot{\bar{\mathbf{q}}} = \left\{ \dot{\bar{q}}_i \right\} = \mathbf{f}_F(\bar{\mathbf{q}}, \bar{\mathbf{p}}, \bar{\mathbf{x}}, \dot{\bar{\mathbf{x}}}) \quad (11)$$

Analytical model of the flexible rotor

The equations of motion for the Jeffcott rotor shown in Fig. 1 are defined in Eq. (12) for the journal and the disc, in the two main directions, horizontal and vertical.

$$\ddot{\bar{x}}_j = \frac{m_d}{2m_j} \bar{k}_s (\bar{x}_d - \bar{x}_j) + \xi \cdot \bar{F}_{B,X}, \quad \ddot{\bar{y}}_j = \frac{m_d}{2m_j} \bar{k}_s (\bar{y}_d - \bar{y}_j) + \xi \cdot \bar{F}_{B,Y} - \sigma \quad (12a)$$

$$\ddot{\bar{x}}_d = -\bar{k}_s (\bar{x}_d - \bar{x}_j) + \bar{F}_{U,X}, \quad \ddot{\bar{y}}_d = -\bar{k}_s (\bar{y}_d - \bar{y}_j) + \bar{F}_{U,Y} - \sigma \quad (12b)$$

The ODEs in Eq. (12) may be written in Eq. (13), in the state space representation, to be used in continue.

$$\dot{\bar{\mathbf{x}}} = \mathbf{f}_R(\bar{\mathbf{p}}, \bar{\mathbf{x}}, \dot{\bar{\mathbf{q}}}, \dot{\bar{\mathbf{q}}}) \quad (13)$$

In Eq. (12) \bar{k}_s is the dimensionless shaft stiffness coefficient, and ξ, σ are dimensionless parameters defined in Eq. (14).

$$\xi = \frac{36\mu^2 LR^5}{m_j p_0 c_r^5}, \quad \sigma = \frac{36\mu^2 R^2 g}{p_0^2 c_r^5} \quad (14)$$

In addition, in Eq. (12), $\bar{F}_{U,X}$ and $\bar{F}_{U,Y}$ are the dimensionless unbalance forces defined in Eq. (15a) for constant rotating speed $\bar{\Omega}$, and in Eq. (15b) for linearly varying rotating speed $\bar{\Omega} = \bar{a} \cdot \tau$ with constant acceleration \bar{a} .

$$\bar{F}_{U,X} = \varepsilon \cdot \bar{\Omega}^2 \cos \bar{\varphi}_r, \quad \bar{F}_{U,Y} = \varepsilon \cdot \bar{\Omega}^2 \sin \bar{\varphi}_r, \quad \bar{\varphi}_r = \bar{\Omega} \tau \quad (15a)$$

$$\bar{F}_{U,X} = \varepsilon (\bar{\Omega}^2 \cos \bar{\varphi}_r + \bar{a} \sin \bar{\varphi}_r), \quad \bar{F}_{U,Y} = \varepsilon (\bar{\Omega}^2 \sin \bar{\varphi}_r - \bar{a} \cos \bar{\varphi}_r), \quad \bar{\varphi}_r = \bar{a} \tau^2 / 2 \quad (15b)$$

Dimensionless unbalance eccentricity $\varepsilon = e_u / c_r$ follows in this paper the ISO unbalance grades (G-grades) for low, medium, and high unbalance as G1, G2.5 and G6.3 correspondingly. The unbalance located in the disc is of magnitude $u = (m_d + 2m_j) e_u$ at each case, and the corresponding eccentricity e_u is given by Eq. (16), where the service speed of the system is selected at $\Omega_r = 2500 \text{ rad/s}$.

$$e_u [\text{mm}] = \frac{G}{\Omega_r [\text{rad/s}]}, \quad G = 1, 2.5, 6.3 \quad (16)$$

Composition and solution of the dynamic system

Eqs. (8), (11), and (13) compose a coupled ODE set which is composed by the discretized Reynolds equation in the \mathbf{f}_B equations, the foil motion in \mathbf{f}_F equations, and the rotor motion in \mathbf{f}_R equations. The coupled nonlinear ODE set is defined in Eq. (17) expressing a non-autonomous dynamic system which will be studied with respect to the bifurcation parameter $\bar{\Omega}$. The ODE set is characterized as non-autonomous due to the explicit time presence in the equations of unbalance forces, see Eq. (15). The state vector $\bar{\mathbf{s}}$ and the respective functions \mathbf{f} are defined in Eq. (18).

$$\dot{\bar{\mathbf{s}}} = \mathbf{f}(\bar{\mathbf{s}}, \bar{\Omega}, \tau) \quad (17)$$

$$\bar{\mathbf{s}} = \{\bar{\mathbf{p}} \quad \bar{\mathbf{q}} \quad \bar{\mathbf{x}}\}^T, \quad \mathbf{f} = \{\mathbf{f}_B \quad \mathbf{f}_F \quad \mathbf{f}_R\}^T \quad (18)$$

The total number of equations in Eq. (17) (size of vector function \mathbf{f}) is $N = (N_x \cdot N_z) + (N_x - 1) + 8$ with the first term coming from the pressure equations, the second term coming from the foil equations, and the third term from the rotor equations in state space.

The ODE set in Eq. (17) renders the time response of the physical system when time integration is applied [32]. The system is numerically stiff and special algorithms are applied in time integration [32]. Furthermore, the Reynolds equation can be reduced in size applying an order reduction method [12], improving the computational cost. The time integration can handle both cases of unbalance equations, for constant rotating speed or for run-up, see Eq. (15).

An orthogonal collocation method [30] is applied for the computation of limit cycle motions produced by the ODE set in Eq. (17) at a constant $\bar{\Omega}$; Eqs. (15a) apply for unbalance forces at this case. Numerical continuation of limit cycles has been programmed by the authors according to pseudo arc length continuation method [29,33] with embedded collocation scheme [30]. The formulation of the method is defined also in Appendix A1. As the collocation method cannot handle non-autonomous ODE systems, Eq. (17) has to be converted to autonomous. This is achieved by coupling the ODE set of Eq. (17) with a two DoF oscillator, see Eq. (19), whose unique solution is a harmonic motion of frequency $\bar{\Omega}$, see Eq. (20) [30].

$$\dot{\bar{s}}_{N+1} = f_{N+1} = \bar{s}_{N+1} + \bar{\Omega} \cdot \bar{s}_{N+2} - \bar{s}_{N+1} \cdot (\bar{s}_{N+1}^2 + \bar{s}_{N+2}^2) \quad (19a)$$

$$\dot{\bar{s}}_{N+2} = f_{N+2} = -\bar{\Omega} \cdot \bar{s}_{N+1} + \bar{s}_{N+2} - \bar{s}_{N+2} \cdot (\bar{s}_{N+1}^2 + \bar{s}_{N+2}^2) \quad (19b)$$

$$\bar{s}_{N+1} = \cos(\bar{\Omega}\tau), \quad \bar{s}_{N+2} = \sin(\bar{\Omega}\tau) \quad (20)$$

The size of the final autonomous ODE set is $N + 2$ and is defined in Eq. (21) with the unbalance forces to be defined at constant rotating speed, in Eq. (22).

$$\dot{\tilde{\mathbf{s}}} = \tilde{\mathbf{f}}(\tilde{\mathbf{s}}, \bar{\Omega}) \quad (21a)$$

$$\tilde{\mathbf{s}} = \begin{Bmatrix} \bar{\mathbf{s}}^T & \bar{s}_{N+1} & \bar{s}_{N+2} \end{Bmatrix}^T, \quad \tilde{\mathbf{f}} = \begin{Bmatrix} \mathbf{f}^T & f_{N+1} & f_{N+2} \end{Bmatrix}^T \quad (21b)$$

$$\bar{F}_{U,X} = \varepsilon \cdot \bar{\Omega}^2 \bar{s}_{N+1}, \quad \bar{F}_{U,Y} = \varepsilon \cdot \bar{\Omega}^2 \bar{s}_{N+2} \quad (22)$$

Results and Discussion

The dynamic system defined in Eq. (19) in autonomous and in Eq. (20) in non-autonomous version is investigated on its potential to develop a variety of bifurcation sets with respect to the key design parameters, namely rotor stiffness \bar{k}_s , foil compliance \bar{a}_f , foil loss factor η , and unbalance magnitude u . In this paper, the key design parameters are defined within specific intervals, composing the case studies which are presented in continue. The design parameters follow a variation of “low”, “reference”, and “high”. This is interpreted to the rotor stiffness values $\bar{k}_s = 0.3, 1, 3$ (flexible to rigid rotor), foil compliance values $\bar{a}_f = 0.01, 0.1, 1$ (stiff to flexible foil), foil loss factor $\eta = 0.005, 0.05, 0.5$ (low to high foil damping), and unbalance magnitude $u(G1), u(G2.5), u(G6.3)$ (low to high unbalance). A reference system is defined with the design parameters to be $\bar{k}_s = 1$, $\bar{a}_f = 0.1$, $\eta = 0.05$, and $u(G6.3)$.

Figure 3: Reference system of $\bar{k}_s = 1$, $\bar{a}_f = 0.1$, $\eta = 0.05$, and $u(G6.3)$ a) Transient response and continuation of limit cycles during run-up b) STFT of the response time history c) Floquet multipliers of the corresponding limit cycles

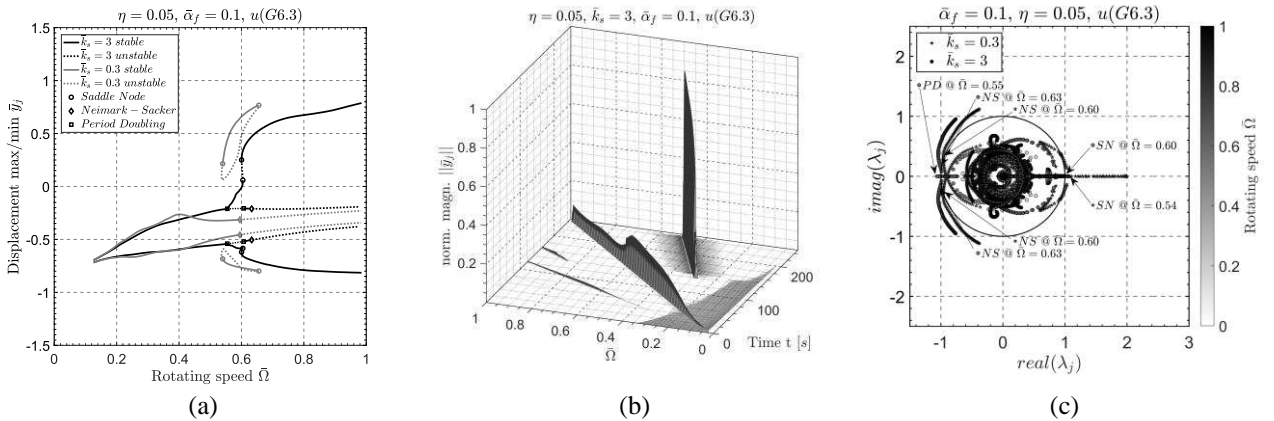

Figure 4: System of $\bar{k}_s^-, \bar{k}_s^+, \bar{a}_f = 0.1, \eta = 0.05, u = (G6.3)$ a) Continuation of limit cycles, b) STFT of the response time history \bar{k}_s^+ , c) Floquet multipliers of the corresponding limit cycles.

In Fig. 3a the time history of the journal motion in the vertical plane is presented together with the maximum and minimum values of the limit cycle at each rotating speed. It has to be clarified that the rotating speed is retained constant when limit cycles are evaluated, and the unbalance forces are applied with different formulas in the ODE system in the transient run-up and in the ODE system for constant rotating speed. A reference bifurcation set is established in Fig. 3a with PD, SN, and NS bifurcations to be presented. The frequency content of the time history

obtained during the run-up is depicted in Fig. 3b where time-frequency decomposition is applied. The Floquet multipliers in Fig. 3c provide information regarding the quality of bifurcations mentioned above. In Fig. 4 considers systems of different rotor stiffness, and two cases are presented in Fig. 4a for $\bar{k}_s^+ = 3$ and $\bar{k}_s^- = 0.3$. One may notice the difference compared to the reference case. Period doubling bifurcation is not noticed in this case.

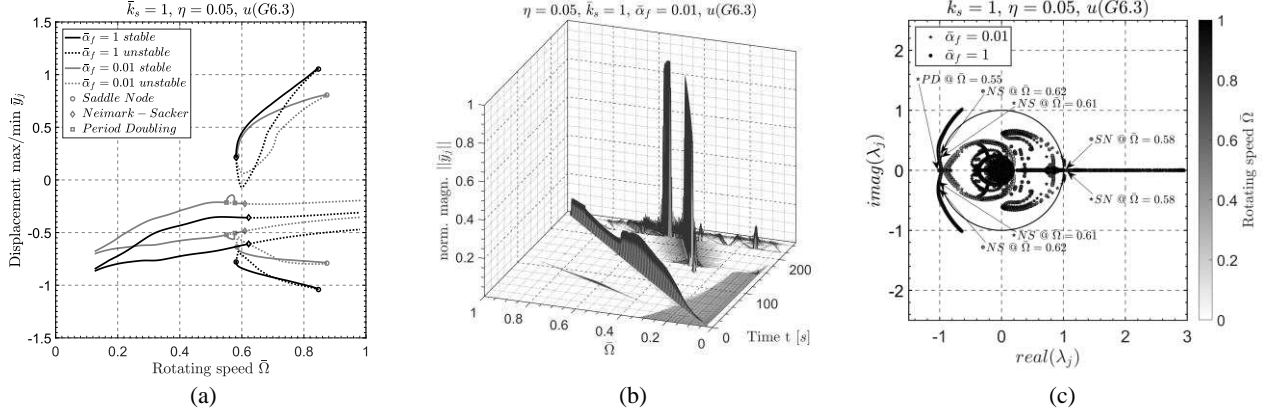

Figure 5: System of $\bar{k}_s = 1$, \bar{a}_f^-, \bar{a}_f^+ , $\eta = 0.05$, $u(G6.3)$. a) Continuation of limit cycles, b) STFT of the response time history for \bar{a}_f^+ , c) Floquet multipliers of the corresponding limit cycles.

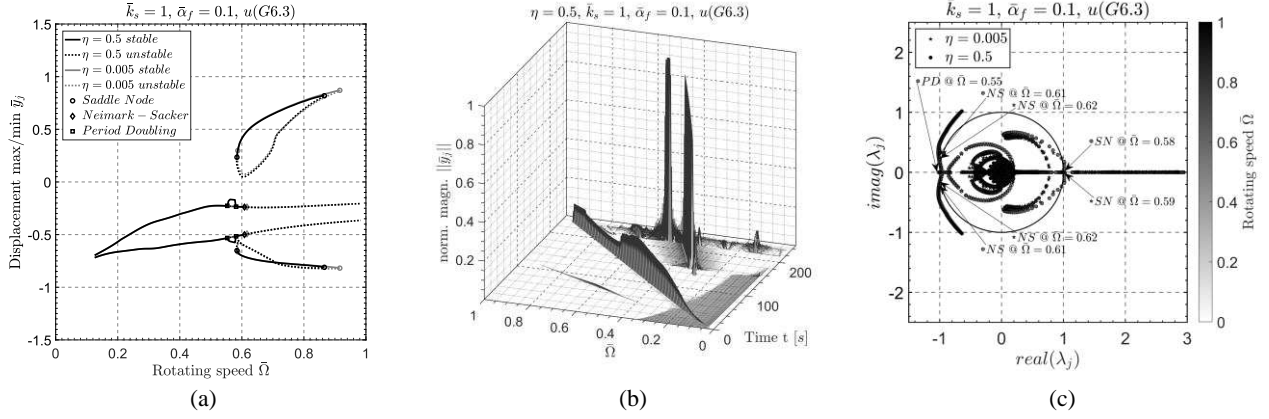

Figure 6: System of $\bar{k}_s = 1$, $\bar{a}_f = 0.1$, η^-, η^+ , $u(G6.3)$. a) Continuation of limit cycles, b) STFT of the response time history for η^+ , c) Floquet multipliers of the corresponding limit cycles for η^+ .

Figure 7: System of $\bar{k}_s = 1$, $\bar{a}_f = 0.1$, $\eta = 0.05$. a) Continuation of limit cycles, b) STFT of the response time history, c) trajectory, Poincare map, and FFT at $\bar{\Omega} = 0.97$, d) Floquet multipliers of the corresponding limit cycles.

In Fig. 5, systems of different foil compliance are considered, and two cases are presented in Fig. 5a, for $\bar{a}_f^+ = 1$ (flexible foil) and $\bar{a}_f^- = 0.01$ (rigid foil). One may notice the different bifurcation sets compared to the reference case, and the previous case. The type of bifurcations are same to this at the reference case, but the speed in which they appear is different.

In Fig. 6, systems of different foil damping are considered, and two cases are presented in Fig. 6a, for $\eta^+ = 0.5$ (high foil damping) and $\eta^- = 0.005$ (low foil damping). The influence of foil damping in the bifurcation set is not severe, compared to the reference design (see Fig. 3).

In Fig. 7, systems of different unbalance are considered. It is worth noticing that the autonomous system of $u(G0)$ loses local stability of fixed point equilibria through an Andronov-Hopf bifurcation, at similar speed where the unbalanced systems lose local stability through NS bifurcations. Further to that, in the unbalanced systems, the higher the unbalance is, the lower the speed of NS bifurcations is. Stable limit cycles close to radial clearance occur with higher amplitude in the balanced system, than in the unbalanced systems. In the balanced system the limit cycles of amplitude close to radial clearance will lose stability through a NS bifurcation at high speeds.

Energy flow and optimization for bifurcation elimination

The work of the bearing forces is evaluated in Eq. (23a), the work of the bump foil forces is evaluated in Eq. (23b), and the work of unbalance forces is evaluated in Eq. (23c).

$$W_B = 2 \sum_{i=1}^{N_i} (F_{B,X}(i) \cdot \delta x_j(i) + F_{B,Y}(i) \cdot \delta y_j(i)) = W_{cb} + W_{kb} \quad (23a)$$

$$W_f = 2 \sum_{i=1}^{N_i} \left(\sum_{j=1}^{N_j} F_{f,j}(i) \cdot \delta q_j(i) \right) = W_{cf} + W_{kf}, \quad W_{fu} = \sum_{i=1}^{N_i} (F_{U,X}(i) \cdot \delta x_d(i) + F_{U,Y}(i) \cdot \delta y_d(i)) \quad (23b,c)$$

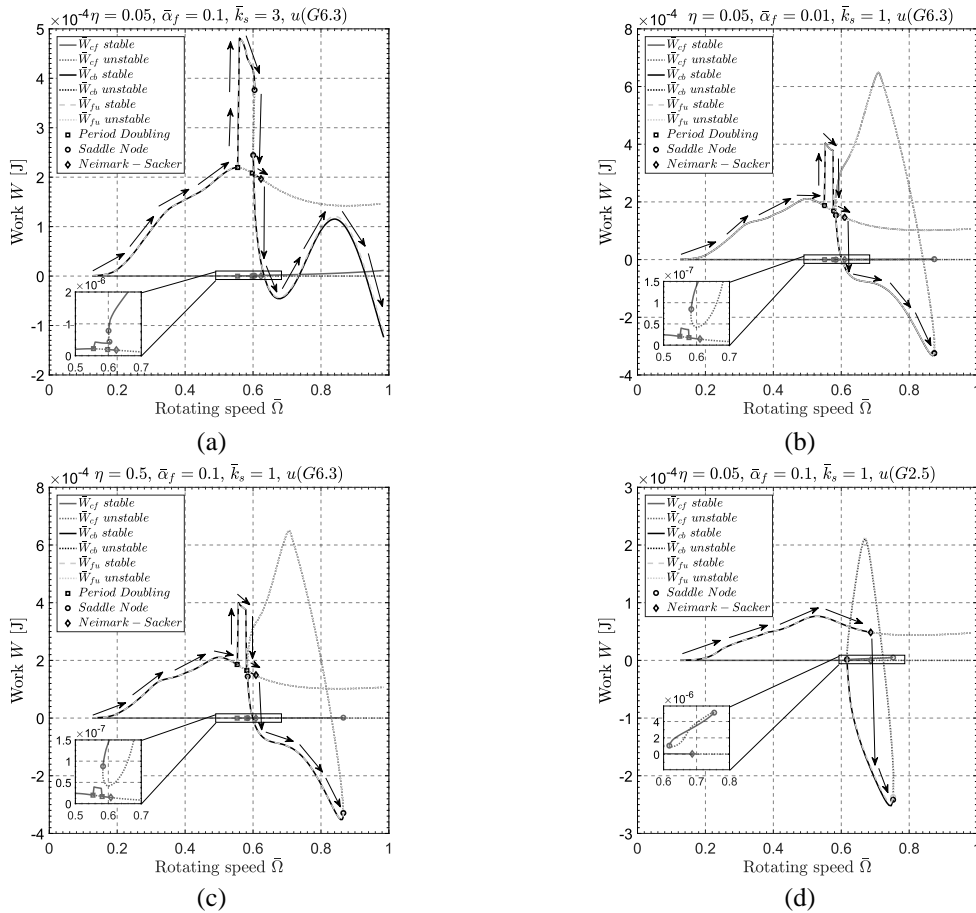

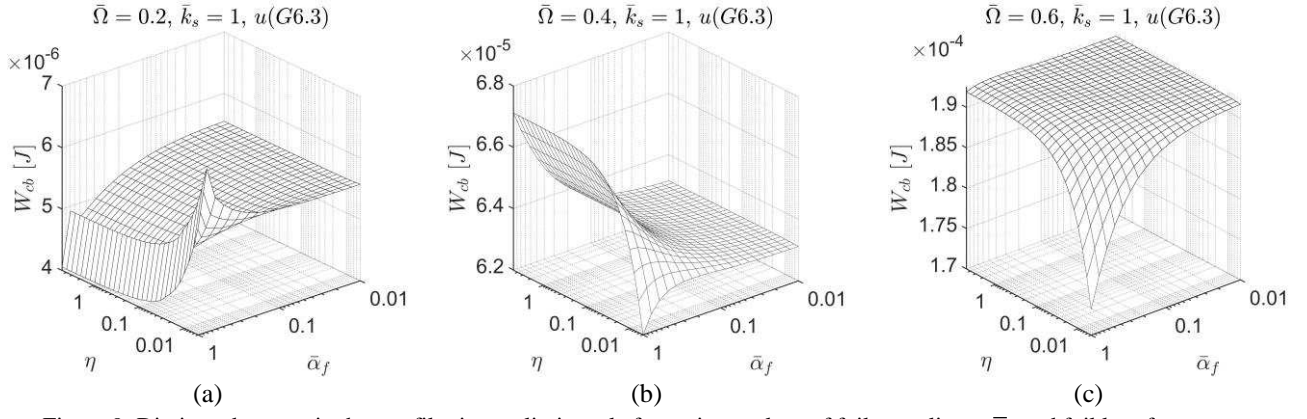

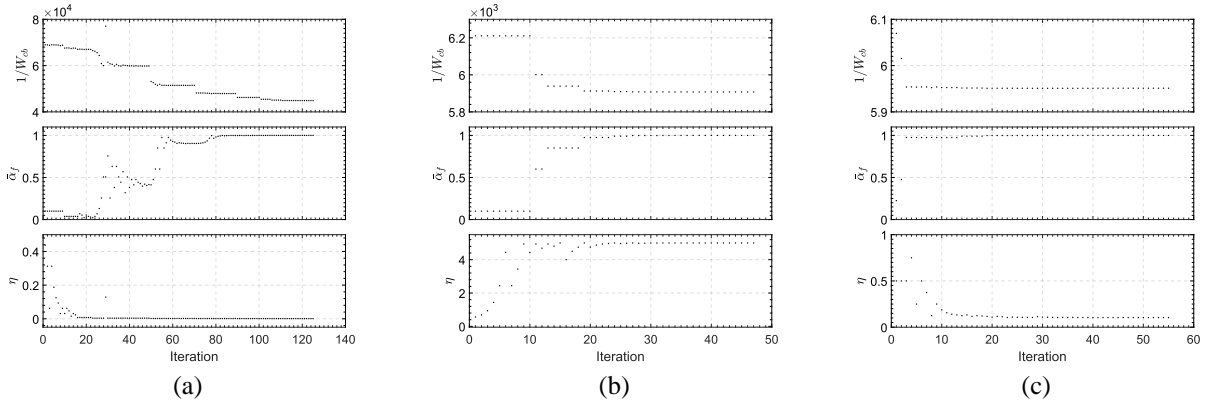

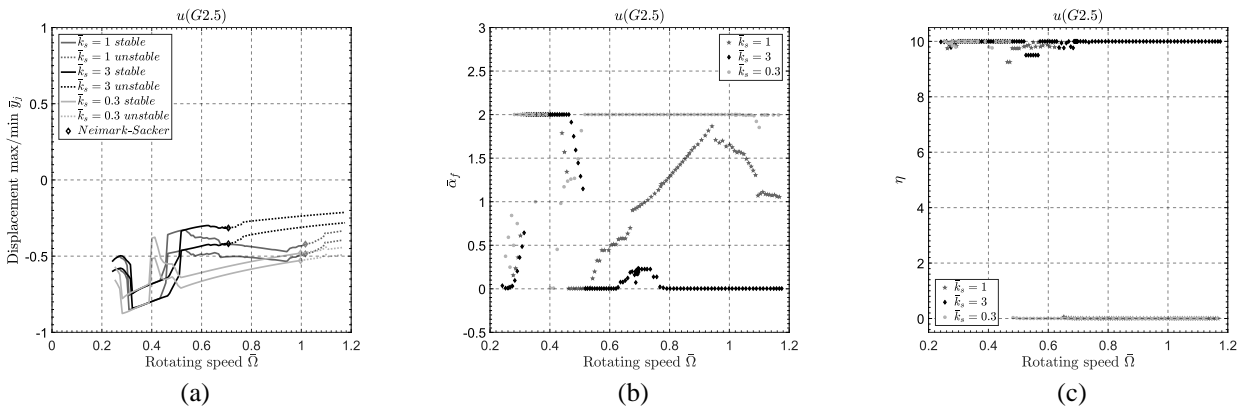

Figure 8: Evaluation of energy flow at the respective limit cycles for a) $\bar{k}_s = 3$, $\bar{\alpha}_f = 0.1$, $\eta = 0.05$, $u(G6.3)$ b) $\bar{k}_s = 1$, $\bar{\alpha}_f = 0.01$, $\eta = 0.05$, $u(G6.3)$, c) $\bar{k}_s = 1$, $\bar{\alpha}_f = 0.1$, $\eta = 0.5$, $u(G6.3)$, and d) $\bar{k}_s = 1$, $\bar{\alpha}_f = 0.1$, $\eta = 0.05$, $u(G2.5)$.

In Figs. 8a-d, both stable and unstable limit cycles are considered with the respective notation. At all cases, it is found that Neimark-Sacker bifurcations are triggered simultaneously to the reverse (from positive values to negative) of the dissipating work in the gas film W_{cb} , meaning that energy is not dissipated in the gas film (when $W_{cb} < 0$) and self-excitation takes place. The respective limit cycles for the cases in Fig. 8 can be found in the previous Section. In Figs. 8a-d, the arrows depict the path that would be followed during the run-up of the system (time integration).

 Figure 9: Dissipated energy in the gas film in one limit cycle for various values of foil compliance $\bar{\alpha}_f$ and foil loss factor η , at

 a) $\bar{\Omega} = 0.2$, b) $\bar{\Omega} = 0.4$, c) $\bar{\Omega} = 0.6$

 Figure 10: Optimization of the dissipated energy in the gas film of the reference system with $\bar{k}_s = 1$ and $u(G6.3)$ with respect to the foil compliance $\bar{\alpha}_f$ and the foil loss factor η , at a) $\bar{\Omega} = 0.2$, b) $\bar{\Omega} = 0.4$, c) $\bar{\Omega} = 0.6$.

The optimization requires the minimization of an objective function OBJ , which is defined as the inverse of dissipated energy in the gas film, $OBJ = 1/W_{cb}$. Starting from random input values for foil compliance $\bar{\alpha}_f$ and foil loss factor η , the optimization pattern renders after some iterations the values of $\bar{\alpha}_f$ and η that maximize W_{cb} at every speed $\bar{\Omega}$. The limit cycle is plotted in Figs. 11 and 12 with the respective values $\bar{\alpha}_f$ and η at each speed $\bar{\Omega}$, for various design cases. Different rotor stiffness is considered in Fig. 11, and different unbalance magnitude applies in Fig. 12; the efficiency of the methodology to suppress bifurcations at a desired speed range is depicted. The operating speed range is limited by the limit values for the foil compliance $\bar{\alpha}_f$ and the foil loss factor η , here defined as $0.01 \leq \bar{\alpha}_f \leq 2$ and $0.0005 \leq \eta \leq 10$. These values may be considered differently according to the design limitations in each application of the rotating system. Considering the bifurcations sets evaluated in Section 3.2 for various designs, Figs. 15 and 16 depict elimination of bifurcations in approximately double speed range. It is also worth noticing that the bifurcation-free speed range is limited by a secondary Hopf (Neimark-Sacker) bifurcation at all cases of design.

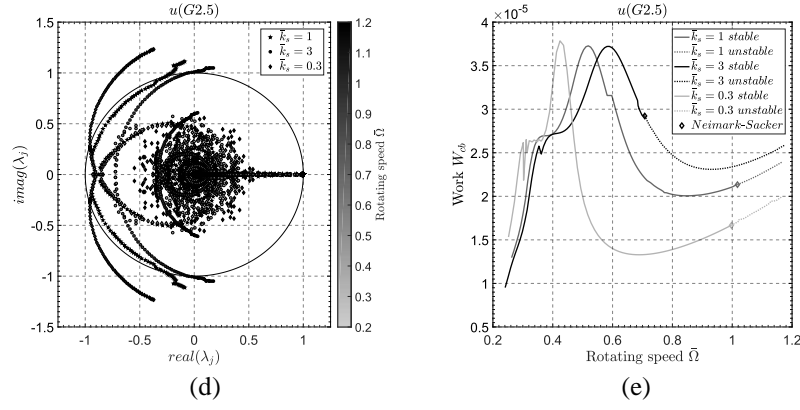

Figure 11: Elimination of bifurcations at a speed range for the system of $u(G2.5)$ and $\bar{k}_s = 0.1$, $\bar{k}_s = 1$, $\bar{k}_s = 3$ a) journal motion limit cycles and corresponding values for b) compliance \bar{a}_f , c) loss factor η , d) Floquet multipliers e) dissipating work in the gas film

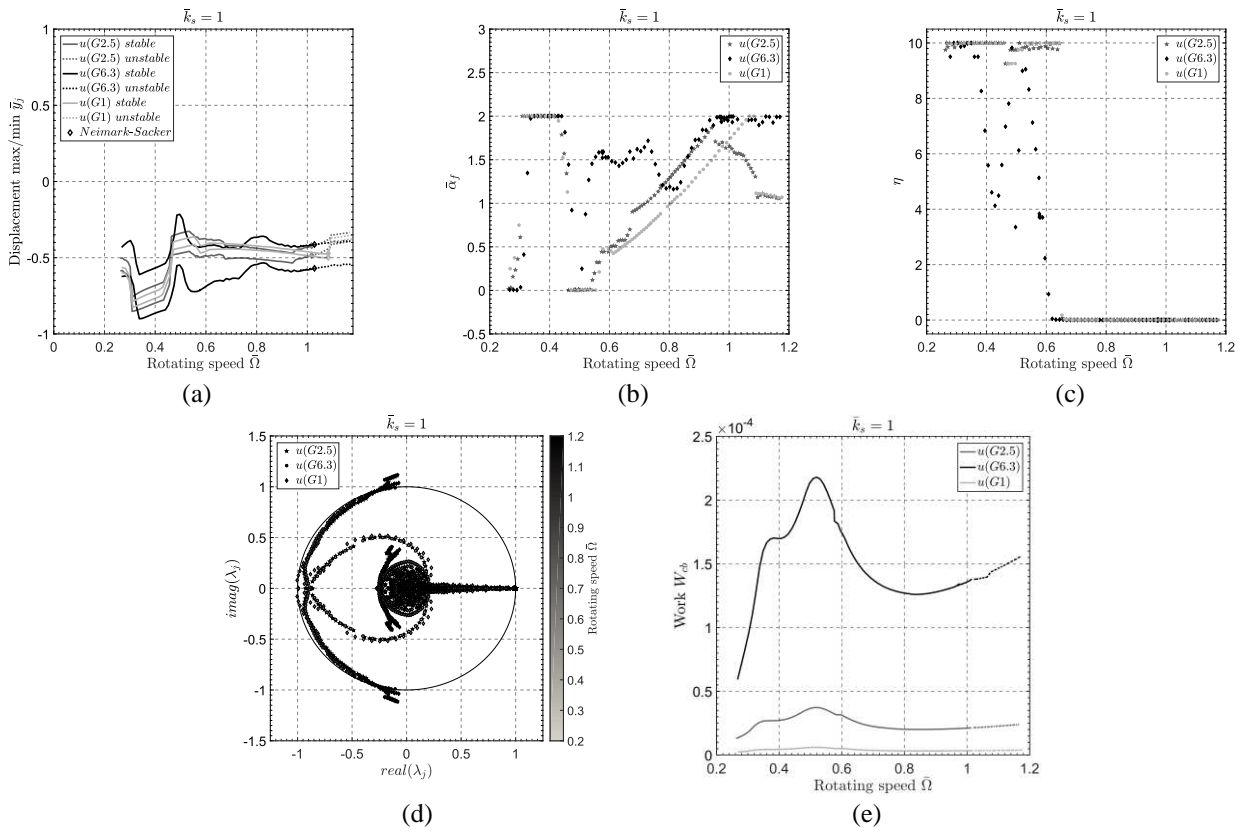

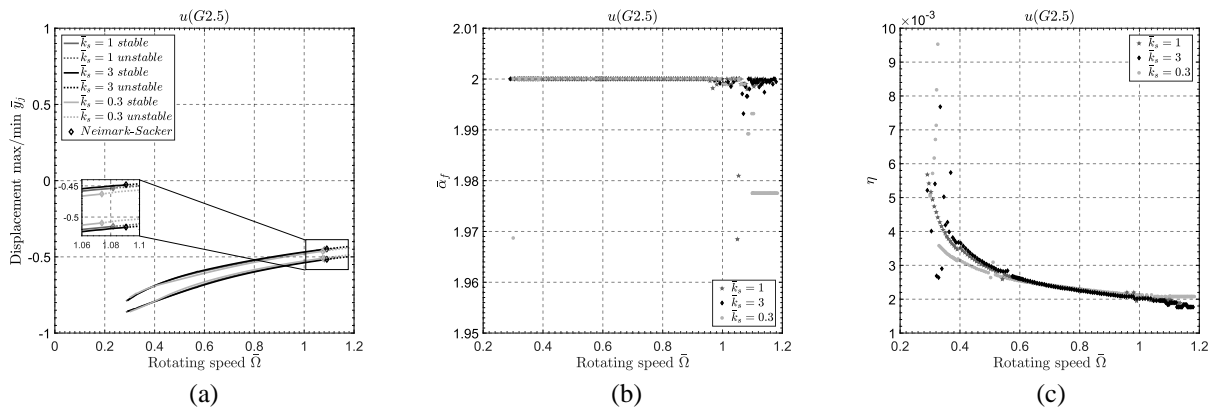

Figure 12: Elimination of bifurcations at a speed range for the system of $\bar{k}_s = 1$ and $u(G1)$, $u(G2.5)$, $u(G6.3)$ a) journal motion limit cycles, and corresponding values for b) compliance \bar{a}_f c) loss factor η , d) Floquet multipliers e) dissipating work in the gas film

Figure 13: Elimination of bifurcations at a speed range for the system of $u(G2.5)$ and $\bar{k}_s = 0.1$, $\bar{k}_s = 1$, $\bar{k}_s = 3$ a) journal motion limit cycles, and corresponding values for b) compliance \bar{a}_f , c) loss factor η d) Floquet multipliers e) dissipating work in the gas film

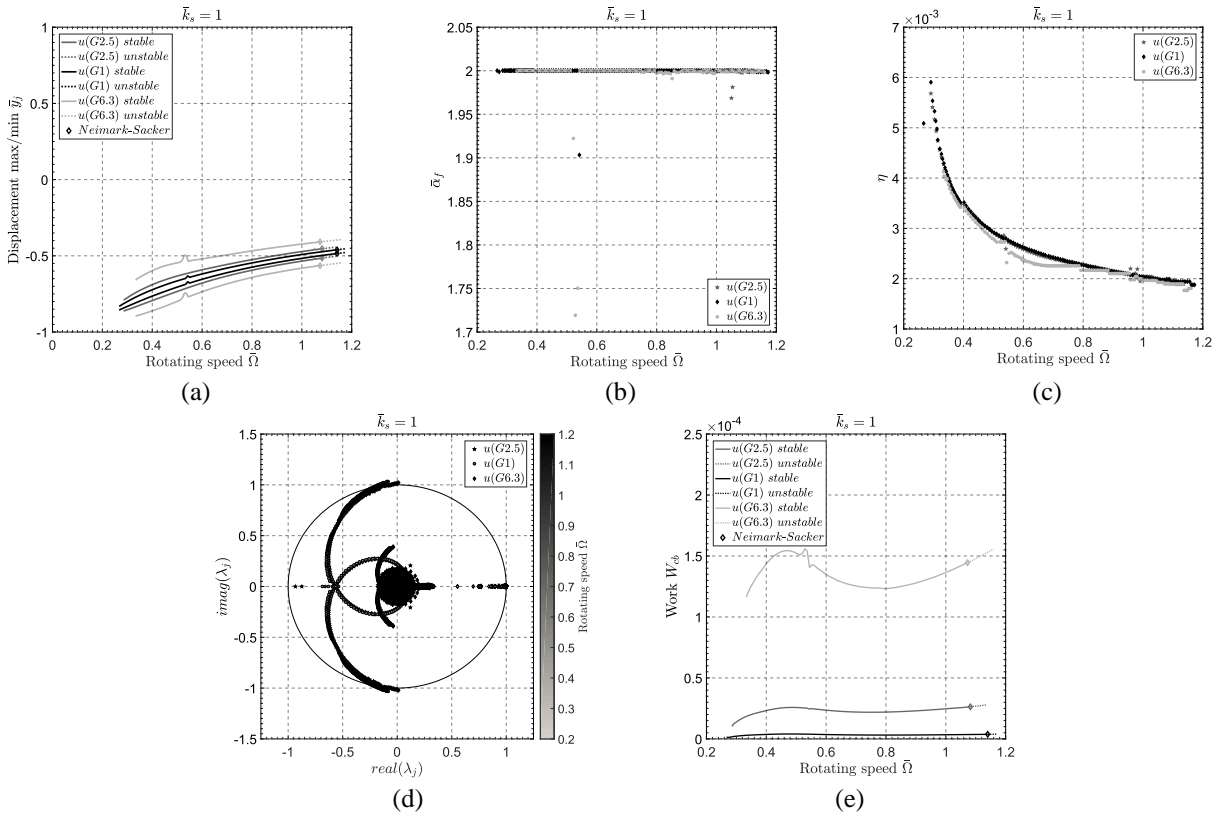

Figure 14: Elimination of bifurcations at a speed range for the system of $\bar{k}_s = 1$ and $u(G1)$, $u(G2.5)$, $u(G6.3)$ a) journal motion limit cycles, corresponding values for b) compliance \bar{a}_f , c) loss factor η , d) Floquet multipliers e) dissipating work in the gas film

An alternative objective function was investigated, in Figs. 13 and 14, on the potential to extend the operating speed range without bifurcation, at higher speeds. At each limit cycle \bar{s} , the highest magnitude of the Floquet multipliers was defined as objective function, $OBJ = \max(|\mu_j|)$, neglecting the one existing always at the unity circle, point $(+1, 0)$. In this way, all Floquet multipliers are retained inside the unity circle, $|\mu_j| < 1$. The evaluation time of limit cycles was lower at this case, as the computation of dissipative work is not required. However, the applicability in a real system is questioned as it not of the authors' knowledge whether Floquet multipliers can be evaluated in real time. However, different index for stability is investigated by the authors though operational modal analysis.

Conclusions

The bifurcation set of a rotating shaft on gas foil bearings is presented in this paper for various design cases of rotor stiffness and gas bearing properties, in a certain range of rotating speed which acts as the bifurcation parameter. The periodic limit cycle motions are evaluated applying a pseudo arc length continuation method with embedded orthogonal collocation. The work of the non-conservative and nonlinear damping force of the gas film is evaluated at each limit cycle motion, even when unstable, as the collocation method allows for this possibility. The dissipative work of the gas

film forces is found to be correlated to the self-exciting mechanism which triggers bifurcations of the solution branches for elastic unbalance response (stable motion). The loss of this local stability (through Neimark-Sacker bifurcation) occurs simultaneously with the reversal in the energy flow in the gas film, meaning that the dissipative work changes sign when the NS bifurcation takes place. At each limit cycle, an optimization pattern utilizing successive polls is applied to maximize the dissipated work in the gas film, defining the values for bump foil stiffness and damping, and thus avoid bifurcations according to the previous notation. The optimization pattern reveals that bifurcations are avoided when reducing the foil stiffness, doubling the operating speed range without bifurcations to take place. The procedure is repeated for several design scenarios of rotor stiffness and unbalance magnitude, and similar efficiency is noticed regarding bifurcation elimination. Research on design solutions to implement the change of foil damping and stiffness in a real system belongs to ongoing work.

Why does the tippedisk invert? Theory and experiments

Simon Sailer and Remco I. Leine

Institute for Nonlinear Mechanics, University of Stuttgart, Stuttgart, Germany

Summary. The *Tippedisk* is a mechanical-mathematical archetype for a peculiar friction-induced inversion phenomenon that occurs when the disk is spun rapidly about an in-plane axis, with the center of gravity rising counterintuitively as the orientation of the disk inverts. To qualitatively understand the dynamical behavior of the tippedisk, a nonlinear analysis is performed leading to a singularly perturbed structure of the system equations. Application of singular perturbation theory implies the study of the long-term behavior on a two-dimensional slow manifold, which finally allows to qualitatively explain the non-intuitive inversion behavior. Due to the technical simplicity of the system, the pronounced nonlinear behavior can be easily compared with real experiments.

Introduction

In the scientific research community, there are various gyroscopic systems which are interacting with a frictional support, such as Euler's disk [1], the rattleback [2], the tippetop [3], and the nonlinear dynamics of rolling basketballs [4]. Because of their technical simplicity, these systems lead to low-dimensional system equations that are ideally suited for the application of nonlinear dynamics theory. The tippetop [5, 6], as well as the related dynamics of spinning eggs [7], correspond to a subclass of gyroscopic systems, which show a counterintuitive rise of the center of gravity (COG), caused by friction-induced instability phenomena. This behavior is counterintuitive since the potential energy increases with the height of the center of gravity, which can be observed directly by eye. The decrease in kinetic energy, on the other hand, can not be detected without measurement because the change in spinning speed is relatively small. The tippedisk, being basically a rigid eccentric disk, was introduced in [9] as a new mechanical-mathematical archetype for a peculiar friction-induced inversion phenomenon that exhibits inversion behavior when rotated rapidly about an in-plane axis, see Fig. 1. The mechanical model derived in [9] forms the basis for the following analysis and was reduced in [10], accompanied by a local stability analysis. We aim to conduct an in-depth stability analysis for the tippedisk

Figure 1: Tippedisk: stroboscopic sequence of the inversion phenomenon.

in order to qualitatively understand the global behavior. In an experimental setup, the qualitative dynamics of the mathematical model can be compared with the dynamic behavior of the real system.

Mechanical model

In [10] a minimal mechanical model was derived, which is able to describe the inversion phenomenon of the tippedisk. The mechanical system consists of an infinitely thin unbalanced disk, with mass m , radius r and eccentricity e . The simplest way to design such a disk, where the COG and the geometric center G do not coincide, is to take a homogeneous disk and to drill a hole (remove mass) at an arbitrary point, which does not coincide with the geometric center G of the disk. As the tippedisk does not detach during inversion, the unilateral constraint at the contact point C can be equivalently replaced by a bilateral one. In Figure 2, the mechanical model is shown.

The body-fixed B -frame is attached to the disk, such that \mathbf{e}_z^B lies perpendicular to the surface of the disk. The \mathbf{e}_x^B -vector is defined as the normalized vector of \mathbf{r}_{GS} , which points from the geometric center G to the center of gravity S . To describe the contact point C , we introduce the grinding G -frame, in which $\mathbf{r}_{GC} = -r\mathbf{e}_y^G$ holds. The comparison with a quaternion based model implies that Euler angles α , β and γ , in common z - x - z -convention, are sufficient to describe the inversion phenomenon of the disk, see [9]. The angle α corresponds to the spinning angle, which describes the rotation around a vertical \mathbf{e}_z^I -axis. The inclination of the disk is measured by the inclination angle β , while γ describes the rolling angle of the disk.

Figure 2: Mechanical model: tippedisk

Dimensions

The dimensions of the considered specimen can be found in Fig. 3 and Table 1. In the previous works [9, 10, 11], the inertial properties were approximated by an assumed density and simplified geometry. In order to ensure better comparability between simulation and experiment, a more exact calculation of the mass and inertia properties is performed here. Therefore, the mass $m = 0.425$ kg of the considered specimen was measured directly on a calibrated scale.

Figure 3: Geometry of the tippedisk

Table 1: Dimensions of the tippedisk

Property	Parameter	Magnitude	Unit
Disk radius	r	0.045	m
Hole radius	a	0.015	m
Distance	b	0.02	m
Disk height	h	0.01	m
Volume	V	$5.359 \cdot 10^{-5}$	m^3

Table 2: Mass properties of the tippedisk

Property	Parameter	Magnitude	Unit
Mass	m	0.425	kg
Density	ρ	7930	kg/m^3
Eccentricity	e	$2.64 \cdot 10^{-3}$	m
${}_B\Theta_G(1,1)$	A	$0.233 \cdot 10^{-3}$	kg m^2
${}_B\Theta_G(2,2)$	B	$0.211 \cdot 10^{-3}$	kg m^2
${}_B\Theta_G(3,3)$	C	$0.437 \cdot 10^{-3}$	kg m^2

In Fig. 3 it is shown that the radius

$$R(\bar{z}) = r - \frac{h}{2} + \sqrt{\left(\frac{h}{2}\right)^2 - \bar{z}^2} \quad (1)$$

of the rounding depends on the \bar{z} coordinate. Under consideration of this rounded edge, the volume yields a triple integral

$$V = \pi h(r^2 - a^2) - \int_0^{2\pi + \frac{h}{2}} \int_{-\frac{h}{2}}^r \int_{R(\bar{z})}^r \bar{r} \, d\bar{r} d\bar{z} d\varphi \quad (2)$$

and, after a little algebra, the corresponding solution for the total volume V of the disk is given as

$$V = \pi h(r^2 - a^2) + \pi \left(\frac{h}{2}\right)^2 \left[\left(\frac{5}{3} - \frac{\pi}{2}\right) h + (\pi - 4)r \right] = 5.359 \cdot 10^{-5} \text{ m}^3. \quad (3)$$

Assuming a homogeneous material, the specific mass density is equal to the relation $\rho = \frac{m}{V}$ of weighed mass m and calculated total volume V , yielding $\rho = 7930 \frac{\text{kg}}{\text{m}^3}$. With this density ρ and the dimensions of the unbalanced disk, the inertia properties are calculated with sufficient accuracy using the commercial CAD software ‘SolidWorks’ and are listed in Table 2.

Singularly perturbed equations of motion

In [10] a reduction of the full model equations was derived to reduce the dimension of the state-space. It turned out that the horizontal position of the COG can be neglected during the inversion process. The spinning speed $\Omega = \dot{\alpha}$ changes only slightly and therefore can be set approximately constant, which allows to introduce the spinning speed Ω as bifurcation parameter.

Defining the new minimal coordinates $\mathbf{z} = [\beta, \gamma]^T$ and the scalar¹ minimal velocity $\mathbf{v} = \dot{\beta}$, the dynamic behavior under longitudinal rolling of the disk is completely described by the system of equations

$$\begin{aligned}\dot{\mathbf{z}} &= \mathbf{B}(\mathbf{z})\mathbf{v} + \boldsymbol{\beta}(\mathbf{z}) \\ \mathbf{M}(\mathbf{z})\dot{\mathbf{v}} - \mathbf{h}(\mathbf{z}, \mathbf{v}) &= -\frac{\mu mg}{\varepsilon} \mathbf{w}_y \gamma_y,\end{aligned}\tag{4}$$

with $\mathbf{B}(\mathbf{z}) = [1, 0]^T$ and $\boldsymbol{\beta}(\mathbf{z}) = [0, -\Omega \cos \beta]^T$ defining the kinematics. The mass matrix \mathbf{M} and the vector of gyroscopic and gravitational forces \mathbf{h} are given as

$$\mathbf{M} = A \cos^2 \gamma + \bar{B} \sin^2 \gamma + m(r + e \sin \gamma)^2 \cos^2 \beta,\tag{5}$$

and

$$\begin{aligned}\mathbf{h} &= +(A \cos^2 \gamma + \bar{B} \sin^2 \gamma) \Omega^2 \sin \beta \cos \beta \\ &\quad - 2(A - \bar{B}) \Omega \dot{\beta} \cos \beta \sin \gamma \cos \gamma \\ &\quad + m(r + e \sin \gamma)^2 \dot{\beta}^2 \sin \beta \cos \beta \\ &\quad + me(r + e \sin \gamma) \Omega^2 \sin \beta \cos^3 \beta \sin \gamma \\ &\quad - me(r + e \sin \gamma) (3 \sin^2 \beta - 2) \Omega \dot{\beta} \cos \beta \cos \gamma \\ &\quad - mg(r + e \sin \gamma) \cos \beta,\end{aligned}\tag{6}$$

where the auxiliary variable $\bar{B} := B - me^2$ has been used. The right-hand side contains the generalized force direction

$$\mathbf{w}_y = (r + e \sin \gamma) \sin \beta,\tag{7}$$

and the lateral sliding velocity

$$\gamma_y = (r + e \sin \gamma) \dot{\beta} \sin \beta - e \Omega \sin^2 \beta \cos \gamma.\tag{8}$$

The friction and smoothing coefficients are assumed to be $\mu = 0.3$ and $\varepsilon = 0.1 \frac{\text{m}}{\text{s}}$. A more detailed derivation of the reduced equations of motion can be found in [10].

According to [11], the dynamics of the tippedisk must be considered on two different timescales, as Eq. 4 yields a singularly perturbed structure. Introducing the slow variables $\mathbf{x} = [\beta, \gamma]^T$ and the fast variable $\mathbf{y} = \eta = \dot{\beta}$, we obtain the singularly perturbed dynamical system

$$\begin{aligned}\dot{\mathbf{x}} &= \mathbf{f}(\mathbf{x}, \mathbf{y}) \\ \varepsilon \dot{\mathbf{y}} &= \mathbf{g}(\mathbf{x}, \mathbf{y}; \varepsilon) = \mathbf{g}_0(\mathbf{x}, \mathbf{y}) + \mathbf{g}_1(\mathbf{x}, \mathbf{y}) \varepsilon,\end{aligned}\tag{9}$$

with

$$\mathbf{f}(\mathbf{x}, \mathbf{y}) = \begin{bmatrix} \eta \\ -\Omega \cos \beta \end{bmatrix} \in \mathbb{R}^2,\tag{10}$$

$$\mathbf{g}_0(\mathbf{x}, \mathbf{y}) = -\mathbf{M}^{-1} \mu mg \mathbf{w}_y(\mathbf{x}) \gamma_y(\mathbf{x}, \mathbf{y}) \in \mathbb{R},\tag{11}$$

and

$$\mathbf{g}_1(\mathbf{x}, \mathbf{y}) = \mathbf{M}^{-1} \mathbf{h}(\mathbf{x}, \mathbf{y}) \in \mathbb{R},\tag{12}$$

by normalizing and pre-multiplying Eq. (4) with the ‘small’ smoothing coefficient $\varepsilon > 0$ of the friction law, cf. [12]. The fast subsystem is then given as

$$\varepsilon \dot{\mathbf{y}} = \mathbf{g}(\mathbf{x}, \mathbf{y}; \varepsilon) = \mathbf{g}_0(\mathbf{x}, \mathbf{y}) + \mathbf{g}_1(\mathbf{x}, \mathbf{y}) \varepsilon.\tag{13}$$

¹Although the minimal velocity is scalar, we stick to vector notation and write \mathbf{v} to keep the singularly perturbed equations of motion in a general, mechanical structure.

For $\varepsilon = 0$, the fast dynamics degenerates to the algebraic equation $\mathbf{g}_0(\mathbf{x}, \mathbf{y}) = 0$, which, according to Eq (11), states that the relative velocity $\gamma_y(\mathbf{x}, \mathbf{y})$ vanishes, i.e., the contact point of the tippedisk is in a state of pure rolling. Since the relative lateral sliding velocity $\gamma_y(\mathbf{x}, \mathbf{y})$ depends linearly on the fast variable $\eta = \dot{\beta}$, the critical manifold exists globally since the Jacobian $\frac{\partial \mathbf{g}_0}{\partial \mathbf{y}} \Big|_{\mathbf{x}, \mathbf{y}}$ is invertible. The corresponding critical manifold \mathcal{M}_c is given as

$$\mathcal{M}_c := \left\{ (\mathbf{x}, \mathbf{y}) \in \mathbb{R}^3 \mid \mathbf{y} = \mathbf{h}_c(\mathbf{x}) = \frac{e \sin \beta \cos \gamma}{(r + e \sin \gamma)} \Omega, \mathbf{x} \in \mathbb{R}^2 \right\}, \quad (14)$$

being the zero order approximation of the slow manifold, which is given up to orders $\mathcal{O}(\varepsilon^2)$ as

$$\mathcal{M}_s := \left\{ (\mathbf{x}, \mathbf{y}) \in \mathbb{R}^3 \mid \mathbf{y} = \frac{e \sin \beta \cos \gamma}{(r + e \sin \gamma)} \Omega + \mathbf{h}_1(\mathbf{x}) \varepsilon + \mathcal{O}(\varepsilon^2), \mathbf{x} \in \mathbb{R}^2 \right\}, \quad (15)$$

with

$$\mathbf{h}_1(\mathbf{x}) = \frac{\partial \mathbf{g}}{\partial \mathbf{y}} \Big|_{\mathbf{x}, \mathbf{h}_c}^{-1} \left[\frac{\partial \mathbf{h}_c}{\partial \mathbf{x}} \Big|_{\mathbf{x}} \mathbf{f}(\mathbf{x}, \mathbf{h}_c) - \mathbf{g}_1(\mathbf{x}, \mathbf{h}_c) \right]. \quad (16)$$

The stability of the slow manifold, characterized by the distance dynamics

$$\mathbf{d}' = \frac{\partial \mathbf{g}_0}{\partial \mathbf{y}} \Big|_{\mathbf{x}, \mathbf{h}_c} \mathbf{d}, \quad (17)$$

is asymptotically stable, since the Jacobian

$$\frac{\partial \mathbf{g}_0}{\partial \mathbf{y}} \Big|_{\mathbf{x}, \mathbf{h}_c} = -\mathbf{M}^{-1} \mu m g (r + e \sin \gamma)^2 \sin^2 \beta \quad (18)$$

is strictly negative for all $\beta \in (0, +\pi)$, i.e., in a basin of attraction the orbits are attracted by the invariant manifold \mathcal{M}_s . Therefore, the asymptotic behavior of attracted solutions is governed by the reduced two-dimensional system

$$\begin{aligned} \mathbf{h}_s(\mathbf{x}) &\approx \mathbf{h}_c(\mathbf{x}) + \varepsilon \mathbf{h}_1(\mathbf{x}) \\ \dot{\mathbf{x}} &= \mathbf{f}(\mathbf{x}, \mathbf{h}_s(\mathbf{x})), \end{aligned} \quad (19)$$

neglecting orders $\mathcal{O}(\varepsilon^2)$.

Qualitative dynamics of the tippedisk

According to the simplification of the systems equations, performed in [10], and the singularly perturbed structure, discussed in [11], the qualitative dynamics of the tippedisk can be analyzed in the β - γ -space. Within this representation, we must first characterize the stationary spinning states of the disk, namely ‘non-inverted’ and ‘inverted’ spinning. Figure. 4 shows the two possible stationary spinning solutions of the tippedisk.

With respect to the chosen parametrization of the disk, the non-inverted stationary spinning corresponds to the point $(\beta = +\frac{\pi}{2}, \gamma = -\frac{\pi}{2})$. Inverted spinning is characterized by $(\beta = +\frac{\pi}{2}, \gamma = +\frac{\pi}{2})$. Due to trigonometric ambiguity, both stationary spinning solutions occur with 2π periodicity in the rolling angle γ , i.e., the point $(\beta = \frac{\pi}{2}, \gamma = +\frac{3\pi}{2})$ can be also identified as non-inverted spinning equilibrium. During the inversion, the disk remains almost in a vertical plane, so the inclination can be restricted to the interval $\beta \in [\frac{\pi}{3}, \frac{3\pi}{4}]$.

Figure 4: Stationary spinning solutions of the tippedisk

According to the linear stability analysis of [10], the equilibrium corresponding to ‘non-inverted spinning’ is unstable for any spinning speed Ω . The stability of ‘inverted spinning’ solutions is characterized by a supercritical Hopf-bifurcation at the critical spinning speed Ω_{crit} , being approximately given in closed-form as

$$\Omega_{\text{crit}} = \sqrt{\frac{(r + e)^2}{r} \frac{mg}{B - me^2}} = 30.21 \frac{\text{rad}}{\text{s}}. \quad (20)$$

At slow spinning speeds $\Omega < \Omega_{\text{crit}}$, the inverted spinning of the disk is unstable, and stable at supercritical spinning velocities $\Omega > \Omega_{\text{crit}}$. Following [11], the dynamical behavior on the slow manifold \mathcal{M}_s is shown in

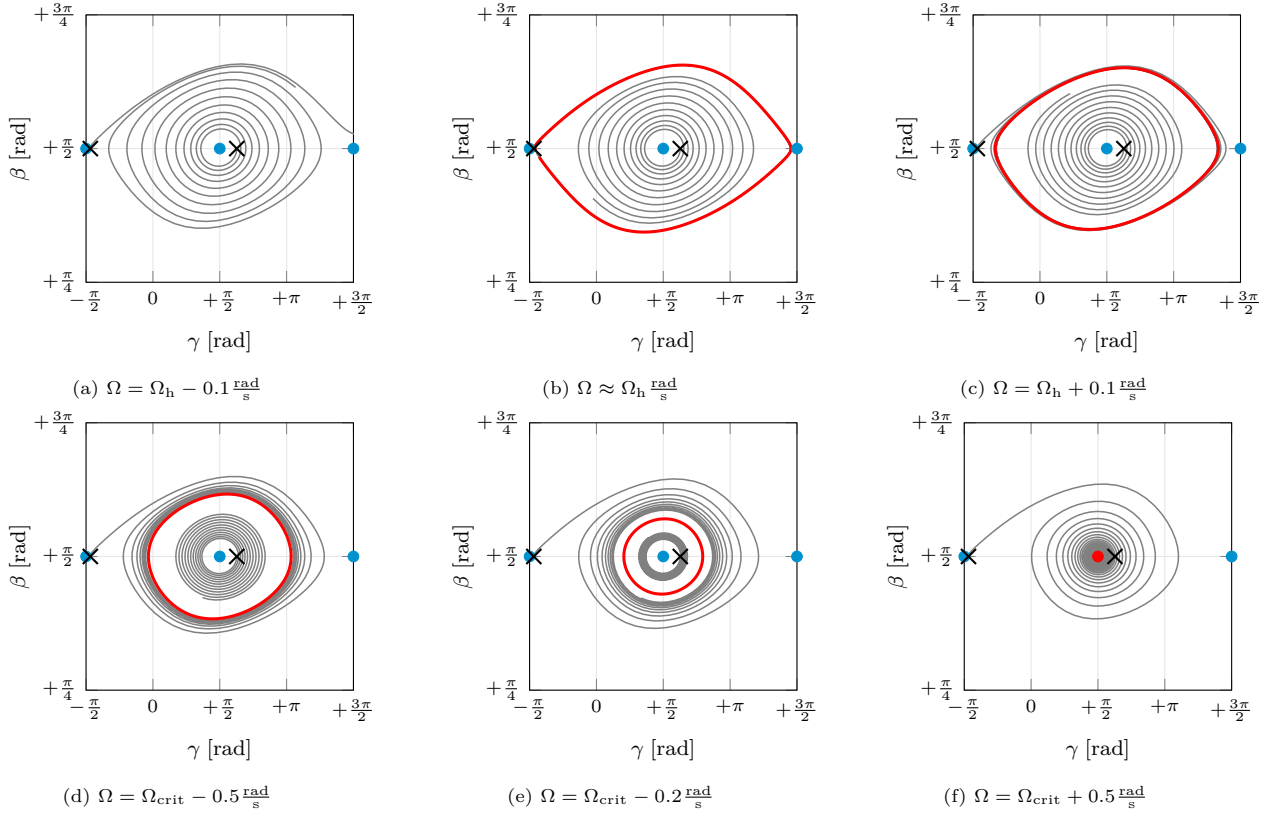

Figure 5: Qualitative dynamics in (β, γ) -plane: Solutions which are depicted in gray are initialized at the corresponding black cross and are obtained by time integration over the time span $\Delta t = 10$ s. Stable periodic solutions (red) originate from numerical shooting.

Fig. 5, using the corrected mass and inertia properties from Table-2. To study the dynamical behavior, we assume that the angular velocity $\dot{\alpha} = \Omega$ is constant, which identifies the bifurcation parameter Ω and leads to a foliation of the state-space. The evolution of solutions for different spinning speeds Ω are shown in β - γ -space, Fig. 5. Two unstable ‘non-inverted spinning’ configurations correspond to the points $(\beta = \frac{\pi}{2}, \gamma = -\frac{\pi}{2})$ and $(\beta = \frac{\pi}{2}, \gamma = \frac{3\pi}{2})$ and are shown in light blue. The inverted configuration is characterized by the dot at $(\beta = \frac{\pi}{2}, \gamma = \frac{\pi}{2})$. Unstable inverted spinning is indicated by a blue dot, stable inverted spinning by a red dot. At time $t_0 = 0$ s, two solutions are initialized at the black crosses at $\mathbf{x}_0^1 = (\beta = \frac{\pi}{2}, \gamma = -\frac{\pi}{2} + 0.1)$ and $\mathbf{x}_0^2 = (\beta = \frac{\pi}{2}, \gamma = \frac{\pi}{2} + 0.4)$ for each subfigure. The resulting trajectories are shown as gray curves. For $\Omega < \Omega_h$, solutions are repelled by the inverted spinning equilibrium (Fig. 5a). At $\Omega_h \approx 29.3 \frac{\text{rad}}{\text{s}}$, a periodic solution (with period time $T = \infty$) arises connecting two non-inverted stationary spinning solutions (Fig. 5b). This connection can be interpreted as two heteroclinic connections because two different equilibrium points $(\beta = \frac{\pi}{2}, \gamma = -\frac{\pi}{2})$ and $(\beta = \frac{\pi}{2}, \gamma = \frac{3\pi}{2})$ are connected. From a physical point of view, this connection can also be called a homoclinic, since both connected points describe inverted spinning. If the spinning speed is increased but still subcritical, i.e., $\Omega_h < \Omega < \Omega_{\text{crit}}$ holds, solutions are attracted by a stable periodic orbit that shrinks with increasing spinning velocity Ω (Figs. 5c-5e). Due to the supercritical Hopf-bifurcation, the periodic solution vanishes at Ω_{crit} . For supercritical spinning speeds, i.e., $\Omega > \Omega_{\text{crit}}$, the inverted spinning equilibrium is stable (shown as red dot), so that the solutions converge asymptotically to the inverted spinning configuration (Fig. 5f), which qualitatively explains the inversion phenomenon.

Experiments

In order to verify the validity of the qualitative dynamics of the tippedisk, presented in [11], preliminary experiments were performed. This was done with the help of an object tracking system that combines the measurements of six high-speed cameras, each of which records the movement of the disk from a different angle and at 500 frames per second. Figure 6a, shows a post-processed image of one high-speed camera with different marker frames. In Figs. 6b and 6c, the spinning angle α and the projection of the state onto the β - γ -plane are shown for four different runs, each starting with a different initial spinning velocity Ω_i^* and all initialized near non-inverted spinning motion. With time, the spinning speed Ω , which is the time derivative of the spinning angle α , gradually decreases due to dissipation caused by frictional forces. The black and the dark gray trajectories belong to very fast spinning speeds and quickly settle near the inverted spinning motion. The gray trajectory is at an intermediate initial spinning speed Ω_3^* and is reminiscent of the periodic limit cycle

Figure 6: Experiments of the tippedisk. All solutions are starting in the neighborhood of non-inverted stationary spinning at different initial spinning speeds.

between heteroclinic and Hopf bifurcation. Finally, the light gray trajectory appears to be qualitatively close to the heteroclinic connection. The measurements seem to agree with the qualitative behavior of the reduced model derived in [11]. Comparing the spinning speeds, the initial rotational velocity Ω_i^* does not match the magnitude of the bifurcation parameter Ω of the reduced model, with similar qualitative inversion behavior. This discrepancy seems to be due to the decrease in angular velocity and needs to be analyzed in future research.

Conclusions

In this work, the dynamic analysis of the tippedisk was studied based on a minimal mechanical model that contains the relevant effects and is able to describe the inversion phenomenon of the tippedisk. Consideration of the singularly perturbed structure allows the dynamics to be reduced to a two-dimensional system, so that the origin of the inversion phenomenon can be studied in the corresponding reduced system. An in-depth analysis suggests a bifurcation scenario in which a heteroclinic bifurcation accompanied by the emergence of an attractive periodic solution is followed by a supercritical Hopf bifurcation in which this periodic solution disappears. Closed-form expressions approximately characterize the associated critical spinning velocity Ω_{crit} . When the corresponding bifurcation point is crossed, the inverted configuration becomes stable and subsequently attracts almost all solutions. Preliminary experiments shown in Fig. 6 support the results of the qualitative analysis from [11] of the reduced model derived in [10]. By studying the mechanical system at all model levels and in conjunction with experimental observations, the nonlinear behavior of the tippedisk can finally be understood and the magic behind the phenomenon of inversion revealed.

Therefore, the tippedisk forms a wonderful archetype system for friction-induced instabilities, linking analytical and nonlinear dynamics with applied mechanics and allowing the comparison of the qualitative behavior of a mechanical model with experiments on a real specimen.

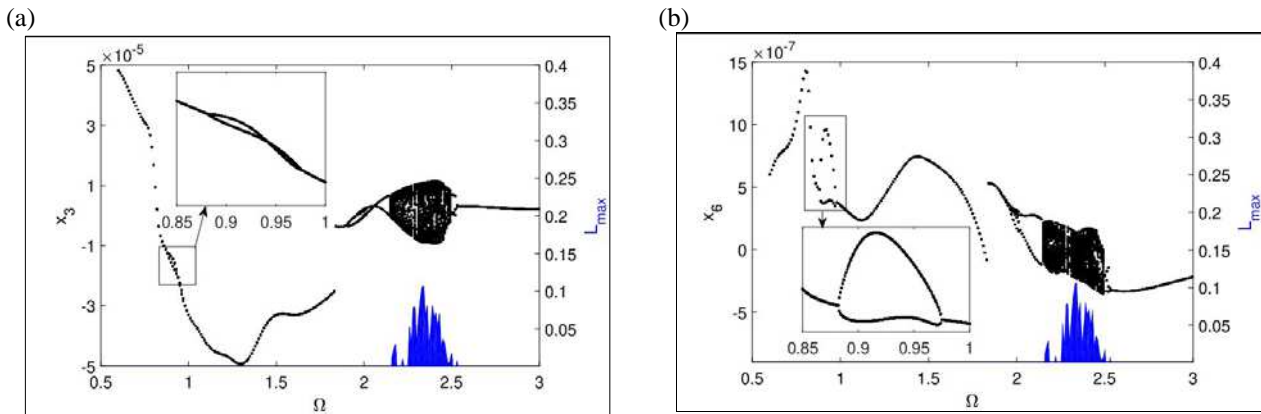

Figure 2: Bifurcation diagrams of stapes motion (a), magnet motion (b) with positive value of maximal Lyapunov exponent (blue).

The results of numerical simulation are presented in Figure 2 as bifurcation diagrams, where Figure 2a presents stapes motion while Figure 2b – motion of the magnet. Both, the stapes and the magnet exhibit regular and chaotic vibrations depending on excitation frequency.

Concluding Remarks

Electromechanical coupling between the electrical circuit and the mechanical part of the implanted middle ear strongly influences system dynamics causing harmonic, subharmonic and even chaotic vibrations for chosen range of excitation frequency.

Multiplicative Road Models with Bounded Realizations Applied in Non-Linear Vehicle Road Dynamics

Walter V. Wedig*

*KIT-Karlsruher Institut für Technologie, Karlsruhe, Germany

Summary. Multiplicative road models generate stationary vehicle excitations which are distributed similar to Gaussian processes but bounded in any given range by means of suitable nonlinearities. For increasing multiplicative noise, the nonlinear process becomes uniformly distributed and change to sinusoidal distributions for growing noise intensities. Both, the multiplicative and sinusoidal roads, are applied to excite quarter car models with one degree of freedom in order to work out the dynamical behavior and stability of vehicle road systems and to discuss them in comparison with classical ground excitations by means of Gaussian models or harmonic wave roads.

1. Introduction to vehicle road dynamics

To introduce basics of vehicle road dynamics, Figure 1 shows the model of a quarter vehicle model [1-6] rolling with constant speed v on a wavy road with level z and frequency $\Omega > 0$ measurable by means of wave length $L = 2\pi/\Omega$. The wavy road defined in Eq. (2), initiates vertical vehicle vibrations y described by the equation (1) of motion

$$\ddot{y} + 2D\omega_1(\dot{y} - \dot{z}) + \omega_1^2(y - z) = 0, \quad (1)$$

$$z(s) = Z\cos(\Omega s), \quad s = vt, \quad (2)$$

where ω_1 is the natural frequency of the vehicle and D denotes its damping, given by $\omega_1^2 = c/m$ and $2D\omega_1 = b/m$, respectively. In Eq. (2), Z is the road amplitude and s the longitudinal coordinate $s = vt$ when the vehicle drives with constant speed v . In the stationary case, Eqs (1) and (2) lead to the amplitude ratio Y/Z of response and excitation

$$(Y/Z)^2 = \frac{1+(2Dv)^2}{(1-v^2)^2+(2Dv)^2}, \quad v = v\Omega/\omega_1. \quad (3)$$

In Figure 2, the amplitude ratio Y/Z is plotted versus the related frequency speed $v = v\Omega/\omega_1$ for the two damping values $D = 0.1$ and $D = 0.2$. Both curves are drawn in red color. They start in $v = 0$ with the ratio $Y/Z = 1$ and end in $v = \infty$ with $Y/Z = 0$. They become maximal near the resonance for $v = 1$. In Figure 2, λ is the image variable of the vehicle velocity in the range $0 \leq \lambda \leq 2$ with two different scales: $\lambda = v$ in the left half and $\lambda = 2 - 1/v$ in the right one. This scaling [6] has the advantage that the amplitude ratio can be drawn for all velocities $0 \leq v < \infty$.

Figure 1: Quarter car model rolling with constant speed v on sinusoidal (orange) or random (cyan) wave roads

Figure 2: Standard deviation (blue) and amplitude (red) ratio of response and excitation versus vehicle speed

Stochastic road models [7-12] are assumed to be normally distributed with zero mean and standard deviation σ_z . They are modeled e.g. by means of the linear first order system under white noise

$$dZ_t = -v\Omega Z_t dt + \sigma\sqrt{v}dW_t, \quad E(dW_t^2) = dt, \quad (4)$$

where $v > 0$ is the vehicle velocity and σ denotes the intensity of noise realized by the Wiener increment dW_t . The application of the noise spectrum $S_w(\omega) = 1$ and the Fourier transforms leads to the road spectrum

$$S_z(\omega) = \frac{v\sigma^2}{\omega^2 + (v\Omega)^2}, \quad \sigma_z^2 = \frac{1}{2\pi} \int_{-\infty}^{+\infty} S_z(\omega) d\omega = \frac{\sigma^2}{2\Omega}. \quad (5)$$

The road spectrum is integrated over all frequencies ω to obtain the variance σ_z^2 , noted in Eq. (5). The same method can be applied to Eq. (1) to obtain the vehicle spectrum $S_y(\omega)$ which is integrated in order to get the associated standard deviation ratio

$$(\sigma_y/\sigma_z)^2 = \frac{2D+(1+4D^2)v}{2D(1+2Dv+v^2)}, \quad v = v\Omega/\omega_1. \quad (6)$$

In Eq. (6), the time frequency $v\Omega$ represents the corner frequency of the road spectrum $S_z(\omega)$ in Eq. (5). Now, it takes the role of the middle frequency of the wavy road surface in Eq. (2). In Figure 2, the standard deviation ratio of vehicle response and road excitation, calculated in Eq. (6), is plotted for the same two damping values, as before. Therewith, the result obtained in Eq. (6) can be directly compared with the amplitude ratio in Eq. (3). Obviously, resonance magnifications are much stronger in the harmonic case in comparison with random roads when the vehicle is driving near the resonance velocity $v = 1$. Outside of the resonant speed range, however, the magnification is inverted, completely. In the over-critical speed range, the amplification of the standard deviation ratio is more than double as big in comparison with the harmonic case when the vehicle is driving e.g. with $v = 2$.

2. Extensions to multiplicative road models

The linear first order road model, determined by the spectrum (5), is extended to multiplicative road models of second order which are introduced by means of the two non-linear stochastic differential (Itô) equations [13, 14]

$$dZ_t = v\Omega U_t dt, \quad V_t^2 = 1 - (Z_t/z_0)^2 - (U_t/u_0)^2, \quad (7)$$

$$dU_t = -v\Omega(2\delta U_t + Z_t)dt + V_t\sigma\sqrt{v}dW_t, \quad E(dW_t^2) = dt, \quad (8)$$

where $v > 0$ denotes the vehicle velocity and σ gives the intensity of white noise dW_t/dt . The parameter Ω is the middle road frequency and δ determines the bandwidth of the two processes Z_t and U_t of the road level and slope, respectively. The non-linear process V_t introduces process limitations by the values z_0 and u_0 which are freely selectable. For infinitely growing values $z_0, u_0 \rightarrow \infty$, Eqn. (7) and (8) become linear and their stationary solutions are normally distributed. For finite values $|z_0|, |u_0| < \infty$, the stationary processes are limited by the ellipse $(z/z_0)^2 + (u/u_0)^2 = 1$. In the symmetric case that $z_0 = u_0 = r_0$, the limitation is a circle. When the stationary solutions take vanishing values, multiplicative noise becomes additive with $V_t = 1$ and the system has the strongest possible driving. When the solutions are on the ellipse, noise is excluded by $V_t = 0$ and the system possesses the strongest possible decay behavior.

Figure 3: Two-dimensional distribution of level and slope with the limitation $z_0 = u_0 = 0.9$ and the exponent $\alpha = 3$

Figure 4: Singular two-dimensional density of road level and slope for the same limitations and exponent $\alpha = 1/2$

The density distribution $p(z, u, t)$ of the road processes is determined by means of the Fokker-Planck equation [15]

$$\frac{\partial p}{\partial t} = \frac{\partial}{\partial u} [v\Omega(2\delta u + z)p] - \frac{\partial}{\partial z} [v\Omega u p] + \frac{1}{2}\sigma^2 v \frac{\partial^2}{\partial u^2} \left\{ \left[1 - \left(\frac{z}{z_0} \right)^2 - \left(\frac{u}{u_0} \right)^2 \right] p \right\}. \quad (9)$$

In the stationary case, the density $p(z, u)$ is independent on time and satisfies the stationary Fokker-Planck equation

$$0 = 2\delta \left(p + u \frac{\partial p}{\partial u} \right) + z \frac{\partial p}{\partial u} - u \frac{\partial p}{\partial z} + \frac{\sigma^2}{2\Omega} \frac{\partial^2}{\partial u^2} \left\{ \left[1 - \left(\frac{z}{z_0} \right)^2 - \left(\frac{u}{u_0} \right)^2 \right] p \right\}. \quad (10)$$

Note that the velocity v is dropped out in Eq. (10) because of $\partial p/\partial t = 0$; i.e. the statistical configuration of the road is independent on velocity and can be applied for all speeds. In the symmetric case $z_0 = u_0 = r_0$, Eq. (10) is solved by

$$p(z, u) = C \left[1 - (z/r_0)^2 - (u/r_0)^2 \right]^{\alpha-1}, \quad \alpha = r_0^2 2\delta\Omega/\sigma^2 > 0, \quad (11)$$

where C is the integration constant of normalization. The two-dimensional density, noted in Eq. (11), can be integrated for $\alpha > 0$. This coincides with the stability condition $\delta > 0$ of the linear oscillator for $z_0, u_0 \rightarrow \infty$. For $\alpha = 1$, the density $p(z, u)$ in Eq. (11) is uniformly distributed. For $\alpha = 2$, it is parabolic. For $\alpha = 3$, the density $p(z, u)$ possesses a forth order shape as shown in Figure 3 for the limitation $r_0 = 0.9$. In this case, the two-dimensional density is zero on

the limitation circle with a vanishing gradient. The two-dimensional density in Eq. (11) becomes singular for $0 < \alpha < 1$. In Figure 4, the density is plotted e.g. for $\alpha = 1/2$. In this case, $p(z, u)$ coincides with the stationary density of the sinusoidal road surface, noted in Eq. (2).

3. Vehicle dynamics with multiplicative road models

The application of Itô's calculus to the multiplicative road model of Eqn. (7) and (8), leads to the three increments

$$\begin{aligned} d(Z_t^2) &= 2v\Omega Z_t U_t dt, & V_t^2 &= 1 - (Z_t/z_0)^2 - (U_t/u_0)^2, \\ d(Z_t U_t) &= v\Omega(U_t^2 - 2\delta Z_t U_t - Z_t^2)dt + Z_t V_t \sigma \sqrt{v} dW_t, \\ d(U_t^2) &= -2v\Omega(2\delta U_t^2 + Z_t U_t)dt + V_t^2 \sigma^2 v dt + V_t \sigma \sqrt{v} dW_t, \end{aligned}$$

in which the expectation operator can be applied to obtain the associated moment's equations. In the stationary case, the first equation and the second one lead to $E(Z_t U_t) = 0$ and $E(U_t^2) = E(Z_t^2)$, respectively. Taking into account that $E(V_t dW_t)$ is vanishing and $E(V_t^2)$ follows from Eq. (7), the third equation gives the stationary square mean

$$E(Z_t^2) = E(U_t^2) = \frac{1}{1/z_0^2 + 1/u_0^2 + 4\delta\Omega/\sigma^2}. \quad (12)$$

The result in Eq. (12) coincides with the square means of the linear road model under white noise obtained for the limiting case $z_0, u_0 \rightarrow \infty$. Note that the above square mean equations are linear although the state equations (7) and (8) are non-linear. Both is possible because of the specially adapted non-linearity in Eq. (7).

Figure 5: Standard deviation ratio of response and excitation for the road bandwidth $\delta = 0$ (Harm.) and $\delta > 0$ (Stoch.).

Figure 6: Standard deviation of the vertical vibration velocity versus the related vehicle speed for the damping $D = 0.105$

The multiplicative road model is applied to the quarter vehicle, shown in Figure 1. The introduction of the coordinate $y = \omega_1 x$ of the vertical vibration velocity into equation (1) of motion leads to the associated first order system

$$dY_t = \omega_1 X_t dt, \quad dX_t = -[2D(\omega_1 X_t - \dot{Z}_t) + \omega_1(Y_t - Z_t)]dt \quad (13)$$

where the time derivative \dot{Z}_t is given by the increment $dZ_t = v\Omega U_t dt$ in Eq. (7). The stationary co-variances of all excitation processes Z_t, U_t times all response processes Y_t, X_t are calculable by means of the matrix equation

$$\begin{bmatrix} 0 & -1 & -v & 0 \\ 1 & 2D & 0 & -v \\ v & 0 & 2\delta v & -1 \\ 0 & v & 1 & 2(D + \delta v) \end{bmatrix} \begin{bmatrix} E(Z_t Y_t) \\ E(Z_t X_t) \\ E(U_t Y_t) \\ E(U_t X_t) \end{bmatrix} = \begin{bmatrix} 0 \\ E(Z_t^2) \\ 0 \\ 2DvE(U_t^2) \end{bmatrix}, \quad (14)$$

where the square means of the road excitation are already calculated in Eq. (12). Note that the co-variance matrix in Eq. (14) is skew-symmetric. Hence, the co-variance matrix is positive definite. Its determinant Δ is calculated to

$$\Delta = (v^2 - 1)^2 + 4v(D + \delta v)(\delta + Dv). \quad (15)$$

Subsequently, the stationary moment's equations of the vehicle processes are set up and solved, as follows:

$$E(Y_t^2)/E(Z_t^2) = [1 + 4v(D + \delta v)(\delta + Dv) + \delta v^3/D]/\Delta, \quad (16)$$

$$E(X_t^2)/E(Z_t^2) = v^2[1 + 4Dv(\delta + Dv) + \delta v/D]/\Delta. \quad (17)$$

In Figure 5 and 6, the square roots of the square mean ratios in Eq. (16) and (17) are plotted versus the related vehicle speed for the damping $D = 0.105$ and five different bandwidth values δ of the road excitation. For vanishing bandwidth $\delta = 0$, the result in Eqn.(16) coincide with the amplitude ratio (3) of a vehicle rolling on wavy roads with harmonic contour surface. The same holds for Eq. (17). For growing bandwidth δ , the resonance peaks in both amplitude-velocity

diagrams are reduced in comparison with the harmonic case. However, the standard deviations (blue) become bigger than the amplitude (red) ratios when the vehicle is driving sufficiently outside the resonance velocity. For higher vehicle speeds e.g. $v = 2$, the magnification by stochastic excitations becomes even stronger in comparison with the harmonic case. For very slow and very high speeds, the standard deviation ratios are independent on the bandwidth of the road frequencies and coincide with the results of harmonic road excitation. For the special case of white noise with infinitely increasing bandwidth, Eq. (16) gives $\sigma_y/\sigma_z = 1$ for all vehicle speeds $v < \infty$ and $\sigma_y/\sigma_z = 0$ for $v = \infty$.

4. Non-stationary models of vehicle speed fluctuations

In Figure 1, the wavy road is modeled by the sinusoidal form $z(t)$. This model is extended to its stochastic version

$$Z_t = \cos\phi_t, \quad d\phi_t = \Omega v dt + \sigma dW_t, \quad (18a, b)$$

where Ωv is the time frequency given by the road frequency Ω times the vehicle velocity v which is perturbed by white noise σdW_t of intensity σ , when speed fluctuations through driving moment and air resistance are measurable and taken into account in a purely kinematic modeling. The application of Itô's calculus to the road process Z_t leads to

$$dZ_t = -(\Omega v dt + \sigma dW_t)\sin\phi_t - (\sigma^2/2)\cos\phi_t dt.$$

The stochastic road model (18a,b) is applied to Eq. (1) of the vehicle road system in the slightly modified form

$$\ddot{Y}_t + 2D\omega_1\dot{Y}_t + \omega_1^2 Y_t = \mu(2D\omega_1\dot{Z}_t + \omega_1^2 Z_t), \quad (19)$$

where μ is the amplitude of the road excitation. Note that sinusoidal excitations like $z(t) = \cos\omega t$ are non-stationary with the mean value $m_z = (\omega T)^{-1}\sin\omega T$ which converge to the stationary zero value with linearly growing time T . In order to eliminate this non-stationary behavior, amplitudes A_t, B_t, G_t, H_t are introduced into Eq. (19) by means of Eqn. (20a) and (21a). The application of Itô's calculus leads to the transformed equations, as follows:

$$Y_t = A_t \cos\phi_t + B_t \sin\phi_t, \quad dA_t = (\sigma^2 A_t/2 - \Omega v B_t + \omega_1 G_t)dt - \sigma B_t dW_t, \quad (20a, b)$$

$$\dot{Y}_t/\omega_1 = G_t \cos\phi_t + H_t \sin\phi_t, \quad dB_t = (\sigma^2 B_t/2 + \Omega v A_t + \omega_1 H_t)dt + \sigma A_t dW_t, \quad (21a, b)$$

$$dG_t = [-\omega_1 A_t - \Omega v H_t + (\sigma^2/2 - 2D\omega_1)G_t - \mu(\omega_1 - D\sigma^2)]dt - \sigma H_t dW_t, \quad (22)$$

$$dH_t = [-\omega_1 B_t + \Omega v G_t + (\sigma^2/2 - 2D\omega_1)H_t - 2D\mu\Omega v]dt + \sigma(G_t - 2D\mu)dW_t. \quad (23)$$

Numerical integrations of the transformed equations (20b), (21b), (22) and (23) are performed by means of the Maruyana scheme with the time step size $\Delta\tau = \omega_1 \Delta t = 10^{-3}$ for $N = 2 \cdot 10^7$ samples. The Wiener increments [16] are approximated by $\Delta W_n = N_n \sqrt{\Delta t}$ where the numbers N_n are normally distributed with zero mean and unit mean square $E(N_n^2) = 1$. Associated parameters are chosen by $D = 0.1$, $\mu = 1$ and $\sigma = 0.2\sqrt{\omega_1}$. In Figure 7, simulation results of the displacement means $E(A_t)$ and $E(B_t)$ as well as the density distributions $p(a)$ and $p(b)$ are plotted versus the related speed $\Omega v/\omega_1$. The density $p(a)$ is marked by blue colour and $p(b)$ is green. Both densities show the resonance effect when the vehicle drives with velocity $v = 1$. For further growing speed, the densities of both displacement processes are concentrated around the zero axes. This represents the self-centering effect, already known in rotor dynamics. For $\sigma = 0$, the density distributions $p(a)$ and $p(b)$ degenerate to delta needles around the means values $E(A_t)$ and $E(B_t)$.

Figure 7: Mean amplitudes and densities of A_t and B_t versus frequency speed related to natural car frequency

Figure 8: Resonance diagram for growing noise intensity: the resonance is first increased and then decreases again.

The application of the expectation operator $E(\cdot)$ to Eqn. (20b), (21b), (22) and (23) leads to the matrix equation

$$\begin{bmatrix} \sigma^2/2 & -\Omega v & \omega_1 & 0 \\ \Omega v & \sigma^2/2 & 0 & \omega_1 \\ -\omega_1 & 0 & \sigma^2/2 - 2D\omega_1 & -\Omega v \\ 0 & -\omega_1 & \Omega v & \sigma^2/2 - 2D\omega_1 \end{bmatrix} \begin{bmatrix} E(A_t) \\ E(B_t) \\ E(G_t) \\ E(H_t) \end{bmatrix} = \mu \begin{bmatrix} 0 \\ 0 \\ \omega_1 - D\sigma^2 \\ 2D\Omega v \end{bmatrix}, \quad (24)$$

by which the stationary mean values of all amplitude processes are calculable. In Figure 8, the resultant mean amplitude $V_m = [E^2(A_t) + E^2(B_t)]^{1/2}$ of both displacement means $E(A_t)$ and $E(B_t)$ is plotted versus the related velocity for vanishing noise (blue) and for growing noise intensity (red). The latter leads to stable mean amplitude with resonance magnifications up to a critical noise intensity where the resonance peak is reduced (green), again. In this case, the mean amplitude mean becomes unstable. This stability behavior follows from the diagonal term $\Delta = (\sigma^2/2 - 2D\omega_1)\sigma^2/2$ in Eq. (24) which is negative for weak noise intensities and become positive for growing noise. More details are obtained when the almost sure stability [17] of the amplitudes in Eqs. (20b), (21b), (22) and (23) is investigated. Stability in mean is investigated by means of the eigen-values [17] of the mean amplitudes matrix in Eq. (24).

5. Resonance reduction and induction by means of filtered noise

It is interesting how the resonance behavior of the amplitude processes is changing when the velocity perturbation by white noise $\sigma\dot{W}_t$ in Eq. (18b) is replaced by the more realistic perturbation of filtered noise $\omega_g\Psi_t$, as follows:

$$\dot{Y}_t = \omega_1 X_t, \quad \dot{\Phi}_t = \Omega v + \omega_g \Psi_t, \quad d\Psi_t = -\omega_g \Psi_t dt + \sigma dW_t, \quad (25 a, b, c)$$

$$\dot{X}_t = -\omega_1(2DX_t + Y_t) + \mu[\omega_1 \cos\Phi_t - 2D(\Omega v + \omega_g \Psi_t) \sin\Phi_t]. \quad (26)$$

The stationary filtered noise in Eq. (25c) is normally distributed with zero mean and mean square $\sigma_\Psi^2 = \sigma^2/(2\omega_g)$. The application of the amplitude processes (20a) and (21a) to the vehicle equations (25a) and (26) leads to

$$d\vec{V}_t = (A\vec{V}_t + \omega_g B\Psi_t\vec{V}_t)dt + \mu(\vec{x} - 2D\omega_g\Psi_t\vec{y})dt, \quad (26)$$

where the vector $\vec{V}_t = (A_t, B_t, G_t, H_t)'$ of the four amplitudes are determined by the matrices A and B as follows:

$$A = \begin{bmatrix} 0 & -\Omega v & \omega_1 & 0 \\ \Omega v & 0 & 0 & \omega_1 \\ -\omega_1 & 0 & -2D\omega_1 & -\Omega v \\ 0 & -\omega_1 & \Omega v & -2D\omega_1 \end{bmatrix}, \quad B = \begin{bmatrix} 0 & -1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 \\ 0 & 0 & 1 & 0 \end{bmatrix}$$

$$\vec{V}_t = (A_t, B_t, G_t, H_t)', \quad \vec{x} = (0, 0, \omega_1, -2D\Omega v)', \quad \vec{y} = (0, 0, 0, 1)'.$$

The vectors \vec{x} and \vec{y} , noted above, determine the inhomogeneous part in Eq. (26). Note that in Eq. (26) there is a non-linear term in form of $\Psi_t\vec{V}_t$ with a product of state processes. The product possesses the increment

$$d(\Psi_t\vec{V}_t) = [A\Psi_t\vec{V}_t + \omega_g B\Psi_t^2\vec{V}_t + \mu(\Psi_t\vec{x} - 2D\omega_g\Psi_t^2\vec{y}) - \omega_g\Psi_t\vec{V}_t]dt + \vec{V}_t\sigma dW_t, \quad (27)$$

which couples the system vector \vec{V}_t to higher potencies of the perturbation Ψ_t . This coupling effect is approximately removed in the stationary moments equations of Eqn. (26, 27) by means of the Gaussian closure, as follows:

$$AE(\vec{V}_t) + \omega_g BE(\Psi_t\vec{V}_t) = -\mu\vec{x}, \quad E(\Psi_t^2\vec{V}_t) = E(\Psi_t^2)E(\vec{V}_t), \quad (28a, b)$$

$$\omega_g\sigma_\Psi^2 BE(\vec{V}_t) + (A - \omega_g I)E(\Psi_t\vec{V}_t) = \mu 2D\omega_g\sigma_\Psi^2 \vec{y}, \quad E(\Psi_t^2) = \sigma^2/(2\omega_g). \quad (29a, b)$$

In Eq. (29a), I denotes the unit matrix. Note that in Eq. (29a) the expectation of the product $\Psi_t^2\vec{V}_t$ is approximately replaced by the product of both mean values. Numerical evaluations of Eqn. (28a) and (29a) are shown in Figure 9 where the mean amplitude V_m is plotted versus the vehicle velocity v for $D = 0.1$, $\mu = 1$ and the noise intensities $\sigma = 0.2\sqrt{\omega_1}$ (green) and $\sigma = 0.5$ (blue). For $\omega_g = 0$, the green and blue lines coincide with the deterministic case of vanishing perturbations. For growing bandwidth of the perturbation, the resonance peak is reduced. The resonance reduction becomes stronger for increasing noise intensities σ and for increasing low-pass frequency ω_g . This effect is physically explainable by the fact that high frequencies are filtered out and only low frequencies are retained in the perturbation. However, low velocity frequencies $v\Omega$ are not contributing to resonance effects.

Figure 9: Resonance reduction in the mean amplitudes V_m for growing noise intensity and perturbation bandwidth

Figure 10: Resonance induction from blue to red line via growing noise intensity and perturbation bandwidth (green)

The resonance reduction is completely inverted when instead of low-pass noise one applies the high-pass perturbation

$$Z_t = \cos \phi_t, \quad \dot{\phi}_t = \Omega v + \dot{\Psi}_t, \quad d\Psi_t = -\omega_g \Psi_t dt + \sigma dW_t, \quad (30abc)$$

where white noise $\sigma \dot{W}_t$ in Eq. (18b) is now replaced by $\dot{\Psi}_t$ in Eq. (30b). Consequently, perturbations with low frequencies are filtered out. High frequency parts are retained. The introduction of Eqn. (30) into Eq. (19) leads to

$$dY_t = \omega_1 X_t dt, \quad d\phi_t = (\Omega v - \omega_g \Psi_t) dt + \sigma dW_t, \quad d\Psi_t = -\omega_g \Psi_t dt + \sigma dW_t, \quad (31a, b, c)$$

$$dX_t = -\omega_1 (2DX_t + Y_t) dt + \mu [(\omega_1 - D\sigma^2) \cos \phi_t + (\omega_g \Psi_t - \Omega v) \sin \phi_t] dt - \mu 2D\sigma \sin \phi_t dW_t. \quad (32)$$

The application of the amplitude processes (20a) and (21a) to Eqn. (31) and (32) leads to the vector equation

$$d\vec{V}_t = (A\vec{V}_t - \omega_g B\Psi_t \vec{V}_t) dt + \mu(\vec{x} + 2D\omega_g \Psi_t \vec{y}) dt + (B\vec{V} - 2D\mu \vec{y}) \sigma dW_t \quad (33)$$

where the vector \vec{V}_t contains the four amplitude processes. The matrix A and the vectors \vec{x} are given by

$$A = \begin{bmatrix} \sigma^2/2 & -\Omega v & \omega_1 & 0 \\ \Omega v & \sigma^2/2 & 0 & \omega_1 \\ -\omega_1 & 0 & \sigma^2/2 - 2D\omega_1 & -\Omega v \\ 0 & -\omega_1 & \Omega v & \sigma^2/2 - 2D\omega_1 \end{bmatrix}, \quad \vec{x} = \begin{bmatrix} 0 \\ 0 \\ \omega_1 - 2D\sigma^2/2 \\ -2D\Omega v \end{bmatrix}.$$

where B and \vec{y} are already noted in the last section. The non-linear term $\Psi_t \vec{V}_t$ in Eq. (33) possesses the increment

$$d(\Psi_t \vec{V}_t) = [A\Psi_t \vec{V}_t + \omega_g B\Psi_t^2 \vec{V}_t + \mu(\Psi_t \vec{x} - 2D\omega_g \Psi_t^2 \vec{y}) - \omega_g \Psi_t \vec{V}_t] dt + \vec{V}_t \sigma dW_t \quad (34)$$

in which the system vector \vec{V}_t is coupled to higher potencies of the perturbation Ψ_t . This coupling is approximately removed by means of the Gaussian closure, noted in Eq. (35b). In the stationary case, the insertion of the Gaussian closure condition into Eq. (34) leads to the linear moments equations

$$AE(\vec{V}_t) - \omega_g BE(\Psi_t \vec{V}_t) = -\mu \vec{x}, \quad E(\Psi_t^2 \vec{V}_t) = E(\Psi_t^2) E(\vec{V}_t), \quad (35a, b)$$

$$BE(\vec{V}_t) \sigma^2/2 + (A - \omega_g I) E(\Psi_t \vec{V}_t) = \mu 2D\vec{y} \sigma^2/2, \quad E(\Psi_t^2) = \sigma^2/(2\omega_g). \quad (36a, b)$$

where I is the unit matrix. Numerical evaluations of Eqs. (35a) and (36a) are shown in Figure 10 where the mean amplitude V_m is plotted versus the related vehicle velocity v for $D = 0.1$ and $\mu = 1$. The blue line stands for $\sigma = 0$ of vanishing noise perturbations. For $\sigma = 0.5 \sqrt{\omega_1}$ and $\omega_g/\omega_1 = 0$, one obtains the red line overlaid by the green one in coincidence with the white noise case shown in Figure 8. For $\omega_g/\omega_1 = 0.1$ and $\omega_g/\omega_1 = 5$ of growing perturbation bandwidth, there is a further increasing of the resonance peak. This resonance induction is probably explained by the destabilizing effect of harmonic parameter excitations when for $\Omega v = 2\omega_1$ the perturbation frequency coincides with the double eigen-frequency of the oscillator.

6. Lyapunov exponents and rotation numbers in vehicle dynamics

Vehicle vibrations which are described by rotating coordinates are physically existent if they are almost sure stable or asymptotically stable with probability one. In the unstable case, the separation into rotating processes is not possible and the vehicle equations must be retransformed back to their original equations in non-rotating coordinates. The stability in mean and the almost sure stability [17] of the vehicle vibrations in rotating coordinates is investigated by means of a projection on hyper-spheres and application of the multiplicative ergodic theorem of Osceledets [18]. For these purposes, Eqn. (20b), (21b), (22) and (23) are reduced with $\mu = 0$ to the homogenous form and transformed by means of the two-dimensional system of polar coordinates (P_t, Γ_t) and (Q_t, θ_t) , which leads to the stability equations

$$\begin{aligned} A_t &= P_t \cos \Gamma_t: & dP_t &= [\omega_1 \cos(\theta_t - \Gamma_t) Q_t + \sigma^2 P_t] dt, \\ B_t &= P_t \sin \Gamma_t: & d\Gamma_t &= [\omega_1 \sin(\theta_t - \Gamma_t) \frac{Q_t}{P_t} + \Omega v] dt + \sigma dW_t, \\ G_t &= Q_t \cos \theta_t: & dQ_t &= [-\omega_1 \cos(\theta_t - \Gamma_t) P_t + (\sigma^2 - 2D\omega_1) Q_t] dt, \\ H_t &= Q_t \sin \theta_t: & d\theta_t &= [\omega_1 \sin(\theta_t - \Gamma_t) \frac{P_t}{Q_t} + \Omega v] dt + \sigma dW_t. \end{aligned}$$

The above equations project the displacements (A_t, B_t) and the velocities (G_t, H_t) on two circles with radii (P_t, Q_t) and angles (Γ_t, θ_t) . A second application of polar coordinates by means of Eqs. (37a) and (38a) eliminates the two radii (P_t, Q_t) and projects the entire motion on hyper-sphere with one radius R_t and three angles determined by

$$P_t = R_t \cos \Psi_t: \quad dR_t = [\sigma^2 - D\omega_1(1 - \cos 2\Psi_t)] R_t dt, \quad (37)$$

$$Q_t = R_t \sin \Psi_t: \quad d\Psi_t = -\omega_1 (D \sin 2\Psi_t + \cos \Delta_t) dt, \quad (38)$$

$$\Delta_t = \theta_t - \Gamma_t: \quad d\Delta_t = \omega_1 \sin \Delta_t (\cot \Psi_t - \tan \Psi_t) dt, \quad (39)$$

$$\Sigma_t = \theta_t + \Gamma_t: \quad d\Sigma_t = \omega_1 \sin \Delta_t (\cot \Psi_t + \tan \Psi_t) dt + 2\omega_e dt + 2\sigma dW_t, \quad (40)$$

where difference and sum angle (Δ_t, Σ_t) are additionally introduced by means of Eqn. (39a) and (40a). Eq. (37) is integrated by means of variable separation and leads to the top Lyapunov exponent

$$\lambda_{top} = \lim_{t \rightarrow \infty} \frac{1}{t} \ln(R_t/R_0) = \sigma^2 - D\omega_1 \left(1 - \lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t \cos 2\Psi_t dt \right). \quad (41)$$

If the top Lyapunov exponent is negative, the stationary solutions of Eqn. (20b), (21b), (22) and (23) are asymptotically stable with probability one or almost surely stable. For $\lambda_{top} > 0$, the solutions are unstable and grow, exponentially.

Fig. 11: Limit cycles of projection angles Δ_τ and Ψ_τ around red centers for under-critical damping $D \leq 1$

Fig. 12: Transient projection angles and their ending in singular fix-points for over-critical damping $D \geq 1$

According to Eq. (41), the top Lyapunov exponent is determined by the noise intensity, the system damping and the time average of the cosine of the stability angle Ψ_t , which is coupled with the difference angle Δ_t . Both angles are determined by Eqn. (38b) and (39b) which are non-linear, noise-free and decoupled from the sum angle Σ_t in Eq.(40b) where additive noise is still active. In Figure 11 and 12, Eqn. (38b) and (39b) are numerically evaluated for the under- and overcritical damping $D = 0.5$ and $D = 1.5$ on the left and right side, respectively. The angle solutions are 2π -periodic in Δ and π -periodic with respect to Ψ . For $D \leq 1$, Figure 11 shows stationary limit cycles of both angles (Δ_τ, Ψ_τ) . They are calculable without any transient time behavior for arbitrary initial values applying an Euler scheme e.g. with the scan rate $\Delta_\tau = \omega_1 \Delta t = 0.001$. All limit cycles in Figure 11 are symmetric with respect to $\Psi = \pm\pi/4$. Because of this symmetry the time average in Eq. (41) can also be obtained by the four stationary fix-points $\Psi = \pm\pi/4$ and $\cos \Delta = \pm D$ which represent the center of the limit cycles marked by red circles. The insertion of these center values into Eq. (41) leads to one top Lyapunov exponent and two rotation numbers, as follows:

$$\lambda_{top} = \sigma^2 - D\omega_1 \quad \text{and} \quad \rho_{\Gamma,\theta} = \Omega v \pm \omega_1 \sqrt{1 - D^2} \quad \text{for } D \leq 1. \quad (42)$$

The rotation numbers are time averages of rotating angle processes, applied to the angles increments $d\Gamma_t$ and $d\theta_t$. They are calculated by the stationary values $(\sin \Delta)^2 = 1 - D^2$ and $Q/P = \tan \Psi = \pm 1$. In Figure 12, Eqn. (38b) and (39b) are evaluated for the overcritical damping $D = 1.5$ where instead of limit cycles transient solutions are obtained. Starting with any initial values, both angles (Δ_τ, Ψ_τ) move to the stationary fix-points $\Delta = 0, \pm\pi$ and $\sin 2\Psi = \pm 1/D$. The insertion of these stationary angle values leads to two Lyapunov exponents and one rotation number

$$\lambda_{1,2} = \sigma^2 - \omega_1 (D \mp \sqrt{D^2 - 1}) \quad \text{and} \quad \rho_{\Gamma,\theta} = \Omega v \quad \text{for } D \geq 1. \quad (43)$$

where the fix-points solutions are inserted into the ergodic integrals of Lyapunov exponent and rotation number.

In Figure 13, the rotation numbers are plotted versus the frequency speed Ωv for the natural frequency $\omega_1 = 1$ and three damping values. For $D = 0$, one obtains two straight lines with positive slopes marked by thick red color. For $D = 0.9$, both rotation numbers are drawn in green and coincide in yellow for $D = 1$. Associated rotation numbers with negative slopes are obtained for negative speed frequencies. In Figure 14, the stability map is obtained by plotting the related critical noise intensity σ_{cr}^2/ω_1 versus the vehicle damping. With $\lambda_{top} = 0$, the stability boundaries are

$$\begin{aligned} \sigma_{cr}^2/\omega_1 &= D & \text{for } D \leq 1, \\ \sigma_{cr}^2/\omega_1 &= D - \sqrt{D^2 - 1} & \text{for } D \geq 1. \end{aligned}$$

In Figure 14, the stability region is marked by green color. Inside the green region, the stationary solutions of Eqn. (20b), (21b), (22) and (23) are asymptotically stable with probability one or almost surely stable. Over the green region, the solutions are unstable. Obviously, one needs linearly increasing to stabilize the system for growing noise. However, this effect holds up to $D = 1$, only. Overcritical damping is less effective since growing damping stabilizes weak noise perturbations, only. For $D \rightarrow \infty$, vehicle and road are rigidly coupled. Hence, stabilization is no longer possible. For an extended stability investigation, the above polar coordinate system (P_t, Γ_t) and (Q_t, θ_t) is applied to Eq.(24). For $\mu = 0$, this leads to the same stability equations for the angles (Γ_t, θ_t) and radii (P_t, Q_t) except that σ^2 in the radii equations is replaced by $\sigma^2/2$ when because of $E(dW_t) = 0$ there is noise in Eq. (24). Therewith, the radius equation (37) reads as

$$dR_t = [\sigma^2/2 - D\omega_1(1 - \cos 2\Psi_t)]R_t dt. \quad (44)$$

As already shown before, the Lyapunov exponents of the mean value solutions are calculated to

$$\begin{aligned} \lambda_m &= \sigma^2/2 - D\omega_1, & \text{for } D \leq 1, \\ \lambda_m &= \sigma^2/2^2 - \omega_1(D \mp \sqrt{D^2 - 1}), & \text{for } D \geq 1. \end{aligned}$$

The rotation numbers of the mean value solutions remain unchanged. In Figure 12, the stability boundaries of the mean

value solutions are plotted in Figure 14, marked by blue lines. Note that stability and rotation behavior of the mean value solutions can also be investigated by means of the four eigen-values of Eq. (24) where the real and imaginary parts take the role of Lyapunov exponents and rotation numbers, respectively. Correspondingly, one finds one real part and four imaginary parts for $D \leq 1$. In the overcritical case $D \geq 1$, the eigen-values of Eq. (24) lead to two real parts and two imaginary parts. According to [19], the stability behavior can also be investigated by means of the p -th mean behavior in order to get the almost sure stability for $p = 0$ and the stability in mean for $p = 1$. In [21], one finds approximations of stability boundaries of second order systems for all exponents $p \geq 0$.

Fig. 14: Boundaries for almost sure stability and stability in mean plotted against system damping

7. Conclusions

There are two multiplicative road models which include the limiting case of deterministic harmonic roads. The first one is obtained by non-linear filter equations driven by white noise. Their stationary solutions are similar to Gaussian but bounded with vanishing mean and standard deviation which coincides with the deterministic behavior in the limiting case of vanishing excitation bandwidth $\delta = 0$. Because of specially adapted non-linearity, the mean square equations calculated by means of Itô's calculus are linear. The second model applies sinusoids where the excitation frequency is perturbed by white noise of intensity σ . Inversely to the first model, standard deviations are zero and mean values coincide with the deterministic harmonic behavior passing to the limit case $\sigma = 0$ of vanishing noise perturbation. New results are found for more realistic perturbations by means of filtered noise. For low-pass filtered perturbations, the resonance peak is reduced. However, it is increased applying white noise perturbations. This resonance induction is even stronger when instead of white noise high-pass filtered perturbations are applied.

Summary. We consider the stochastic FitzHugh-Nagumo equations, whose deterministic equivalent allows for fast and stable traveling-pulse solutions. In this talk, we investigate the stability of fast pulses in case of additive noise and derive a multiscale decomposition for small stochastic forcing. Our method is based on adapting the wave velocity by solving a stochastic ordinary differential equation and tracking perturbations of the wave meeting a stochastic partial differential equation coupled to an ordinary differential equation. Previous works have focused on applying this method to scalar equations, such as the stochastic Nagumo equation, which carry a self-adjoint structure. This structure is lost in case of the FitzHugh-Nagumo system and the linearization does not generate an analytic semigroup. We show that this problem can be overcome by making use of Riesz spectral projections in a certain way. This provides a relevant generalization as our approach appears to be applicable also to general stochastic nerve-axon equations, the stochastic periodically-forced NLS equation, or systems of stochastic reaction-diffusion equations with spectrum parallel to the imaginary axis.

The talk and the following presentation are based on and adapted from [4], respectively.

The stochastic FitzHugh-Nagumo equations

Consider the *stochastic FitzHugh-Nagumo equations* driven by additive noise

$$du(t, x) = (\nu \partial_x^2 u(t, x) + f(u(t, x)) - v(t, x)) dt + \sigma dW(t, x) \quad \text{for } (t, x) \in \mathbb{R}_+ \times \mathbb{R}, \quad (1a)$$

$$dv(t, x) = \varepsilon (u(t, x) - \gamma v(t, x)) dt \quad \text{for } (t, x) \in \mathbb{R}_+ \times \mathbb{R}, \quad (1b)$$

in which the *electric potential* u and the *gating variable* v are functions of time t and position x on a neural axon. Here, $\nu \partial_x^2 u$ determines the spatial diffusion on the axon with $\nu > 0$ and the reaction term $f(u)$ is nonlinear and typically reads $f(u) = \chi(u) u (1 - u) (u - a)$ with $0 < a < 1$ and a suitable cut off χ . The term σdW is additive noise, with W denoting an infinite-dimensional Wiener process taking values in a suitable Hilbert space H . The parameter $\varepsilon > 0$ determines the coupling strength of the electric potential u to the gating variable v and will be assumed to be sufficiently small. The parameter $\gamma > 0$ is a decay constant of the gating variable v .

Traveling-pulse solutions and their stability

The deterministic variant of (1) with $\sigma = 0$ allows for traveling-pulse solutions of the form $u(t, x) = \hat{u}(\xi)$ and $v(t, x) = \hat{v}(\xi)$, where $\xi = x + st$ and $s \in \mathbb{R}$ is the pulse's velocity. The vectorial function $(\hat{u}, \frac{d\hat{u}}{d\xi}, \hat{v})$ is a nontrivial homoclinic orbit of a three-dimensional continuous and autonomous dynamical system

$$\frac{d\hat{u}}{d\xi} = \hat{u}', \quad \frac{d\hat{u}'}{d\xi} = \frac{1}{\nu} (s\hat{u}' - f(\hat{u}) + \hat{v}), \quad \frac{d\hat{v}}{d\xi} = \frac{\varepsilon}{s} (\hat{u} - \gamma\hat{v}) \quad \text{for } \xi \in \mathbb{R}. \quad (2)$$

Existence of nontrivial pulses with $(\hat{u}, \hat{v})^t \rightarrow (0, 0)^t$ as $\xi \rightarrow \pm\infty$ is ensured if $\gamma \geq 0$ is sufficiently small [11]. Indeed, a singular perturbation argument around $\varepsilon = 0$ and $s = 0$ yields existence of a *slow pulse* with wave speed $s \approx 0$, which by Sturm-Liouville theory turns out to be unstable. Nonetheless, there is also a *fast pulse*, in what follows denoted by (\hat{u}, \hat{v}) , corresponding to much higher wave speeds $s = s(f, \varepsilon)$, constructed in [1, 2] employing the method of isolating blocks of the fast and slow subsystems [3]. Using an Evans function analysis, stability of the fast pulse in the space of bounded uniformly continuous functions was first proved in [7]. Stability in $L^2(\mathbb{R}; \mathbb{R}^2)$ and $H^1(\mathbb{R}; \mathbb{R}^2)$ was proved in [5, 12, 13].

Our approach for computing the velocity correction

We investigate the following decomposition

$$u(t, x) = \hat{u}(x + st + \varphi(t)) + u_\varphi(t, x), \quad v(t, x) = \hat{v}(x + st + \varphi(t)) + v_\varphi(t, x) \quad (3)$$

of solutions to (1), in which the function $\varphi(t)$ is a random correction to the pulse's position, and $u_\varphi(t, x)$ and $v_\varphi(t, x)$ denote lower-order fluctuations that are uniquely defined through (3) for any $\varphi = \varphi(t)$. Ideally, we would like to choose φ to minimize the distance in the direction of the traveling wave between the solution $X := (u, v)^t$ of the FitzHugh-Nagumo SPDEs (1) and the suitably translated traveling wave $\hat{X} = (\hat{u}, \hat{v})^t$, i.e.,

$$\varphi(t) \in \operatorname{argmin}_{\varphi \in \mathbb{R}} \left\| \Pi_{st+\varphi}^0 \left(X(t, \cdot) - \hat{X}(\cdot + st + \varphi) \right) \right\|_H^2, \quad \text{with } X := \begin{pmatrix} u \\ v \end{pmatrix}, \quad \hat{X} := \begin{pmatrix} \hat{u} \\ \hat{v} \end{pmatrix}, \quad (4)$$

where $\|\cdot\|_H$ is the H -norm in the spatial variable and $\Pi_{st+\varphi}^0$ is a suitable projection onto the pulse such that $\Pi_{st+\varphi}^0 \frac{d\hat{X}}{d\xi}(\cdot + st + \varphi) = \frac{d\hat{X}}{d\xi}(\cdot + st + \varphi)$. However, as problem (4) is not necessarily convex, uniqueness of a minimizer is not certain. Following [8] and replacing (4) by the weaker condition for a critical point of finding $\varphi = \varphi(t)$, we may impose

$$0 = \left(\Pi_{st+\varphi}^0 \left(X(t, \cdot) - \hat{X}(\cdot + st + \varphi) \right), \frac{d\hat{X}}{d\xi}(\cdot + st + \varphi) \right)_H, \quad (5)$$

where $(\cdot, \cdot)_H$ is the inner product of H . This approach has been employed in [6] for more general classes of SPDE systems, but the results only hold up to the first stopping time when the local minimum becomes a saddle point. Here, we follow [8], i.e., $\varphi(t)$ is approximated by a process $\varphi^m(t)$ fulfilling the random ordinary differential equation

$$\frac{d\varphi^m}{dt}(t) = m \left(\Pi_{st+\varphi^m(t)}^0 \left(X(t, \cdot) - \hat{X}(\cdot + st + \varphi^m(t)) \right), \frac{d\hat{X}}{d\xi}(\cdot + st + \varphi^m(t)) \right)_H \quad (6)$$

for given initial data and a sufficiently large relaxation parameter $m > 0$.

Results

We obtain the following results:

1. We establish existence and uniqueness of solutions to (1) using the variational approach for equations with locally monotone coefficients [9, 10].
2. We give a short proof of deterministic stability in $L^2(\mathbb{R}; \mathbb{R}^2)$ of the fast pulse $\hat{X} = (\hat{u}, \hat{v})^t$, which simplifies the presentations in [5, 12, 13].
3. We derive an SODE defining the correction of the wave's velocity. The leading-order part of this SODE contains a linear damping term due to the relaxation method of the frame and additive stochastic fluctuations obtained from projecting the infinite-dimensional noise onto a translate of $\frac{d\hat{X}}{d\xi}$.
4. We prove a multiscale expansion

$$X(t, \cdot) = \hat{X}(\cdot + st + \sigma\varphi_0^m(t)) + \sigma X_0^m(t, \cdot) + o(\sigma), \quad (7)$$

where $(\sigma\varphi_0^m, \sigma X_0^m)$ solves the scaled linearized evolution of (φ^m, X^m) .

5. We consider the limit $m \rightarrow \infty$ of immediate relaxation. Here, we prove that
 - the multiscale expansion (7) remains satisfied as $m \rightarrow \infty$,
 - as $\sigma \searrow 0$ the first exit time where the multiscale decomposition cannot be guaranteed to hold anymore converges to the entire time interval,
 - by employing deterministic stability, the second moment $\mathbb{E} \|X_0^\infty(t, \cdot)\|_H^2$ of fluctuations transverse to the traveling pulse mode after correcting the wave velocity stays bounded,
 - the second moment $\mathbb{E} \|X(t, \cdot) - \hat{X}(\cdot + st)\|_H^2$ of fluctuations transverse to the traveling wave mode without correcting the wave velocity asymptotically can grow linearly in time.

We conclude by discussing generalizations of our work, such as the application to other (systems of) SPDEs with spectrum parallel to the imaginary axis or the stability of more complicated patterns.

Nonlinear and stochastic dynamics in a forced vibro-impact energy harvester

Daniil Yurchenko*, Larissa Serdukova† and Rachel Kuske †

† *School of Mathematics, Georgia Tech, Atlanta, GA, USA*

Summary. Vibro-impact (VI) energy harvesting (EH) systems represent a class of highly nonlinear (non-smooth) systems with impact-type component interactions. A recently proposed VI-EH device, comprises a main mass, subjected to an external excitation, and a smaller mass within, traveling freely in a slot in between two dielectric elastomer (DE) membranes, deforming them at impact. As a highly flexible polymer with high dielectric permittivity and nonlinear responses properties, DE has desirable properties given its chemical composition, response to excitation, superior energy density and suitability for low frequency applications. In order to predict the specific performance of the VI-EH device, we develop a new (semi)-analytical approach for analysis of nonlinear stochastic dynamics in non-autonomous non-smooth impacting systems. This methodology relies on capturing the bifurcation structure and its influence on output energy, providing insight into the role of dynamics in energy harvesting efficiency and in the optimal design of the device. The analysis also reveals a generic mechanism and energy transfer phenomenon in nonlinear impacting systems.

Complex dynamics of the vibro-impact energy harvester (VI-EH)

The proposed VI-EH device is a vibro-impacting mechanical system, consisting of a cylinder of length s and mass M , an inner ball with mass m ($M \gg m$) moving within the cylinder between impacts with dielectric elastomer (DE) membranes at both ends of the cylinder. The system is inclined with an angle of β and forced with a harmonic excitation $F(\omega t + \phi)$ along the direction of its axis. We neglect friction between the ball and the cylinder, and track the relative position $Z = X - x$, for X the non-dimensionalized displacement of the cylinder center and x the location of the ball. The equation of motion and impact condition for the k^{th} impact at time $t = t_k$ are

$$\ddot{Z} = f(t) + \bar{g}, \quad f(t) = F(\omega t + \varphi), \quad \dot{Z}_k^+ = -r\dot{Z}_k^-, \quad Z_k = \pm \frac{d}{2}, \quad Z_k = Z(t_k). \quad (1)$$

Here $\bar{g} = -Mg \sin \beta / \|F\|$, where g is gravity, and $\|F\|$ the norm of F . The impact condition is applied on the bottom (top) ∂B (∂T) membrane of the VI-EH device at $(x - X) = \pm d/2$ for $d = \frac{s}{x_c}$, with \dot{Z}^\pm the non-dimensionalised relative velocity of the ball before (-) (after (+)) impact and r the restitution coefficient. The parameter d captures the influence of length, amplitude of excitation, and frequency via the factor $x_c = \frac{\|\hat{F}\| \pi^2}{M\omega^2}$. Integrating (1) between impacts for $t \in (t_{k-1}, t_k)$ yields

$$\dot{Z}(t) = -r\dot{Z}_{k-1}^- + \bar{g}(t - t_{k-1}) + F_1(t) - F_1(t_{k-1}), \quad F_1(t) = \int f(t)dt, \quad (2)$$

and integrating (2) we get the analogous equation for $Z(t)$. At the k^{th} impact, the maps for \dot{Z}_k^- and Z_k^- are obtained by taking $t = t_k$ in (2) and the similar equation for Z , with $Z_k = \pm d/2$ at impact. Combining these maps we get all possible motions of the ball, $P_1 : \partial B \mapsto \partial T$, $P_2 : \partial T \mapsto \partial B$, $P_3 : \partial B \mapsto \partial B$, $P_4 : \partial T \mapsto \partial T$.

Using P_j together with the impact conditions and F periodic, we first study periodic motions of an inclined VI-EH, such as those shown in the phase planes of Fig. 1 (Left). The nonlinear analysis provides the bifurcation and stability conditions for different types of behavior within a non-dimensionalized framework, allowing us to capture the results in terms of dependence on parameters d, r , and β , and excitation, also considered in [1] for $\beta = 0$. For an incline $\beta \neq 0$, gravity naturally contributes to the asymmetric state and different nonlinear behaviors. We find transitions and stability for two families of periodic solutions. The first has a 1:1 ratio of impacts on ∂T to ∂B per excitation period, obtained by alternating P_1 and P_2 . The analysis shows that these 1:1 behaviors are characterized by the triples $(\dot{Z}_k, \phi_k, \Delta t_k)$. Here ϕ_k is the phase difference between the impact and a trough (or peak) of F , and $\Delta t_k = t_{k+1} - t_k$. A second family has a 1:n ratio of impacts on ∂T and ∂B . These follow from grazing bifurcations and are composed of P_3, P_1, P_2 . In Fig. 1 (Middle) we show these families in terms of \dot{Z}_k from numerics for a range of d . Analytical solutions reproduce these branches in [2]. As shown in Fig. 1 (Left and Middle) for decreasing d , there are periodic doublings of the 1:1 family ($d > d_{\text{graz}} \approx .2$, d_{graz} corresponding to a grazing bifurcation), until the grazing bifurcation leads to the 1:2 ratio of impacts ($d < .2$). Following an impact on ∂B , non-monotonic behavior of the relative velocity \dot{Z} appears as a loop in the phase plane trajectory after \dot{Z} crosses 0 on the trajectory away from $Z = \pm d/2$. For d_{graz} we have $\dot{Z}_{k+1} = Z_{k+1} = 0$, corresponding to a transition to P_3 before P_2 , yielding a 1:2 solution.

Energy is harvested via impacts with the DE membranes, with $U_{\text{imp}}^{(i)}$ the voltage at the i^{th} impact obtained from geometrical parameters of the membrane and \dot{Z}_i [4]. The harvested voltage $U_{\text{imp}} - U_{\text{in}}$ is shown in Fig. 1 (Middle), for U_{in} a constant input voltage applied to the membranes, and d decreases with increasing amplitude of forcing $\|F\|$. Note that grazing bifurcations and 1:2 periodic solutions correspond to low velocity impacts, yielding an abrupt loss of average energy output per impact.

Figure 1: (Left). Limit cycles in the phase plane for Z, \dot{Z} with different sequences of impacts in the VI-EH model (1) for decreasing d ; all but lower right with 1:1 ratio per period of forcing, lower right is 2:1. Middle Upper: Impact velocity \dot{Z}_{imp} vs. d ; Lower: Corresponding output voltage (black), red (blue) for average output per impact (unit time); Right: Average energy output per impact. Red circles for small constant β and no feedback; Upper: blue for larger β , symmetrically distributed, green and black for asymmetric distribution of β with small mean. Lower: blue and black for different levels of feedback.

Influence of randomness

The analytical results provided by the nonlinear maps reveal potential sensitivities to certain parameters for the different states, indicating conditions under which stochastic effects influence transitions. For example, the dependency of grazing bifurcations on ϕ_k suggests that stochastic fluctuations in the phase can benefit energy output by disrupting low velocity impacts. We derive stochastic nonlinear maps describing probabilistic transitions between states, thus capturing both detrimental and beneficial effects of random fluctuations on the energy output.

The stochastic variations of the maps P_j are derived from the physical model, depending on the stochastic source and transition of interest. Such variations were found in [3], which considered stochastic versions of the Nordmark map for compliant impacts near grazing. The phase plane analysis in [2] motivates a simple efficient formulation to study the behavior near the underlying period doubling bifurcations, based on considering separately the stochastic versions of P_1 and P_2 to capture the dilation of trajectories in \dot{Z}_k on P_2 . A similar dilation of ϕ_k on P_1 indicates a complementary approach, that capitalizes on the sensitivity to $\phi_k \ll 1$, as already suggested from the nonlinear expressions of $\sin \phi_k$ in the triple $(\dot{Z}_k, \phi_k, \Delta t_k)$ for the 1:1 families [2]. To capture the influence of parameter uncertainties, we break P_j into submaps, between key points corresponding to $\dot{Z} = 0$, $Z = \pm d/2$, and $\ddot{Z} = 0$, all important features in the approach to grazing shown in Fig 1 (Left).

We find that certain noise in ϕ , relaxing rapidly to fluctuations about its mean, yields an averaging effect that generates an effective reduction in the forcing amplitude. Then the attracting 1:1 periodic behavior is sustained over a larger range of d . Specifically, for smaller d , the 1:2 behavior is displaced, as is the corresponding lower average energy output per impact.

Fig. 1 (Right) shows the influence of other noise and asymmetries on U_{ave} vs. d . Certain random fluctuations in β advance d_{graz} to larger values, even counter-intuitively for asymmetric distributions of β with a small average $\bar{\beta} \ll 1$. If there is a non-negligible tail probability for $\beta = O(1)$ (green and black markers in Fig. 1 (Right upper)), the average energy output is closer to that obtained for random $\beta = O(1)$ (blue diamonds) than for smaller deterministic β (red circles), suggesting that even for short transient periods of $\beta = O(1)$, the system remains in the 1:2 behavior over a longer time period. Also, feedback of the capsule motion at a lagged time leads to an effective phase shift in the forcing, potentially avoiding repeated ∂B impacts for $\phi_k \ll 1$ (blue and black markers in Fig. 1 Right lower) and shifting reduced U_{ave} to smaller d . There are a number of ways to model this effect, including randomness to capture lack of precise feedback. The newly derived stochastic maps near the critical transitions related to 1:1 and 1:2 periodic solutions explain how noise influences transitions between different levels of energy output.

Conclusions

Semi-analytical nonlinear analyses of a novel model for vibro-impact energy harvesting (VI-EH) captures parametric and excitation dependencies of the output voltage. The results point to parameter ranges and scenarios where noise and asymmetries can be either detrimental or beneficial for the energy output. Via novel stochastic analyses and computations, we reveal the sensitivities of the system to random fluctuations and asymmetries. These indicate analysis-based design features for the VI-EH device.

^{**}*Wolfson School of Mechanical, Electrical and Manufacturing Engineering, Loughborough University, Loughborough, UK*

Summary. A nonlinear vibration energy harvester for converting energy from the torsional oscillations of an automotive powertrain is considered under random engine running speeds. Engine data recorded from several real-life routes are used to describe the spectral properties of the powertrain vibrations, and particularly their frequency distribution in city and highway driving cycles. Joint response Probability Density Functions of the stochastic coupled electromechanical oscillator are calculated with a numerical Path Integration approach. The impact of noise on the mean power output is assessed by comparing the resulting random power output statistics with deterministic expressions based on the mean engine speed.

Introduction

Vibration energy harvesting is a recent concept that involves scavenging energy from ambient mechanical vibrations and converting it to useful electricity to power small electronic devices, such as sensors and wireless data transmitters [1]. These systems are designed such that mechanical power take-off is optimised, and this is usually achieved by establishing high-amplitude response to the exciting vibrations of the host system, such as resonant linear response or broadband high energy response in the case of nonlinear harvesters [2]. However, vibrations in structures and machines are usually the result of complex interactions between nonlinearly coupled components, exhibiting a diverse interaction with system modes and the inherent randomness of environmental forces. This is particularly pertinent to automotive vibrations whereby linear and torsional vibrations of the powertrain components are subject to a multi-factor dependence on environmental conditions, road surface conditions, driving behaviour, route and mode of driving (city/highway). As a result, harvesters are essentially required to capture energy from vibrations that cannot be adequately described by conventional deterministic approaches.

Recently, a concept for harvesting energy from the torsional vibrations of a propulsion shaft has been introduced [3]. In this paper, a stochastic framework for calculating this device's mean harvested power is presented. Randomness of the powertrain vibrations frequency is modelled by exploiting the direct link of the dominant vibration frequency to the engine speed and the engine architecture. Transient and steady-state driving scenarios are considered through a statistical analysis of engine speeds recorded in real-life driving scenarios. Expressions of the spectral distributions of the input vibrations are then used within an advanced computational framework to accurately calculate joint Probability Density Functions (PDF) of the harvester's mechanical and electrical generalised variables.

Problem Formulation

Consider a rotational vibration energy harvester as the one shown in Figure 1(a). This concept has been recently introduced for harvesting energy from the torsional vibrations of propulsion shafts [3]. The system has been designed to harvest energy from torsional vibrations rather than the main shaft speed, thereby minimising the impact of the device on the main transmission of power with potentially favourable reduction of the shaft speed fluctuations. The reader is referred to [3] for a detailed description of the device and the ensuing analysis that leads to the following equations of motion:

$$\begin{aligned} J\ddot{\phi} + c_m\dot{\phi} + k_1\phi + k_3\phi^3 - \hat{\Theta}I &= J\ddot{a} \\ LI + (R_{load} + R_{int})I + \hat{\Theta}\dot{\phi} &= 0 \end{aligned} \quad (1)$$

where \ddot{a} denotes the shaft vibrations which act as base excitation to the rotational harvester with inertia J , mechanical damping c_m and potential energy $U(\phi) = k_1\phi^2/2 + k_3\phi^4/4$. The electrical properties are denoted by L – inductance, R_{load} – load resistance, R_{int} – coil resistance and $\hat{\Theta}$ – electromagnetic coupling. Dominant vibration frequencies in rotary applications are linked with orders of the main rotation speed. In 2-cylinder, 2-stroke IC engines for example, powertrain vibrations are dominated by the 2nd engine order. However, as it is shown in Figure 1(b), the engine speed that determines the dominant vibration frequency is a randomly varying quantity (see Figure 1(d)). This data has been recorded in a real driving cycle down the route shown in Figure 1(c). Therefore, the exciting base vibrations can take the following form to consider random modulations of the excitation's phase:

$$\begin{aligned} \ddot{a} &= A \cos(q) \\ \dot{q} &= v + \sigma\zeta(t) \end{aligned} \quad (2)$$

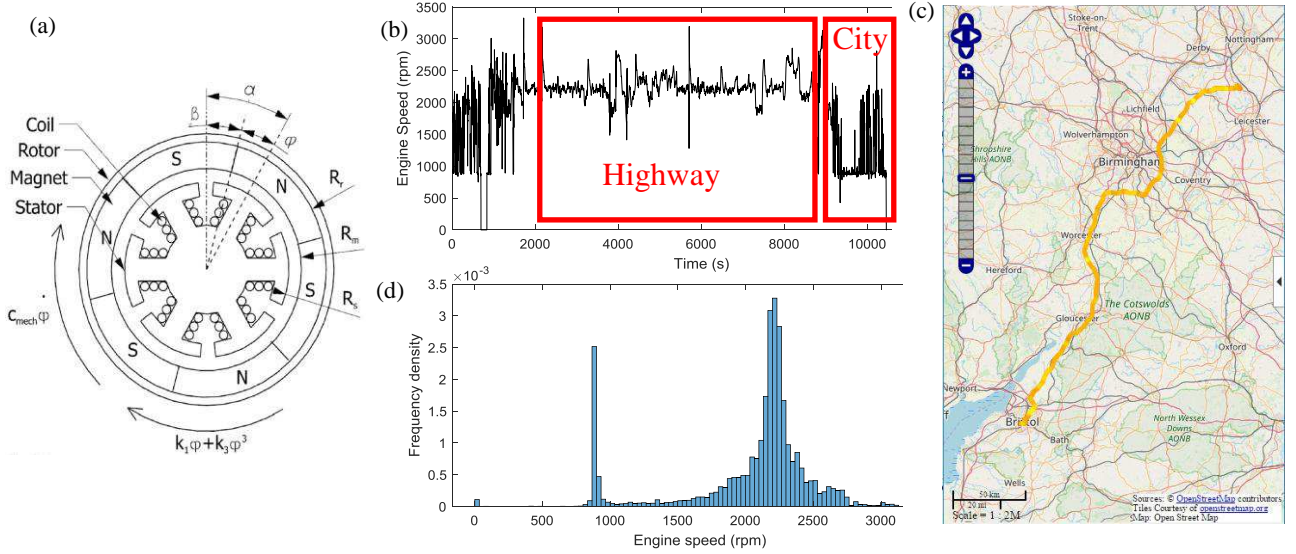

Figure 1: (a) sketch of the rotational vibration energy harvester; (b) engine speed during mixed drive cycle; (c) route map of displayed data; (d) distribution of engine speed in mixed cycle.

where $\zeta(t)$ is a Gaussian delta-correlated white noise process with $\langle \zeta(t)\zeta(t+\tau) \rangle = 2\pi D\delta(\tau)$. Note that randomness is only considered in the phase of the vibrations since the vibration amplitude can be considered to be slow-varying. More explicit representation of the speed's spectral properties can be used by colouring the white noise process with higher order linear filters.

Path Integration

The joint response PDF of the stochastic system described by Eqs (1) and (2) is computed by means of a numerical Path Integration (PI) technique. The response PDF contains probabilistic information for the harvester's kinematic and electrical variables, allowing accurate calculation of the electrical power output probability distribution. This method is based on an iterative approach for calculating in short time steps the response PDF, which at time t can be expressed from the PDF at $t' = t - \Delta t$ exploiting the Markov property of the solution vector and the total probability law [4]:

$$p(\mathbf{z}, q, t) = \int_{\text{state space}} p(\mathbf{z}, q, t | \mathbf{z}', q', t') p(\mathbf{z}', q', t') d\mathbf{z}' dq' \quad (3)$$

where $p(\mathbf{z}, q, t | \mathbf{z}', q', t')$ is the transition probability density function (TPD) and \mathbf{z} is the system's state vector. The short time propagation TPD is Gaussian distribution and thus, the TPD may be written as [4]:

$$p(\mathbf{z}, q, t | \mathbf{z}', q', t') = \delta[\mathbf{z} - \mathbf{z}' - \mathbf{r}(\mathbf{z}', q', \Delta t)] \frac{1}{\sqrt{2\pi D \Delta t}} \exp \left\{ -\frac{[q - q' - r_4(\mathbf{z}', q', \Delta t)]^2}{2D \Delta t} \right\} \quad (4)$$

where δ is the Dirac delta function and $\mathbf{r}(\mathbf{z}', q', \Delta t)$, $i = 1, 2, 3, \dots$ are 4th order Runge-Kutta increments of \mathbf{z} and q . Iterative application of Eqs (3) and (4) lead to the computation of the joint response PDF, whereby standard rules are applied to compute the marginal PDF of the current and the electrical power.

Discussion

Preliminary calculations have shown that randomness has a significant impact on the mean power output compared with using the average engine speed in deterministic models. This is particularly important for vibrations in the frequency range in-between the deterministic saddle-node bifurcations, where multiple attractors co-exist. Early results indicate that randomness particularly affects the establishment of high energy solution branches as the solution approaches the jump-down bifurcations. This is due to the shrinking area of the deterministic basin of attraction which makes the high-amplitude desired solution more sensitive to random fluctuations. Further analysis using the described procedure will reveal the full impact of randomness on the harvested electrical power.

Simulation of Road Surfaces Profiles by a Stochastic Parametrical Model

Alfons Ams

Institute of Mechanics and Fluidynamics

Technical University of Freiberg, Freiberg, Germany

Summary. Road irregularities have an important influence on the dynamic behavior of vehicles. Knowledge of their characteristics and magnitude is essential for the design of the vehicle. The problem of interest is the simulation of road surfaces profiles because modern test facilities and computer simulations of vehicle dynamics needs driving excitations. An import issue is the power spectral densities and the approximation by analytical formulas. In the paper a stochastic parametrical nonlinear model of first order with bounded amplitudes will be discussed. Some analytical and numerical results will be shown.

Road Surface Profiles

The road surface profiles are defined by ISO8608 Mechanical vibration – Road surface profiles – Reporting of measured data [1]. Figure 1 shows an example of a measured road.

Figure A.4 — Smoothed PSD of track 2 (characterization: see annex B)

Figure 1: Measured road surface profile [1]

Figure 2: A quarter car (1 DOF) with road surface profile Z_t

Stochastic Parametrical Model

The stochastic parametrical nonlinear model of first order

$$\dot{Z}_t = \left(\frac{1}{2} \sigma^2 - \omega_0 \right) Z_t + \sqrt{Z_0^2 - Z_t^2} \sigma \dot{W}_t$$

with σ intensity of white noise, Z_0 the maximum amplitude, ω_0 the corner frequency and W_t the Wiener process with the mean value $E\{dW_t\} = 0$ and the variance $E\{dW_t^2\} = dt$. The stochastic differential equation (Ito) is

$$dZ_t = -\omega_0 Z_t dt + \sqrt{Z_0^2 - Z_t^2} \sigma dW_t \quad |Z_t| \leq Z_0$$

The Fokker Planck equation of the probability density function is

$$\frac{\partial p}{\partial t} - \omega_0 \frac{\partial}{\partial z} [zp] - \frac{\sigma^2}{2} \frac{\partial^2}{\partial z^2} [(Z_0^2 - z^2)p] = 0$$

The stationary solution of the density function can be calculated to

$$p(z) = C (Z_0^2 - z^2)^{(-1+\omega_0/\sigma^2)} \quad \sigma^2 < \omega_0$$

The constant C fulfilled the normalization condition $\int_{-Z_0}^{+Z_0} p(z) dz = 1$. The auto correlation function of the stationary process Z_t is

$$R_z(\tau) = \sigma_z^2 e^{-\omega_0 |\tau|}$$

Figure 3: Stationary density distributions $p(z)$ with $\omega_0 = 10$, $Z_0 = 1$ and different σ

Figure 4: Auto correlation function $R_z(\tau)$ with $\sigma_z = 1$ and different ω_0

A numerical realization of the stationary process Z_t with the parameters $\omega_0 = 10$, $Z_0 = 1$, $\sigma = 0.5$ and $N = 10^6$ time steps shows figure 3.

Figure 3: Numerical realization of the stationary process Z_t ($\omega_0 = 10$, $Z_0 = 1$, $\sigma = 0.5$, $N = 10^6$)

Electrostatic Nonlinear Trimming of Ring-Based MEMS Coriolis Vibrating Gyroscopes

Davin J. Arifin, Stewart McWilliam

Faculty of Engineering, University of Nottingham, UK

Summary. The effects of electrostatic nonlinearity on rate measuring performance of a capacitive MEMS Coriolis Vibrating Gyroscope (CVG) with an imperfect sensing element are investigated. The electrostatic nonlinearity is a result of large amplitude vibration of the ring, which modifies the capacitive forcing and induces self-induced parametric amplification. A cubic-order nonlinear mathematical model is used to describe the electrostatic nonlinearity and expressions are developed for the scale factor and bias. It is shown that parametric pumping induces an amplification range that enhances rate sensitivity and electrostatic non-linearity has potential to negate the effects of imperfection.

Model Description

For MEMS rate-measuring CVG's having a ring resonator [1] the dominant source of nonlinearity is electrostatics due to capacitive actuation and sensing of ring displacements. The dynamics of the sense mode used to detect rate is significantly affected by self-induced parametric amplification [1, 2] when the vibration amplitude is large and the modal properties modulate at twice its vibration frequency. In the small amplitude regime imperfections degrade the scale factor and bias [3]. The potential for nonlinearity to negate or reverse these effects is presented here.

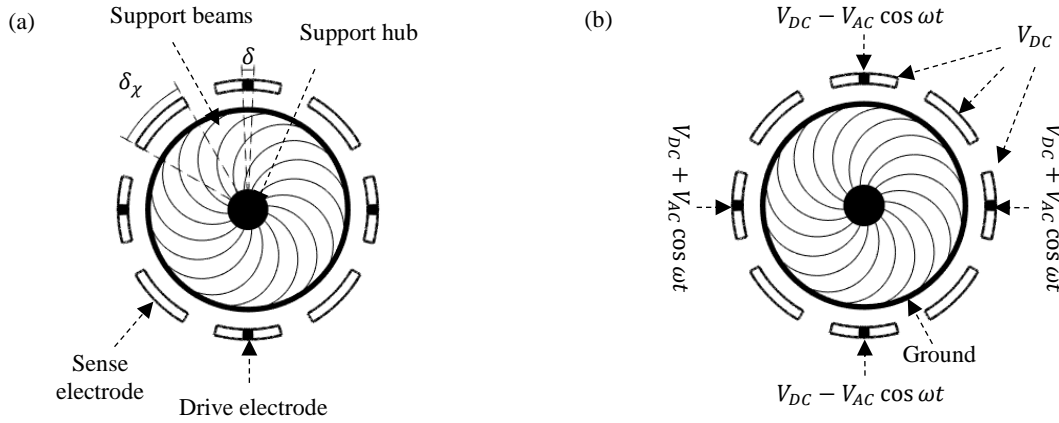

Figure 1: (a) Schematic general layout; (b) voltage profile applied by individual electrodes

Figures 1(a) and 1(b) show the ring element, capacitive electrodes and support structure for a typical device together with the voltages applied across electrode gaps. Voltage V_{AC} drives the ring into its 2θ flexural primary mode. Voltage V_{DC} is primarily responsible for electrostatic nonlinearity. A cubic-order nonlinear model is used to describe the dynamics of the primary (drive) and secondary (sense) modes. Assuming the applied angular rate is much smaller than the natural frequency, $V_{AC} \ll V_{DC}$, and the ring is thin and midsurface-inextensional, the equation of motion for the sense mode is:

$$\ddot{Y} + \frac{\omega_0}{Q} \dot{Y} + Y \left[\omega_0^2 (1 - \mu_\omega \cos 4\theta_\omega) + \kappa \frac{X^2}{g_0^2} \right] = -\frac{8}{5} \dot{X} \Omega - \omega_0^2 \mu_\omega \sin 4\theta_\omega X \quad (1)$$

X, Y are modal coordinates describing the drive and sense modes respectively; ω_0 is the undamped natural frequency and Q is the Q factor for the perfect ring. In practice, $Y \ll X$ so nonlinear terms in Y have been neglected. κ is the nonlinear elastic coupling strength from the drive mode to the sense mode and results in amplitude-dependent resonance. μ_ω is an imperfection parameter and Ω is the applied angular rate. The sense mode is subjected to: i) Coriolis forcing proportional to $\dot{X} \Omega$; ii) imperfection-induced quadrature force proportional to μ_ω ; and iii) parametric excitation arising from nonlinear elastic coupling κ . The drive mode modulates the stiffness of the sense mode at approximately twice its effective vibration frequency. The amplitude and phase of the sense mode oscillation are obtained using the averaging method and the scale factor S^c and bias Ω_0^c are found to be:

$$S^c = -\frac{\frac{8}{5} x \omega_x^2 \left(\frac{\omega_0}{Q} \right)}{\omega_x^2 \left(\frac{\omega_0}{Q} \right)^2 + (\Delta_\omega^2 + \xi_y)(\Delta_\omega^2 - \xi_y)} \quad \Omega_0^c = -\frac{\omega_0^2 \mu_\omega \sin 4\theta_\omega (\Delta_\omega^2 + \xi_y)}{\frac{8}{5} \omega_x^2 \left(\frac{\omega_0}{Q} \right)} \quad (2,3)$$

Here $\Delta_\omega^2 = 2\omega_0^2 \mu_\omega \cos 4\theta_\omega + \frac{x^2}{4g_0^2} (3\gamma - 2\kappa)$ is the frequency detuning parameter and $\xi_y = \kappa \frac{x^2}{4g_0^2}$ is the pumping strength, where γ is the modal Duffing coefficient and x is the drive amplitude. $\kappa, \gamma < 0$ characterize the nonlinear modal stiffnesses and $|\kappa| \leq |\gamma|$, where $|\kappa| = |\gamma|$ when $\delta_x = 45^\circ$. For small-amplitude operation, $\xi_y = 0$ and $\Delta_\omega^2 \propto \mu_\omega$.

Nonlinearity causes amplitude-dependent frequency detuning and parametric pumping and both interact with the imperfection to modify the scale factor and bias at large amplitude.

Scale factor and bias

The scale factor for an ideal, linear CVG behaves linearly with drive amplitude x and inversely with bandwidth, so a high Q factor is desirable. In (2) the $(\Delta_\omega^2 + \xi_y)(\Delta_\omega^2 - \xi_y)$ term plays a key role in the nonlinear modification of the scale factor when the amplitude-dependent frequency detuning parameter and parametric pumping strength interact i.e.:

- i. $(\Delta_\omega^2 + \xi_y)(\Delta_\omega^2 - \xi_y) > 0$ - nonlinearity interacts constructively with imperfection, reducing the scale factor.
- ii. $(\Delta_\omega^2 + \xi_y)(\Delta_\omega^2 - \xi_y) = 0$ - nonlinearity negates imperfection effectively trimming the device.
- iii. $(\Delta_\omega^2 + \xi_y)(\Delta_\omega^2 - \xi_y) < 0$ - nonlinear amplification occurs as the effective bandwidth is reduced.

Figure 2: Variation of (a) S^C normalized relative to the trimmed, linear case for continuous ($\kappa = \gamma$) and discontinuous ($|\kappa| < |\gamma|$) biasing electrodes, and (b) Ω_0^C with the gap-normalised drive amplitude

When $(\Delta_\omega^2 + \xi_y)(\Delta_\omega^2 - \xi_y) < 0$ the result is a pure nonlinear effect, because without parametric pumping the imperfection always acts to reduce the scale factor. Figure 2 shows that nonlinear amplification occurs for a range of drive amplitudes. A consequence of this is that the imperfect device has an enhanced scale factor compared to a linear, trimmed device. This amplification range is defined by $-\xi_y < \Delta_\omega^2 < \xi_y$ and the amplification increases as the pumping strength ξ_y increases. The upper bound of this range grows without bound when $\gamma = \kappa$ because the variation of $(\Delta_\omega^2 + \xi_y)(\Delta_\omega^2 - \xi_y)$ with drive amplitude is monotonic in this case, so nonlinear trimming only occurs at the lower bound when the parametric pumping negates the effects of frequency detuning, i.e. $\Delta_\omega^2 = -\xi_y$. In practice higher order nonlinearities play a role in limiting the vibration amplitude. On the other hand, if the difference between γ and κ is large such that $|\kappa| \ll |\gamma|$, which corresponds to the case when the biasing electrode span is small, the upper and lower bounds approach each other and the amplification range reduces. The lower bound of this range when $\Delta_\omega^2 = -\xi_y$ also plays a role in nullifying the bias. Figure 2(b) indicates that the bias is increasingly sensitive to the operational drive amplitude as the amplitude increases. The bias variation is monotonic, either increasing or decreasing, and nonlinear trimming of the device to nullify the bias is only possible if the amplitude dependent frequency detuning is negated by the parametric pumping, i.e. Δ_ω^2 and ξ_y have opposite signs. As electrostatic nonlinearity is softening, this can only occur when the drive excitation is applied at an angular position close to the maximum frequency axis, i.e. $\mu_\omega \cos 4\theta_\omega > 0$.

Conclusions

Electrostatic nonlinearity in ring-based MEMS CVGs interacts with ring imperfections due to self-induced parametric pumping and amplitude-dependent frequency detuning of the modes. These nonlinear effects have potential to negate performance degradation caused by imperfection, effectively trimming the device, but can enhance sensitivity in particular drive amplitude ranges. The lower bound of the amplification range effectively nullifies the bias in the specific case where the frequency detuning is negated by parametric pumping. The performance enhancement offered by electrostatic nonlinearity for imperfect devices is most significant when the cubic-order modal stiffnesses are balanced.

Summary. Parametric amplifiers have been well known in the electronic industry as well as in micro electromechanical systems (MEMS). However, they are typically confined to amplify the signals of these systems at primary or secondary resonance frequencies. Parametric amplification can nonetheless be extended to be broadband under certain conditions and system parameters. To the best of the authors' knowledge, this is not yet applied in microsystems, although being highly promising especially for the industry of micro sensors and transducers. On the other hand, in the industry of rate gyroscopes, the micro-ring gyroscope is being developed for over a decade in order to reach the accuracy level of tactical or inertial grade gyroscopes, while maintaining relatively low production costs of MEMS. For that sake, parametric amplification was studied for micro-ring gyroscopes with different excitation methods. However, the idea of having "global" amplification was not yet applied. For this reason, this contribution aims at presenting a parametric excitation method for nonlinearly modeled micro-ring gyroscopes which can provide "global" improvement in the amplification and the performance for a broadband frequency spectrum.

Introduction

Parametric resonances have long been studied since the 1831 by Faraday. They were up to this date in practice the only useful phenomenon acquired through parametric excitation, i.e. through having a time-varying coefficient in the system's partial differential equation (PDE). The common practice, at least in the microsystems industry, did not make use so far from an important observation by Cesari in 1939. He found in at least two degree-of-freedom (DOF) systems, that an asynchronous parametric excitation can lead to "global" phenomena across the whole frequency spectrum [1]. This will be explained in the next section.

On the other hand, researchers aim at improving micro gyroscopes to attain the tactical grade level (0.1 deg/h bias stability), seeking the level of inertial grade (<0.01 deg/h) afterwards. For micro gyroscopes, nonlinear resonances were used in the literature to overcome asymmetries due to fabrication, as they allow energy transfer between vibration modes [2], thus improving sensitivity. Moreover, parametric resonances proved to "squeeze" mechanical and electrical noises [3], which contribute in improving the Angle Random Walk (ARW) and bias stability. Also by operating in the nonlinear regime, parametric excitations were found to provide much higher amplification, however, this was not adequately theoretically investigated till recently [4]. To this end, this work aims at extending the authors' investigation of the global effects induced by phase-shifted parametric excitations in linearly modeled micro-ring gyroscopes [5] to the nonlinear case.

Global effects

The previously mentioned global effects are discussed here for a linear system. In the current practice of parametric excitation mechanisms, instability or amplification were exhibited at the primary resonance frequency equal to double the natural frequency, i.e. $\Omega = 2\omega_i$, or at the countably infinite secondary frequencies $\frac{\omega_i \pm \omega_j}{n}$, where $i = 1, 2, j = 1, 2, n \in \mathbb{N}$. But by applying the theory of Cesari we could get an amplification and/or instability at every excitation frequency, hence, that is named as a "global" effect. One such consequence can be driving the system in a state of "total instability", i.e. at every frequency. Having said that, it may seem as bad news to engineering applications, however, for a system that behaves nonlinearly this could be translated to having higher amplitude, gain or amplification at a non-trivial stable stationary solution. This can be achieved by having phase-shifted off-diagonal time periodic functions in the parametric excitation matrix $C(t)$. This effect can be simply illustrated for a two DOF system

$$\ddot{\mathbf{q}} + (\mathbf{D} + \mathbf{G})\dot{\mathbf{q}} + (\mathbf{K} + \mathbf{C}(t))\mathbf{q} = \mathbf{0}, \quad (1)$$

where $\mathbf{D}, \mathbf{G}, \mathbf{K}$ and $\mathbf{C}(t)$ are the damping, gyroscopic, stiffness and parametric excitation matrices, respectively. The resulting phenomenon can be illustrated in Fig.1. The figure shows a global destabilization of the system in absence of other excitation mechanisms, explained by having a positive eigenvalue at all frequencies except for *anti-resonances*.

Modeling of the nonlinear micro ring gyroscope

As shown in Fig. 2, the micro ring gyroscope is modeled as an elastic inextensible ring totally surrounded by curved electrodes, each at an angle θ_k . The ring was found to exhibit two degenerate modes at the first vibration frequency, the antinodes for the first mode and second modes are at angles $\theta_k = (\frac{n\pi}{2}), (\frac{n\pi}{2} + \frac{\pi}{4})$ respectively. For modeling the ring's elastic dynamics we follow Natsiavas [7] by considering only flexural vibrations in thin rings. The elastic and electrostatic potential energy, U_d and U_e respectively, are then found to be

$$U_d = \frac{EI}{2R^3} \int_0^{2\pi} \left[u + \frac{\partial^2 u}{\partial \theta^2} + \frac{1}{2R} \left(\frac{\partial u}{\partial \theta} \right)^2 \right]^2 d\theta, \quad U_e \simeq \frac{-\epsilon_0 b R}{2d} \sum_{n=0}^4 \int_0^{2\pi} (V_{DC} + V_{AC})^2 \frac{u^n}{d^n} d\theta,$$

Figure 1: Global destabilization of a 2 DOF system

Figure 2: A sketch of the micro ring gyroscope

where R is the mean radius, u and v are the radial and circumferential displacements of a point on the centroidal axis respectively (s. Fig. 2), ϵ_0 is the electric constant, b, h are the ring's thickness and width respectively, d is the initial gap between each electrode and the ring's body, and V_{DC}, V_{AC} are the direct and alternating voltages respectively applied on the electrodes. On the other hand, the kinetic energy for the ring in a rotating frame will be

$$T = \frac{\rho b h}{2} \int_0^{2\pi} [u, v]^T \cdot [u, v]^T R d\theta.$$

Applying the *ansatz* proposed by Natsiavas but for only two vibration modes, $u(\theta, t) = A(t) \cos(2\theta) + B(t) \sin(2\theta) - \frac{9}{16R} [A^2(t) + B^2(t)]$, and considering the alternating voltage to be distributed approximately according to $V_{AC}(\theta, t) = V_{AC}(t) \cos(2\theta)$, we get two nonlinear ordinary differential equations in $A(t)$ and $B(t)$ representing the system dynamics for the drive (primary) and sense (secondary) modes respectively.

Normal form transformation

However, since the resulting equations of motions are highly nonlinear, an analytical method is required to develop a better understanding of the gyroscope's dynamics. Different perturbation methods are widely used to analyze those systems, but we prefer here to use the normal form method, since it proved to have comparatively better accuracy for highly nonlinear systems involving parametric excitation. An approximate analytical solution is therefore derived, through which the highest eigenvalue could be calculated in terms of system's and excitation parameters, this was used as an indication for system stability. This can be seen in Fig. 1, in which the normal form method was used to simulate the eigenvalues of the system in (1) for all but resonant frequencies, complying with the numerical results calculated by the Floquet method. Two main findings are specially important; firstly the system is destabilized for approximately the whole frequency spectrum, that is specially important in tuning the excitation frequency. Since this would overcome the problem of the loss of sensitivity by mistuning. And secondly, this can give a new method of controlling the gyroscope's response through frequency control. This method will then be applied on the already derived equations of motion, and thereby the effect of the parametric excitation on the nonlinear micro gyroscope will be illustrated, in a similar way to what is explained for the linear system in (1).

Conclusions

This work contributes to understanding the observed nonlinear behavior of the micro-ring gyroscopes, since its nonlinear model was not sufficiently discussed in the literature [4]. Moreover, we propose a novel excitation method in the field of micro sensors, which offers an unprecedented flexibility in tuning as well as amplifying the micro ring gyroscope. This is believed to contribute to the development of current MEMS gyroscopes towards achieving an inertial grade accuracy.

Chaos in a non-linear non-buckled microresonator

Martial Defoort, Libor Rufer and Skandar Basrour

Univ. Grenoble Alpes, CNRS, Grenoble INP, TIMA, Grenoble 38000 France

Summary. Chaos is a phenomenon describing the complex dynamics of many systems, from the evolution of the weather to the dynamics of cosmic entities. Since a few decades, generating chaos from a physical system has triggered a lot of research, especially in the optical domain. In the mechanical domain, chaos generation has been investigated mainly with buckled structures. These bistable systems enter in a chaotic regime upon the application of a strong enough alternative force. However, in the micromechanical domain, buckling a structure is demanding and typically requires a large voltage, incompatible with available technology. In this paper, we describe a new way of generating chaos from a Micro Electro-Mechanical System (MEMS) using the dynamical bistability of a nonlinear system, activated by a modulated signal within the resonance of the system. We measured the generated chaos experimentally with a microresonator, and characterized it with Poincaré sections and Lyapunov exponent measurements. In our case, the chaos generation does not need any specific requirement, and it is readily applicable in many structures, opening a new path for MEMS-based chaos generators.

Introduction

For half-a-century, chaos has triggered a lot of research around the world, both for fundamental and applied research. Chaos is characterized mainly by a non-periodic regime whose evolution is extremely sensitive to initial conditions. However, it is a deterministic system: an absolute knowledge of these initial conditions would enable to fully describe the system evolution, without the need to introduce any form of randomness. In practice, the knowledge of the initial conditions is limited by the precision of the measurement, such that the long-term prediction of the evolution of a chaotic system diverges, giving the illusion of a random system. This property is at the core of many researches, such as fluid mixing [1] or noiseless sensing [2].

Since the discovery of chaos synchronization [3], a tremendous amount of work has been dedicated to physical chaos generation, using either electronic [4] or optical [5] approaches. However, in the mechanical domain, chaos generation has mainly been limited to theoretical studies [6]–[8] since its experimental implementation is usually too complex, especially in micromechanical systems. Indeed, a common way to generate chaos consists in the realization of a bistable system, which is usually obtained by buckling the structure. However, the force required to perform the necessary buckling is typically generated through an electrostatic coupling, with an applied voltage ranging from a few tens to hundreds of volts [9], [10]. In this paper, we present an original way of generating chaos with a nonlinear non-buckled MEMS structure, requiring low voltages.

Methodology and results

We performed our experiment using a thin disk of radius of 400 μm and thickness of 10 μm . Using a piezoelectric transduction, the device is driven by applying a voltage between the bottom and the outer top electrode, and the mechanical displacement is then measured through the inner top electrode (Fig. 1 a). For small displacements, the device being in a linear regime, the amplitude varies proportionally with the driving force. The structure has a resonant frequency of 71.5 kHz and a quality factor of 1100 at low pressure (≈ 1 mbar). By increasing the driving force beyond the regime of small displacements, the MEMS will gradually enter in a nonlinear regime, mainly due to a cubic nonlinearity known as the Duffing nonlinearity. In this regime, for a positive nonlinearity, the shape of the resonance line bends towards higher frequencies, creating a hysteresis. In this frame, the resonator experiences a dynamical bistable regime similar to the one induced by buckling (Fig. 1 b).

Figure 1: Dynamically bistable chaos. **a)** The microphotograph of the MEMS showing the outer and inner electrodes (the common bottom electrode covers the opposite side). **b)** At low amplitudes (grey), the MEMS response is linear, but as the drive amplitude increases, its resonance bends to form a hysteresis (black) with two available states (low and high amplitude) for a large frequency range. **c)** Applying a modulation on the driving signal, the system switches between the two states, and at a high enough modulation frequency the system's response displays a chaotic pattern. Grey dashed lines highlight the periodicity of the applied modulation, demonstrating no correlated periodicity in the output signal.

By driving the structure with an amplitude-modulated signal within its hysteresis, the system switches from one to the other state, namely high and low amplitude, and at a sufficiently high modulation frequency this switching becomes

erratic and the MEMS response exhibits a chaotic signal (Fig. 1 c). In our case, we used a modulation frequency of three times the bandwidth of the system, corresponding to 195 Hz.

Because of both non-periodic and non-reproducible features, specific tools are used to study the chaotic regime. In order to characterize the complexity of a chaotic regime, a common approach consists in a stroboscopic analysis of the generated signal, called the Poincaré section. This is performed by sampling a temporal signal at regular intervals defined by the modulation frequency (grey dashed lines in Fig. 1 c) and plotting the results in the phase space (Fig. 2 a). The generated Poincaré section presents the structure of the non-periodic chaos, extracting order from the apparent noise of the signal. Although a chaotic signal is unique, its Poincaré section represents a reproducible signature testifying the complexity of the generated chaos.

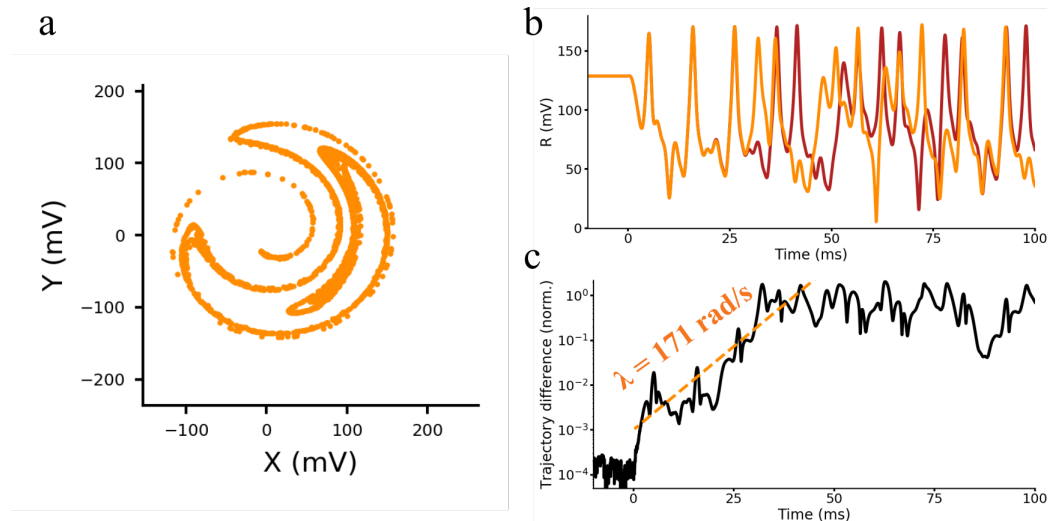

Figure 2: Poincaré section and Lyapunov exponent measurement. The chaotic signals are generated at a modulation frequency of 195 Hz with a driving voltage of 1 V. **a)** By sampling the chaotic signal every 1/195 second, a specific signature emerges from the chaos, forming a Poincaré section. **b)** In the chaotic regime, two measurements (orange and red) with extremely close initial conditions will tend to diverge in the chaotic regime (starting at the time $t = 0$). **c)** From the difference between the two trajectories, the Lyapunov exponent is extracted using an exponential fit.

Another interesting property of chaos lies in how sensitive to the initial conditions the system is. This property is characterized by the Lyapunov exponent, which describes how two initially close trajectories of the same system converge or diverge after some time. For a positive Lyapunov exponent, the trajectories diverge, which is the main property of chaotic systems, and its absolute value characterizes how fast the divergence is: it describes the memory of the system. The precision with which the Lyapunov exponent can be experimentally measured directly depends on how precisely the system can be set at similar initial conditions, ultimately limited by the noise of the system. In our case we were able to get initial conditions as close as 100 ppm, enabling to fit correctly the Lyapunov exponent, which we find to be 171 rad/s for our system (Fig. 2 b, c).

Conclusion

We demonstrated a new technique for MEMS-based chaos generation, using the dynamical bistability of the nonlinear system combined with an amplitude modulated driving force. We characterized the generated chaos with Poincaré sections and Lyapunov exponent measurements, giving information about the complexity and the memory of the system, essential to understand the behavior of the chaotic system.

Summary. In this paper the nonlinear free vibrations of a hanging cable are investigated. The analysis is carried out by applying the method of multiple scales directly on the planar equations of motion for a cable with arbitrary sag and inclination. The only simplification used is that the static strain is small. The methodology allows to obtain results regarding the corrections in modal shape and variations of frequency as function of the initial amplitude. The obtained results show that the hard/softening behaviour that this kind of structure can undergo is in qualitative agreement with previous works.

Introduction

The use of hanging cables as structural elements is commonly found in several engineering application. This type of use can be found in transmission lines, bridges, offshore oil exploration activities, among others. These structures exhibit a rich dynamics, being under extensive efforts in research practice. In order to better understand the dynamic behaviour of these structures, the study of the free vibrations is a problem of interest. This study provides the behaviour of the natural frequencies and modes depending on the structural properties, both from linear and nonlinear perspectives.

The linear modes for a horizontal hanging cable with small sag were deeply investigated in [1], making an analytical study regarding modal properties and the cross-over phenomenon. Following, in [2], the linear modal properties are obtained for inclined taut strings. The results show the mode hybridization and the veering phenomenon that occurs in the inclined configuration. In [3], the linear modes for an arbitrarily sagged inclined cable are obtained. The latter considers an inextensible cable causing modal hybridization to be missed, which can be an important drawback in some problems.

In [4] nonlinear modes are obtained for a vertical beam under tension, with the vertical cable as a particular case. The nonlinear modal properties of a horizontal cable are investigated in [5], using the method of multiple scales (MMS) on a discrete model obtained with the Galerkin method. In [6], the nonlinear modes for an inclined cable with small sag are obtained directly from the partial differential equations (PDEs), disregarding the axial dynamics.

To the best of the authors' knowledge, the investigation of the nonlinear free vibrations of an arbitrary inclined sagged cable with a direct analytical approach on the PDEs is not reported in the literature. One important motivation for this kind of investigation can be found in [7], where it is stated and shown with examples that model discretization using the Galerkin method may furnish wrong qualitative behaviour for the system under study due to obtaining the wrong sign in some coefficients. The major contribution of the present work is then the investigation of nonlinear free vibrations of hanging cables with arbitrary sag and inclination using the MMS directly applied to the PDEs.

Mathematical model

The model herein considered is that of a hanging elastic cable, immersed in fluid, with axial stiffness EA , immersed weight γ_s and axial and transversal masses per unit length m and m_t respectively. The difference between directions is kept in order to allow to include added mass effects. The cable is hanging between two fixed supports with an horizontal distance d and a vertical distance h . It is also considered that the tension $T_e(s)$ and the angle with the horizontal direction $\theta(s)$ in the static configuration are known, with s being the arclength in the static configuration. Being u and v the axial and transversal displacements with respect to the static configuration, the equations of motion obtained from the balance laws for a cable element (see [8] for example) are given as:

$$T'_e(\cos \gamma - 1) - T_e(\theta' + \gamma') \sin \gamma + T'_d \cos \gamma - T_d(\theta' + \gamma') \sin \gamma = m\ddot{u} \quad (1)$$

$$T'_e \sin \gamma - T_e \theta' + T_e(\theta' + \gamma') \cos \gamma + T'_d \sin \gamma + T_d(\theta' + \gamma') \cos \gamma = m_t \ddot{v} \quad (2)$$

In the equations the static equilibrium is already substituted. T_d stands for the dynamic tension variation, γ is the dynamic variation of θ , u is the displacement in the tangential direction and v is the displacement in the transversal direction. Primes denote differentiation with respect to s while dots represent differentiation with respect to time. Now, the hypothesis of small static strain is used, which allows to write for the strain $\varepsilon = \varepsilon_s + \varepsilon_d$, with the subscripts denoting the static and dynamic parts. With that, it is possible to simply write $T_d = EA\varepsilon_d$. Finally, from differential geometry, the compatibility conditions are obtained, namely $\sin \gamma = (u\theta' + v') / (1 + \varepsilon_d)$, $\cos \gamma = (1 + u' - v'\theta') / (1 + \varepsilon_d)$ and

$\varepsilon_d = \sqrt{1 + 2(u' - v'\theta' + uv'\theta' - u'v\theta' + (u'^2 + v'^2 + (u\theta')^2 + (v\theta')^2)/2)} - 1$. The MMS is then applied considering three terms in the expansion for u and v , alongside with three time scales. The development is not reported for the sake of the size of the extended abstract.

Application example

In order to show the functionality of the methodology, some backbone curves for three different cables are obtained. The data for the material properties are obtained from a typical steel catenary riser. The common properties for the three cases are $EA = 2314\text{MN}$, $m = 108\text{kg/m}$, $m_t = 141.24\text{kg/m}$, $\gamma_s = 727\text{N/m}$ and structural diameter $D = 0.2032\text{m}$. For the horizontal cable, $d = 1500\text{m}$ and $h = 0\text{m}$. For the almost vertical cable, $d = 1\text{m}$ and $h = 1800\text{m}$. Finally for the inclined cable, $d = 1500\text{m}$ and $h = 1800\text{m}$. In all the cases the natural length of the cable was taken as the one obtained from an inextensible catenary configuration. The horizontal component of the tension is $T_h = 680550\text{N}$ for the horizontal and the inclined cable, while is taken as 680N for the vertical one. The backbone curves showing the vibration frequency ω with respect to the natural linear frequency ω_0 as a function of the amplitude A_0 are presented in Fig. 1. It is possible to see

Figure 1: (a) Backbone curves for three modes of the inclined cable; (b) Backbone curves for two modes of the almost vertical cable; (c) Backbone curves for one mode of the horizontal cable. Motion amplitude made dimensionless by the structural diameter.

that both hardening and softening behaviours are obtained, as well as the more intense hardening when going from the chosen inclined model to the almost vertical one. Further examples and analysis of the results are left to the full paper. For the sake of comparison of the qualitative behaviour, the softening behaviour for the horizontal configuration is obtained in [5] while the terms of the fourth order in the expansion are not noticeable. The almost vertical configuration can be compared to the results in [6]. Finally, examples of hardening in inclined cables can be seen in [9].

Conclusions

From the nonlinear equations of motion for a hanging cable, with the small static strain as only simplification hypothesis, nonlinear solutions for the free vibrations were obtained with the method of multiple scales applied directly to the PDEs of motion. The results presented show that the methodology is capable of reproducing some known qualitative results for the dependency of the frequency of vibration with the amplitude of vibration. Further results and comparisons are planned for the full paper and the presentation.

^{**}Institute of Mechanics, Bulgarian Academy of Sciences, Sofia, Bulgaria

Summary. In the present work a thermo-elastic model of a circular plate is analyzed. Nonlinear oscillations of a heated plate subjected to dynamic loading are studied. A model of the plate is based on the geometrically nonlinear Mindlin plate theory. Two different approaches are used to study the problem: a pure numerical study by the finite element method (FEM) and an analytical study based on the harmonic balance method applied to the reduced model taking into account the first vibration mode. The influence of the loading and the elevated temperature on dynamic behaviour is studied for buckling and post buckling states.

Introduction

The plates are used in many technological areas. Being fundamental structural elements often the plates are subjected to mechanical and thermal loadings which lead to intensive large amplitude vibrations. The temperature can change the reaction of mechanical structures and in some cases, close to critical points, even a small temperature variation may give unexpected change in the system response. The case when the studied problem of thermally induced vibrations or vibrations produced by coupled mechanical and thermal loads is nonlinear its detailed investigation is specially important. Detailed analysis of local and global nonlinear dynamics of plates for various thermal and mechanical loads are conducted in [1,2].

In this work we analyze the effect of thermal loading on the nonlinear vibrations of a circular plate according to the extended Mindlin plate theory taking into account the geometrically nonlinearities due to the large displacements. FEM is used to study the response of the plate in the time domain. A reduced model based on the Galerkin orthogonalization method is the second approach to study the problem. By harmonic balance method the response of the plate is studied in the frequency domain. The resonance curves are determined from the analytically obtained modulation equations. Stability of the solution is studied in details.

Physical method

A circular plate with radius R and thickness h vibrating asymmetrically due to a harmonic mechanical loading is taken into consideration. It is accepted that the plate gets an elevated temperature instantly and the temperature is distributed uniformly along the plate surface and thickness. Based on extended Mindlin plate theory, and accepting that the inertia term in mid-plane can be neglected, the equations of the plate vibration are:

$$\begin{aligned} Ah \left[\frac{\partial^2 u}{\partial r^2} + \frac{\partial w}{\partial r} \frac{\partial^2 w}{\partial r^2} + \frac{1}{r} \frac{\partial u}{\partial r} - \frac{u}{r^2} + \frac{1}{2r} (1-\nu) \left(\frac{\partial w}{\partial r} \right)^2 \right] &= 0 \\ D \left[\frac{\partial^2 \psi}{\partial r^2} + \frac{1}{r} \frac{\partial \psi}{\partial r} - \frac{\psi}{r^2} \right] - k^2 Gh \left(\frac{\partial w}{\partial r} + \psi \right) - c_2 \frac{\partial \psi}{\partial t} - \frac{\rho h^3}{12} \frac{\partial^2 \psi}{\partial t^2} &= 0 \\ k^2 Gh \left(\frac{\partial^2 w}{\partial r^2} + \frac{1}{r} \frac{\partial w}{\partial r} + \frac{\partial \psi}{\partial r} + \frac{\psi}{r} \right) + Ah \left[\frac{\partial u}{\partial r} + \frac{1}{2} \left(\frac{\partial w}{\partial r} \right)^2 + \frac{\nu}{r} u - \frac{1+\nu}{h} \alpha_T \Delta T \right] \left(\frac{\partial^2 w}{\partial r^2} + \frac{1}{r} \frac{\partial w}{\partial r} \right) + \\ Ah \left[\frac{\partial^2 u}{\partial r^2} + \frac{\nu}{r} \frac{\partial u}{\partial r} - \frac{\nu}{r^2} u + \frac{\partial w}{\partial r} \frac{\partial^2 w}{\partial r^2} \right] \cdot \left(\frac{\partial w}{\partial r} \right) + c_1 \frac{\partial w}{\partial t} - \rho h \frac{\partial^2 w}{\partial t^2} &= -p(r, t) \end{aligned}$$

Where u and w are in-plane and transversal displacements, ψ is the angular rotation, c_1 and c_2 are damping coefficients, ρ is the density, ν is Poisson's ratio, E is the Young modulus, T is the temperature and

$$A = \frac{E}{1-\nu^2}, D = Ah^3/12$$

The boundary conditions for a clamped, in-plane fixed plate are:

$$u(0, t) = u(R, t) = w(R, t) = 0, \psi(R, t) = 0$$

The model of the plate represented by PDE is reduced to the ODE by the Galerkin method based on the modes projection and taking into account excitation, distributed according to the first mode shape. For the first mode reduction we obtain just one nonlinear differential equation:

$$\ddot{q}_1 + 2\xi_1 \omega_1 \dot{q}_1 + \omega_1^2 q_1 + F_{NL1} q_1^3 + F_{NT1} \Delta T q_1 = F_{NP1} \sin \omega t$$

Here F_{NL1} , F_{NT1} and F_{NP1} are constants obtained numerically, ω_1 is the first natural frequency and ξ_1 is a damping coefficient. Applying harmonic balance method, after some algebraic manipulations we obtained a cubic algebraic equation:

$$\begin{aligned} -16P^2 + 9z^3\gamma^2 + z^2(24\lambda T\gamma + 24\alpha\gamma - 24\gamma\omega^2) + z(16\lambda^2 T^2 + 32\lambda T\alpha + 16\alpha^2 \\ - 32\lambda T\omega^2 - 32\alpha\omega^2 + 16\beta^2\omega^2 + 16\omega^4) = 0 \end{aligned}$$

which is solved analytically.

FEM and numerical results

Using the FE program ANSYS Mechanical APDL the plate is discretized by a quad mapped mesh with 2700 elements and 2884 nodes. Four nodes finite element SHELL 181 is used. The response of the plate is studied for different values of the loading, excitation frequencies and different temperatures. Generally, the elevated temperatures lead to enlarging of the amplitude of vibrations. At Fig. 1 we show time history diagrams of response of the plate centre for 4 different temperatures. It is clear seen that at $\Delta T=30$ and $\Delta T=40$ the plate buckles and continues to vibrate around a new equilibrium state.

Fig. 1: Time history diagrams of the plate centre of the plate subjected to harmonic loading with $p=1500 \text{ N/m}^2$ and $\omega_e=312.5 \text{ Hz}$. Black colour – $\Delta T=10$; Blue colour – $\Delta T=20$; Purple colour – $\Delta T=30$, Red colour – $\Delta T=40$.

Fig. 2: Resonance curves by HBM for $\Delta T=20$ (black), $\Delta T=30$ (red) and $\Delta T=40$ (blue).

HBM solution

The algebraic equation obtained by HBM is solved for different values of the loading parameters and the temperature. An example for such solutions are the resonance curves shown in Fig. 2. The hardening behaviour of the resonance curves are clearly expressed due to the large deflections. The elevated temperature increases the amplitudes and changes the resonance curve in the direction of lower frequencies. It is seen that multiple and unstable solutions can occur.

Conclusions

Geometrically nonlinear thermo-elastic vibration of a Mindlin circular plate is studied by two different methods. In the first approach by FEM is demonstrated that the elevated temperature can change dramatically the response of the plate and could provoke the plate to complex response, including buckling and bifurcations. The second approach allows to obtain easily the resonance curves and to study the influence of the loading parameters and the elevated temperature on the behaviour of the plate. The computations based on the first mode reduction show the stiffening effect of the resonance curve.

Summary. Curvilinear reinforcement fibres can, within limits, be used to tailor the stiffness of composite laminated plates so that they have specific dynamic properties. The dynamic response of a plate to external forces is strongly affected both by boundary conditions and by the stiffness of the plate near the boundaries. Using a combination of experimental and numerical analyses, this work intends to analyse how the stiffness of the boundaries and the stiffness of tow placed composite plates near the boundaries interact to influence the geometrically non-linear response to harmonic external forces.

Introduction

The application of curvilinear reinforcement fibres in laminated composite plates leads to a variation of the stiffness within the plate domain, allowing designers to tailor the plate so that it meets specific demands more efficiently. Hence, there has been a considerable amount of research on this type of laminated plates [1]. The stiffness of the plate near the boundaries and its relation with the boundary conditions themselves have a major influence on the dynamic response. Classical boundary conditions, i.e., combinations of free, hinged or clamped edges, are typically considered by researchers. However, in practice it is not possible to exactly implement classical boundary conditions, with the clamped edge case particularly difficult to approach [2]. A more realistic representation of “real clamps” is achieved by considering elastically restrained edges [3].

This work intends to analyse how the non-linear response is affected by changes of the fibre path near the plate’s edges, when the latter are elastically restrained. For that purpose, a physical/mathematical model, which considers that the edges are supported on translational and rotational springs, is developed. The values of the stiffness of the boundary springs are adjusted so that the theoretical linear modes of vibration approach experimentally identified ones [4].

Mathematical model

An equivalent single-layer type formulation, based on Kirchhoff’s hypothesis, but accounting for geometrical non-linear terms in the Von Kármán sense, is adopted. Components u , v and w (respectively in directions x , y and z) of the middle-plane displacements are written as series with products of shape functions by generalized coordinates and the principle of virtual work is applied. Apart from new stiffness terms due to the elastically restrained edges, the equations of motion are similar to the ones given in [5].

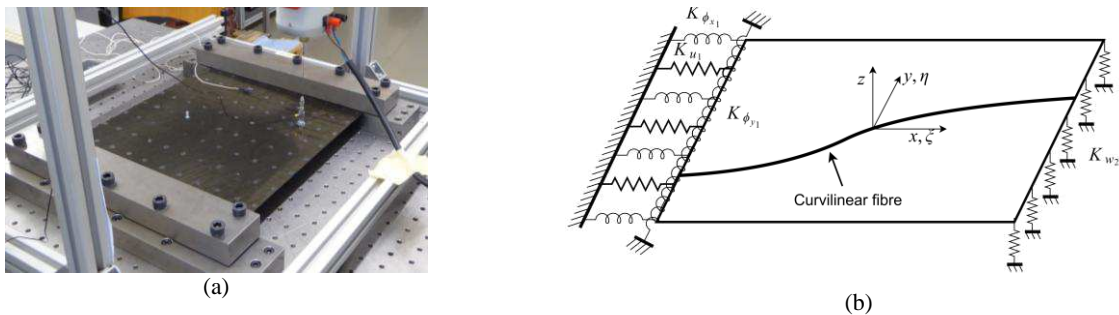

Figure 1: Experimental set-up (a) and schematic representation of a plate supported by distributed springs (b); only some springs are depicted.

In the laboratory, the plate is fixed only on two opposite edges using stiff steel blocks, as shown in Figure 1 (a). The corresponding model with translational and torsional distributed springs is shown in Figure 1 (b), where some distributed springs are drawn on the left-hand side and one on the right-hand side, for the sake of clarity. K_{u_i} and K_{w_i} represent the values of the stiffness per unit length of translational springs along the x and z axes, respectively; $K_{\phi_{x_i}}$ and $K_{\phi_{y_i}}$ represent the torsional stiffness per unit length of springs that rotate, respectively, about the x and the y axes. Index i is equal to 1 if $\xi=-1$ and equal to 2 if $\xi=1$. Displacement at the boundaries is small, so it is still reasonable to assume that these stiffness coefficients are constant, even though this work is in the geometrically non-linear regime.

The virtual works done by the distributed forces and moments due to the various boundary springs are

$$\delta W_{K_u} = -\int_{-1}^1 K_{u_1} u(-1, \eta, t) \delta u(-1, \eta) \frac{b}{2} d\eta - \int_{-1}^1 K_{u_2} u(1, \eta, t) \delta u(1, \eta) \frac{b}{2} d\eta \quad (1)$$

$$\delta W_{K_w} = -\int_{-1}^1 K_{w_1} w(-1, \eta, t) \delta w(-1, \eta) \frac{b}{2} d\eta - \int_{-1}^1 K_{w_2} w(1, \eta, t) \delta w(1, \eta) \frac{b}{2} d\eta \quad (2)$$

¹ Now at Vestas Design Centre Porto, Portugal

$$\delta W_{K_{\phi_1}} = - \int_{-1}^1 K_{\phi_1} w_{,x}(-1, \eta, t) \delta w_{,x}(-1, \eta) \frac{b}{2} d\eta - \int_{-1}^1 K_{\phi_2} w_{,x}(1, \eta, t) \delta w_{,x}(1, \eta) \frac{b}{2} d\eta \quad (3)$$

$$\delta W_{K_{\phi_2}} = - \int_{-1}^1 K_{\phi_1} w_{,y}(-1, \eta, t) \delta w_{,y}(-1, \eta) \frac{b}{2} d\eta - \int_{-1}^1 K_{\phi_2} w_{,y}(1, \eta, t) \delta w_{,y}(1, \eta) \frac{b}{2} d\eta \quad (4)$$

The ordinary differential equations of motion are obtained by applying the principle of virtual work and have the following form [5]

$$\mathbf{M} \ddot{\mathbf{q}}_w(t) + \mathbf{C} \dot{\mathbf{q}}_w(t) + \mathbf{K} \mathbf{q}_w(t) + \mathbf{K}_{nl}(\mathbf{q}_w(t)) \mathbf{q}_w(t) = \mathbf{p}_w(t) \quad (5)$$
