where \mathbf{M} is the mass matrix, \mathbf{C} a matrix due to viscous damping, \mathbf{K} a constant stiffness matrix and $\mathbf{K}_{nl}(\mathbf{q}_w(t))$ a stiffness matrix that represents non-linear effects. Most of the terms due to the elastic supports are explicitly given in [4], they alter stiffness matrix \mathbf{K} ; the remaining matrices are given in [5]. Vector $\mathbf{q}_w(t)$ contains the transverse generalised coordinates; $\mathbf{p}_w(t)$ is the vector of generalised transverse external forces. Although we are accounting for in-plane displacements at the boundaries, these are still extremely small and so is the in-plane inertia. Hence, the latter is neglected and, consequently, the non-linearities of the set of equations of motion (5) are of the cubic type.

Sample results and closure

Several frequency response functions were measured (Figure 2) and employed to obtain natural modes of vibration in the linear regime [4]. With this data, the stiffnesses of the boundary springs were adjusted, resulting in models that provide modal data that is reasonably similar to the experimentally obtained results [4]. As an example, Table 1 shows that the linear natural frequencies of vibration computed by the model with elastic supports ($\omega_i^{Springs}$) are much closer to the experimental ones ($\omega_i^{experimental}$) than the frequencies computed using a model that adopts theoretical, exact, clamped boundary conditions (ω_i^{CFCF}).

Figure 2: Frequency response functions from measurements on the plate represented on Figure 1 (a).

Table 1. Experimental and theoretical natural frequencies (in Hz).

Mode number	1	2	3	4	5	6	7
$\omega_i^{experimental}$	95.13	117.6	165.0	258.0	275.8	307.3	361.6
$\omega_i^{Springs}$	97.35	116.1	175.7	277.5	286.3	321.6	405.4
ω_i^{CFCF}	136.7	153.1	211.7	315.7	379.9	403.0	486.1

Harmonic excitations are applied and the non-linear response is computed using the harmonic balance and continuation methods [5]. Simulations are carried out for diverse fibre paths. The dynamic response is analysed, with particular attention paid to the combined influence of the elasticity of the supports and of the plate's stiffness near the boundaries.

The Effects of Screen Curvature On The Transient Dynamics Of Automotive Windscreen Wipers

Bradley Graham*, James Knowles* and Georgios Mavros*

**Aeronautical & Automotive Engineering Department Loughborough University, UK*

Summary. In this paper we study the effects of automotive windscreen curvature on the transient dynamics of a wiper blade. To do this we utilise a finite element (FE) model to obtain contact force distributions for multiple screen curvatures in a single axis. The distributions obtained are directly integrated into a multiple connected mass-spring-damper (MSD) system to analyse the transient dynamics.

Introduction

The primary function of windscreen wipers is to remove water and debris from the windscreen, ensuring the driver has a clear view of the road ahead. The successful operation of windscreen wipers is therefore imperative for the vehicle occupants' safety. Predicting wiper performance at the design stage is important to ensure their safe operation: whilst the purpose of windscreen wipers is simple, the non-linear contact and sliding mechanisms which govern the operation are complex. Because of these complexities, a lot of preliminary design decisions are based on empirical data rather than predictive models. This can present constraints of unknown necessity on other aspects of a vehicle's design (e.g. windscreen curvature). There is hence a need to develop physics-based models of wiper performance that can be used as evaluative tools early in the design stage.

Approach

This work presents an analysis of the impact that the contact distribution has on the transient dynamics of a windscreen wiper blade. We consider the curvature of the screen in a single axis, the y axis. For the purpose of our model we maintain the geometry of the wiper blade used in the FE model. Initially we take a commercially available screen, of curvature G for analysis. We subsequently establish a mathematical expression of the screen to adjust the curvature to $\frac{1}{3}G$ and $\frac{5}{3}G$. We utilise multiple connected mass spring damper systems to represent the full length of the blade, and to allow for direct integration of the distributions computed via a finite element (FE) model. A continuously differentiable Stribeck curve[1] which features six constants is used to capture the transient friction characteristics of the blade. The Stribeck curve is modified to agree with a recognised range of friction coefficients, $0.1 - 0.6$, associated to wet friction[2]. Additionally, we use experimental values for both the stiffness, K , and damping, C , which were presented by Shigeki Okura and Tohru Sekiguchi[3]. For our study we consider a discretisation that corresponds to a real-life discretisation distance of $2mm$ on a $600mm$ wiper blade, providing much greater resolution than currently offered by experimental measures.

Figure 1: Fourier Decomposition of Transient Dynamics Associated to Nominal Screen Curvature G and $\frac{1}{3}G$

Figure 1 shows the Fourier decomposition of the transient dynamics data for a nominal curvature, G and $\frac{1}{3}G$. In the nominal case, we find a peak in the amplitude of frequency at $30Hz$. Additionally, there are a number of underlying beats with a greater frequency than the peak, but significantly lower amplitude. When considering the a reduced curvature case, we find that the peak frequency remains constant at $30Hz$, but has a much greater amplitude. The underlying beats that were visible in the nominal case are also present in the reduced curvature case. As with the peak frequency, the amplitude of the beat frequencies also increase. However, the increase in amplitude, decreases as we consider higher frequencies. Additionally we find that a uniform distribution does not yield a more desirable dynamic response than the current contact distributions that feature on flat style wiper blades, but in fact a screen of greater curvature can yield reduced amplitudes of the frequencies observed. Throughout our study we observe a dominant peak frequency, $30Hz$, such a frequency is associated to a chatter response of wiper blades[4].

Conclusions

The non-linear complexities and current reliance on empirical data associated to windscreen wipers necessitate the development of models and analyses such as presented above. The work presented shows how small design decisions such as the curvature of a windscreen, can dramatically affect wiper system performance, and shows how some small design changes can aid in the functional operation of windscreen wipers. These results show the importance of understanding the effects that screen curvature has on not only the transient dynamics but also the frequency response of the blade, providing insight into improving wiper quality.

Using Spectral Submanifolds for Forced Response Prediction in Nonlinear Finite Element Models: Direct and Nonintrusive methods

Shobhit Jain*, Mattia Cenedese* and George Haller*
**Institute for Mechanical Systems, ETH Zürich, Switzerland*

Summary. Finite element models of realistic nonlinear structures are characterized by very high dimensionality that renders simulations of the full system infeasible. Exact model reduction aims to achieve a drastic reduction of the full system's variables in a mathematically justifiable fashion. Specifically, Spectral Submanifolds have recently been shown to result in exact reduced-order models for periodically and quasiperiodically forced, nonlinear mechanical systems. In this work, we demonstrate recent advances towards the computation of SSMs that enable the treatment of realistic finite-element models using direct as well as non-intrusive/data-driven methods.

Background

The prediction of a steady-state response to an externally applied dynamic load is of special significance in engineering applications. Mechanical structures are usually characterized by light damping which results in exceedingly long integration times before a steady state is reached. Despite the broad availability of dedicated software packages [2, 3], the computation and continuation of the steady-state in response to periodic forcing remains a serious computational challenge for full-scale nonlinear finite element models.

Direct computation of SSMs

We consider finite-element discretized system of second-order ordinary differential equations for the generalized displacement $\mathbf{x}(t) \in \mathbb{R}^n$ given as

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} + \mathbf{f}(\mathbf{x}, \dot{\mathbf{x}}) = \epsilon \mathbf{f}^{\text{ext}}(\Omega t), \quad (1)$$

where $\mathbf{M}, \mathbf{C}, \mathbf{K} \in \mathbb{R}^{n \times n}$ are the mass, stiffness and damping matrices; $\mathbf{f}(\mathbf{x}, \dot{\mathbf{x}}) \in \mathbb{R}^n$ is the purely nonlinear internal force; $\mathbf{f}^{\text{ext}}(\Omega t) \in \mathbb{R}^n$ denotes the external forcing, which is periodic in t with frequency Ω ; and $0 < \epsilon \ll 1$ is a scalar forcing amplitude parameter.

The recent theory of Spectral Submanifolds (SSM) [1] has laid the foundation for a rigorous model reduction of such nonlinear systems, leading to reliable steady-state response predictions within feasible computation times. Further developments [4] have enabled the computation of SSMs and their reduced dynamics by solving the associated invariance equations directly in physical coordinates using only the eigenvectors associated to the master modal subspace. The software implementation of the method has been available in an open-source package, *SSMTool* [5], making direct SSM computations scalable to realistic, nonlinear finite-element models.

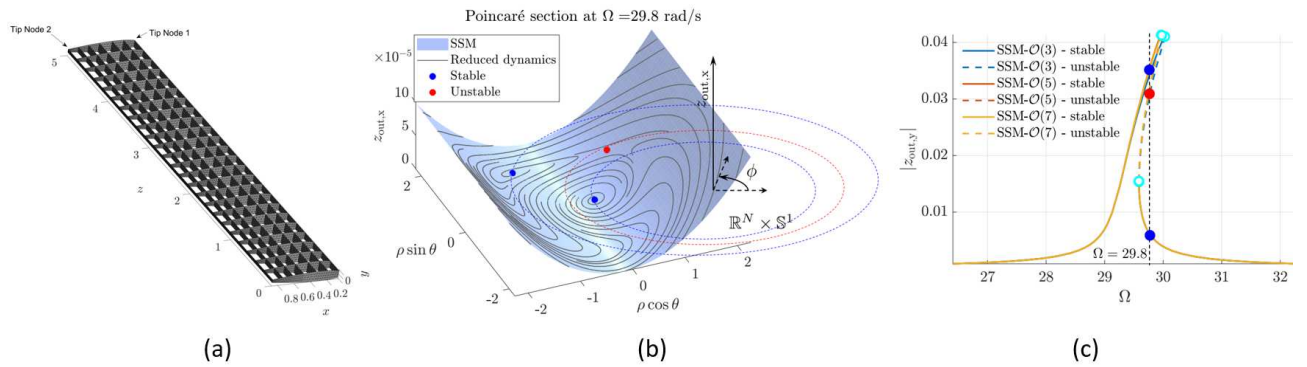

Figure 1: (a) The finite-element mesh of a geometrically nonlinear aircraft wing (illustrated after removing the skin panels) with $n = 133,290$ degrees of freedom. The wing is cantilevered at the $z = 0$ plane (see ref. [6] for model details.) (b) Poincaré section of the non-autonomous SSM computed around the first mode for the near-resonant forcing frequency $\Omega = 29.8$ rad/s. (c) Forced response curves obtained using local SSM computations at $\mathcal{O}(3)$, $\mathcal{O}(5)$ and $\mathcal{O}(7)$ that converge towards a hardening response. (see ref. [4] for computational details.)

In this contribution, we demonstrate applications of SSMs towards the extraction of *forced response curves* (FRC) directly from finite element models. For instance, Figure 1a shows the finite element mesh of a geometrically nonlinear aircraft wing structure containing 133,920 degrees of freedom. We extract the forced response of this model around its first natural frequency by analyzing the reduced dynamics on the two-dimensional SSM associated to the first mode, as shown in Figure 1b. The hyperbolic fixed points of the reduced dynamics on this SSM in polar-coordinates (ρ, θ) directly provide us the stable (blue) and unstable (red) periodic orbits on the FRC for different values of forcing frequency Ω (see Figure 1c.) We refer to ref. [4] for further details.

Nonintrusive computation of SSMs

As commercial finite element software seldom provide intrusive access to the nonlinearity \mathbf{f} of system (1), the direct SSM computation procedure discussed above has limited applicability for the users of commercial codes. At the same time, however, recent advances [7, 8] towards data-driven computation of SSMs and their reduced dynamics have paved the way for nonintrusive applications of SSM theory.

To this end, we construct data-driven, nonlinear reduced-order models on SSMs using the open-source package `SSMLearn` [9]. We base this construction on unforced decaying trajectory data obtained from black-box finite-element simulations. We also take advantage of the knowledge of the master modes associated to the underlying SSM, which is readily available from commercial finite element software and aids computations. Thanks to the rigorous theory backing SSMs, our reduced-order models, which are trained on a minimal number of *unforced* simulation trajectories, are capable of accurately predicting the forced response of the full nonlinear mechanical systems.

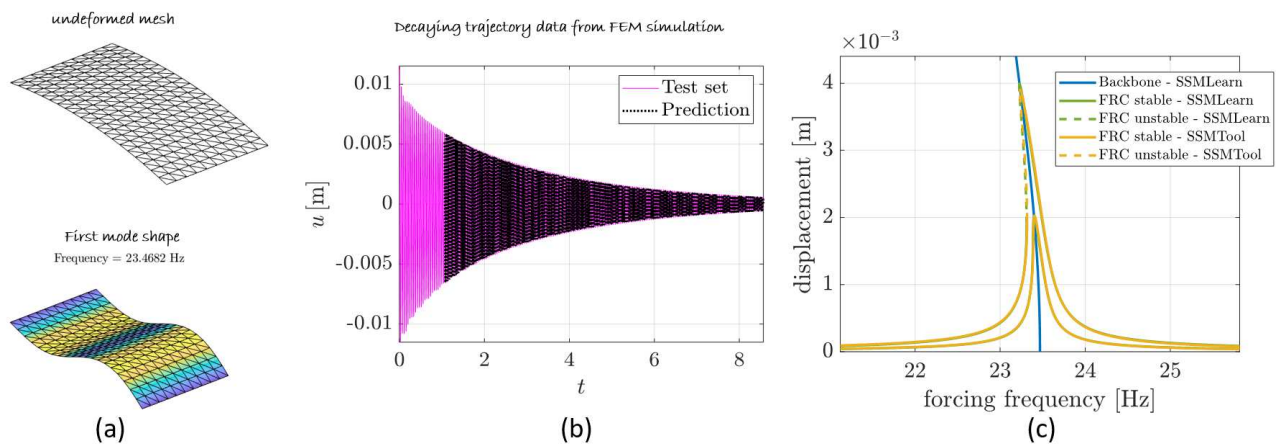

Figure 2: (a) The finite element mesh and the first mode shape of a shallow curved rectangular arch which is simply-supported on opposite ends. (b) Decaying trajectory data of the unforced system (c) Forced response predictions obtain from the data-driven reduced-order model trained on unforced trajectory data via `SSMLearn` agree with the analytic predictions based on direct SSM computations via `SSMTool`.

As an illustration, we consider a finite element model of a geometrically nonlinear shell structure [4] with 1,320 degrees of freedom, as shown in Figure 2b. Assuming linear viscous damping, we simulate two trajectories decaying from initial deflections given to the structure in the shape of the first vibration mode scaled by two different magnitudes. We use truncated simulation data from one of these trajectories to learn the slowest two-dimensional SSM and its nonlinear reduced dynamics up to an a priori determined accuracy. The second trajectory, which is unseen for the training procedure, is then used for testing the prediction of our data-driven model, as shown in Figure 2b.

Finally, we observe that our data-driven model is capable of predicting the forced response of the full system around the first natural frequency as shown in Figure 2c. Here, we obtain agreement with the analytic predictions of the reduced-order model on the same SSM when computed directly [4] via `SSMTool`.

Summary. This paper is concerned with nonlinear dynamic analysis and design of a novel ring-based Bi-stable energy harvesting device that is considered as an alternative to the beam and tube models used thus far. The Mathematical model for the ring structure to generate nonlinear harvester model as well as the nonlinear magnetic force that acts on the ring structure is formulated. The highly sensitive ring second flexural mode when combined with the nonlinear harvester model as well as nonlinear external magnetic force results in an ideal combination that yields increased frequency range. Numerical predictions of nonlinear dynamic response characteristics when the system is subjected to ambient harmonic excitation have been performed for the purposes of gaining an insight into the dynamics and power generation of this new class of harvesters.

Concept and Modeling

In this paper, the nonlinear governing equations of flexural motion of vibrating thin circular rings are developed for the purposes of investigating the nonlinear dynamic behavior of ring harvester. Galerkin's procedure is used to discretize the nonlinear equations for numerical response predictions. Gebrel et al [1] have presented the first study of a novel ring-based mono-stable energy harvesting device employing a linear system model subjected to ambient as well as nonlinear magnetic forces. The geometry and parameters used in the present study have been described in detail in [1]. The general equations of motion that govern the transverse and circumferential motions are derived via Hamilton's principle, as described in [2]. In the present study, models using various configurations for the magnets are examined so that efficient bi-stable energy harvesting systems utilizing the sensitive second mode of a ring structure may be realized in practice. A schematic diagram of the magnetic configurations system is shown in Figure 1. In order to represent the oscillatory nonlinear magnetic force that acts on the ring structure, a novel design and analysis of a theoretical model formulation is employed. This analysis is restricted to mono-stable/bi-stable configurations that depend on the nonlinear terms. Magnets B and C are considered identical and their distance from magnet A is designated as d as shown in Figure 1.

Figure 1: A schematic of ring and magnet configurations

The present study focuses on bi-stable energy-harvesting based on ring structure using the primary and secondary co-ordinates. System equations (1) and (2) have been employed together with equation (3) that represents the output power generation. The final nonlinear equations of motion that govern the nonlinear dynamic behavior of ring harvester employing the second flexural mode with nonlinear magnetic force as well as harmonic ambient excitation are derived as

$$\left[\rho h \pi + 2 \rho h \pi \left(\frac{n\gamma}{2r} \right)^2 A_n^2 \right] \ddot{A}_n + 2 \rho h \pi \left(\frac{n\gamma}{2r} \right)^2 A_n B_n \ddot{B}_n + 2 \zeta \omega_0 \dot{A}_n + \left[\frac{EI}{br^4} (n^2 - 1) n^2 + k_r \right] \pi A_n + \left[\frac{EA}{br^2} + k_r \right] \left(\frac{n\gamma}{2r} \right)^2 [A_n^2 + B_n^2] \pi A_n + 2 \rho h \pi \left(\frac{n\gamma}{2r} \right)^2 [\dot{A}_n^2 + \dot{B}_n^2] A_n - \gamma_1 \underline{I} = f_{Nm1}(A_n, B_n, \theta_i) + f_e \quad (1)$$

$$\left[\rho h \pi + 2 \rho h \pi \left(\frac{n\gamma}{2r} \right)^2 B_n^2 \right] \ddot{B}_n + 2 \rho h \pi \left(\frac{n\gamma}{2r} \right)^2 A_n B_n \ddot{A}_n + 2 \zeta \omega_0 \dot{B}_n + \left[\frac{EI}{br^4} (n^2 - 1) n^2 + k_r \right] \pi B_n + \left[\frac{EA}{br^2} + k_r \right] \left(\frac{n\gamma}{2r} \right)^2 [A_n^2 + B_n^2] \pi B_n + 2 \rho h \pi \left(\frac{n\gamma}{2r} \right)^2 [\dot{A}_n^2 + \dot{B}_n^2] B_n = 0 \quad (2)$$

$$L \underline{\dot{I}} + \tilde{R} \underline{I} + \gamma_1 A_n = 0. \quad (3)$$

The parameters A_n and B_n represent the displacement of the ring in the transverse primary and the secondary directions, E is the Young's modulus, I denotes area moment of inertia for the ring cross-section, ρ is the mass density, and EI denotes flexural rigidity. The quantification of the nonlinear terms are governed by the parameter γ . Also, A is the cross

sectional area of ring, b the axial thickness of ring, h the radial thickness, r the mean radius of the ring, ζ the mechanical damping ratio while ω_0 and n , respectively, represent the natural frequency and the number of modes. Oscillatory external nonlinear magnetic force magnitude is represented by $f_{Nm}(A_n, B_n, \theta_i)$, while the area moment of inertia of the ring cross section about its neutral axis is expressed as $I = bh^3/12$. The harmonic excitation to be received from the ambient vibratory energy sources is represented by $f_e = f \cos(\omega t)$, where ω is the excitation frequency, and f is the excitation amplitude. The positions of magnets on the system correspond to θ_i , $i = 1, 2, 3, 4$. Induced electrical current is denoted by I , L is the inductance of the coil, and R represents the load resistance, while γ_1 denotes the transducer constant [3]. The expressions for the nonlinear magnetic force that affects the system at four positions are derived in the primary co-ordinate A_n as

$$f_{Nm1}(A_n, B_n, \theta_i) = \frac{\mu_0}{2\pi} M_A M_B V_A V_B \sum_{i=1}^4 \left(\cos(n\theta_i) - \frac{n\gamma}{2r} A_n \right) * \left[\frac{3}{\left(d - A_n \cos(n\theta_i) - B_n \sin(n\theta_i) + \frac{n\gamma}{4r} [A_n^2 + B_n^2] \right)^4} - \frac{3}{\left(d + A_n \cos(n\theta_i) + B_n \sin(n\theta_i) - \frac{n\gamma}{4r} [A_n^2 + B_n^2] \right)^4} \right], \quad (4)$$

where M_A, M_B are the magnetization, V_A, V_B represent the volume of the source magnet, and d is the distance between magnets.

Results and Discussion

In the present study, a nonlinear model which includes a complex nonlinear inertia/stiffness terms as well as a nonlinear magnetic force as depicted in equations (1) and (2) have been employed. For the purposes of predicting the nonlinear response characteristic of the bi-stable ring harvester, equations (1) and (2) have been solved numerically. The system parameters are chosen based on the available experimental set up that has been used to investigate the system natural frequency in the previous study [1]. The details regarding the electrical subsystem have been described in detail in ref [1]. Figure 2(a) shows the phase-plane trajectory for bi-stable behavior depicted via two-well potential when the harvester is under ambient excitation and excitation frequency of 60 rad/sec . The nonlinearities seem to be evident from the plot, hence suggesting the behavior of the bi-stable configuration for the harvester due to nonlinearities of the system as well as nonlinear magnetic force. Furthermore, nonlinearity can be seen in the Poincare' map results as shown in Figure 2(b), where the map appear as a cloud of unorganized points in the phase plane in Figure 2(a) due to the influence of nonlinear terms. Figure 2(c) shows the bifurcation diagram of the response current under various excitation levels. The excitation level ranging from $0 - 20 \text{ m/s}^2$ has been considered for this study. It may be inferred from this Figure that the bi-stable harvester undergoes alternating periodic and chaotic responses with the increase of the excitation level, which demonstrates a strong nonlinear behavior.

Figure 2: (a) Two well-potential bi-stable harvester, (b) Poincare' map for bi-stable harvester, and (c) Bifurcation diagram of response versus excitation amplitude for bi-stable harvester.

Conclusions

The main objective of this paper is to present the feasibility as well as nonlinear dynamic characteristics of a ring-based vibratory bi-stable energy harvester. When compared with the corresponding mono-stable harvester, an increased frequency range have been demonstrated. The dynamics of this class of harvester has been examined via dynamic response, Poincare map as well as bifurcation plots. The results provide confidence in employing the inherent bi-stability behavior available in this class of energy harvesters for energy production, in practice.

Non-smooth nonlinearities as restoring forces in a mass-in-mass cell

Camila da Silveira Zanin^{†‡}, Alireza Ture Savadkoobi[†], Sébastien Baguet[‡] and Régis Dufour[‡]

[†]Univ Lyon, ENTPE, CNRS, LTDS, UMR5513, 69518 Vaulx-en-Velin Cedex, France

[‡]Univ Lyon, INSA Lyon, CNRS, LaMCoS, UMR5259, 69621 Villeurbanne, France

Summary. The energy exchanges between particles of a mass-in-mass cell with nonlinear restoring forcing function are studied. Two types of non-smooth compound nonlinearities are considered as restoring forcing function acting on the inner mass. The governing equations of the system are treated analytically with the time multiple scale method in order to find the slow invariant manifold (SIM) as well as singular and equilibrium points of the system. Finally, quasi-analytical system responses are confronted with numerical ones obtained by direct time integration. Interestingly, the SIM of the system possesses several unstable zones and the frequency response curves exhibit isolated solutions.

Figure 1: Model of the mass-in-mass cell.

The studied system is represented in Fig. 1. It is composed of an outer mass, m_1 , grounded by a constant stiffness k_1 and a damping coefficient c_1 . The outer mass is coupled to an inner mass, m_2 , with a damping coefficient c_2 and a nonlinear restoring force $F(\alpha)$ which depends on the relative displacement of the two masses. The general governing equations of a 2-dof meta-cell systems are similar to a main system coupled with an attached nonlinear absorber [1].

$$\begin{cases} m_1 \ddot{u}_1 + k_1 u_1 + c_1 \dot{u}_1 + F(u_1 - u_2) + c_2(\dot{u}_1 - \dot{u}_2) = P \sin(\Omega t) \\ m_2 \ddot{u}_2 + F(u_2 - u_1) + c_2(\dot{u}_2 - \dot{u}_1) = 0 \end{cases} \quad (1)$$

Two types of non-smooth compound nonlinearities are considered for $F(\alpha)$, which are plotted in Fig. 2:

Figure 2: Considered nonlinearities for the restoring force $F(\alpha)$: a) Pure cubic and linear; b) Piece-wise linear.

A nondimensionalized time $\tau = \sqrt{\frac{k_1}{m_1}} t$ and the coordinates of relative displacement and the center of masses of two oscillators are introduced to the system variables. After this, the complex variables of Manevitch [2] are applied. A Galerkin method based on truncated Fourier series, involving the first harmonics of the system, is employed and a time multiple scales method [3] is carried out in order to find the SIM and the dynamical characteristic points of the system [1]. In more details, the SIM is detected at fast time scale, while the equilibrium and singular points are detected at slow time scale, leading to prediction of periodic and non-periodic regimes [4].

For a given set of system parameters, two SIMs of the system corresponding to the restoring forcing functions of Figs. 2a and 2b are illustrated in Figs. 3a and 3b, respectively. In these plots, N_1 and N_2 represent the amplitudes of the center of mass and of the relative displacement of the two oscillators, respectively. These figures are accompanied by free responses obtained by direct numerical time integration of Eq. 1 without external excitation. In both figures, it is seen that, starting

from the initial condition, the system follows the SIM and it bifurcates twice before going to the rest position (expected position for free responses of the damped system).

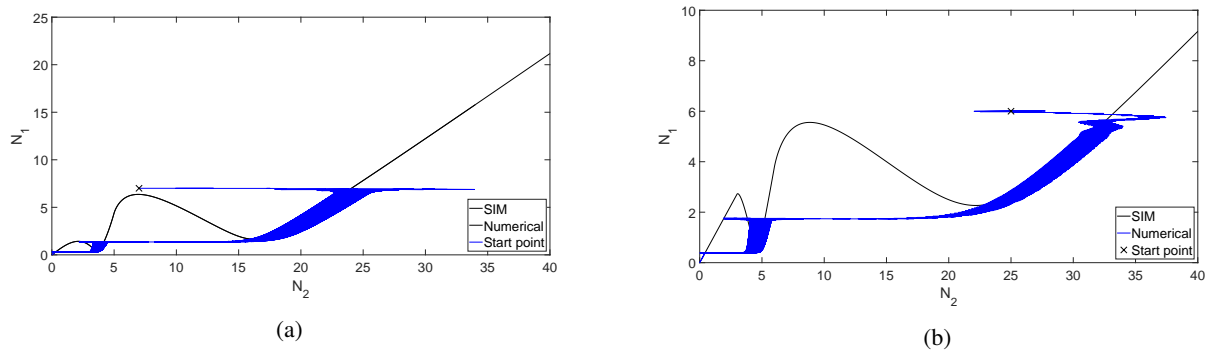

Figure 3: SIM and corresponding numerical free responses: a) System with the nonlinearity of Fig. 2a and initial conditions $(w, v, \dot{w}, \dot{v}) = (7, 7, 0, 0)$; a) System with the nonlinearity of Fig. 2b and initial conditions $(w, v, \dot{w}, \dot{v}) = (6, 25, 0, 0)$.

Furthermore, the equilibrium points can be determined for sweeping de-tuning parameter σ . This parameter represents a sweep of the frequency of excitation around the frequency of the outer mass (the system is studied around a 1 : 1 resonance). Thus, frequency responses curves can be obtained for a given forcing amplitude, which permits identifying the position of all equilibrium points and predict the amplitude levels of the cell. As an exemple, Fig. 4 shows the frequency response curve of the system corresponding to the nonlinearity of Fig. 2a for a given forcing amplitude. In this figure, the equilibrium points located in the unstable zones of the SIM are in green colour.

Figure 4: Detected equilibrium points of the system with respect to the de-tuning parameter σ for the system with restoring forcing function of Fig. 2a. σ is a de-tuning parameter representing a sweep of the frequency of excitation around the frequency of the outer mass (the system is studied around a 1 : 1 resonance).

The developments presented here provide design tools for tuning the non-smooth nonlinearities of the inner mass in order to control the system, which presents different leves of energy reduction, acting like a gearbox. As a perspective, these theoretical results will be compared with a designed experimental test setup.

Noise control via exploiting nonlinear interactions

Emmanuel Gourdon*, Alireza Ture Savadkoobi* and Claude-Henri Lamarque*

*Univ Lyon, ENTPE, CNRS UMR5513, LTDS, France

Summary. Nonlinear behaviours of acoustical resonators, such as Helmholtz resonators in nonlinear regimes [1] or electroacoustic absorbers [2], are used to obtain targeted energy transfer [3] from an acoustical mode to the resonators. It is shown that the noise control is carried out via nonlinear interactions between acoustical mode and the absorbers leading to periodic or modulated regimes.

Nonlinear noise control

Let us consider an acoustical resonator which is composed of a cavity (container of the air) and the orifice (the neck). If the length of the neck is smaller than the wavelength, then the overall system can be modelled as a mass-spring oscillator where the lumped mass is in fact the encased mass of the air in the orifice while the air inside the cavity acts as the spring. With analogy of mechanical engineering, we are interested to create a nonlinear restoring forcing function which can be coupled to an acoustical mode for creation of acoustical energy tunnelling between the mode and the resonator with nonlinear responses.

Nonlinear behaviours of the acoustical resonator

Figure 1 depicts different geometries of the neck of the resonator: The classical straight neck (H_1) of the acoustical resonator is tailored in a linear (H_2) and quadratic manner (H_3). Table 1 summarises dimensions of each configuration while the length of the cavity for all case is 25 mm. The resonators are coupled to the Kundt tube [4] and the system is excited by different sinusoidal forces while the pressures inside the cavity during the resonance are measured. All resonators show three regimes categorizing as linear, almost linear and nonlinear. Moreover, it is seen that tailoring the geometry of the neck accelerates reaching to the nonlinear domain. The actual limitation of current study is that even via tailoring the system, it reaches to the nonlinear domain at high sound pressure levels, around 125-130 dB. There are ongoing works to reduce this pressure level so that the proposed system can be applied for buildings.

	H_1	H_2	H_3
l	8.5	8.5	8.5
r_0	1.5	1.5	1.7
r_1	1.5	2	3.25

Table 1: Characteristics of different configurations of necks (mm). l stands for the length of the neck.

Figure 1: Considered geometries for the neck of the resonator.

The governing equation of the acoustical resonator can be represented by following equation (see for example [5]):

$$\frac{d^2x}{dt^2} + \sigma \frac{dx}{dt} \left| \frac{dx}{dt} \right| + \delta \frac{dx}{dt} + (x - \alpha x^2 + \beta x^3) = -p \quad (1)$$

Equation 1 shows that the system possesses linear and nonlinear damping terms together with the linear, quadratic and cubic (until third order developments) restoring forcing function. This system has been studied in detail by Alamo Vargas et al. [1] for different excitation terms p showing that it can present softening and hardening behaviours. The idea is to couple this resonator with nonlinear responses (or other resonators such as electroacoustic absorbers with similar behaviours) to an acoustical mode for nonlinear noise control. The next section discusses about noise control via proposed system.

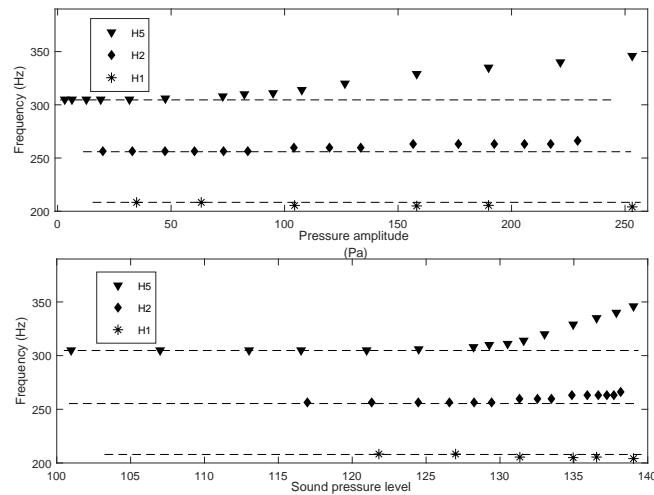

Figure 2: Variations of resonant frequency versus pressure amplitude (Pa) and sound pressure level (dB) inside the cavity.

Figure 3: Free vibration responses at the middle of the tube for different excitation amplitudes. These amplitudes create pressures of 144 dB, 150dB and 153.5dB at the bottom of the cavity of the resonator [6]. N_1 stands for the amplitude of the acoustical mode.

Passive noise control: coupling an acoustical mode to the resonator with nonlinear response

The explained resonator in previous section is coupled to a tube via a coupling box [6]. The first acoustical mode of tube with the frequency of 378.6Hz has been generated. For creation of the free vibration, several sinusoidal signals with the frequency of 378.6Hz are sent, then stopped and measurements are registered. Experimental results are collected in Fig. 3. It is seen that the resonator is capable of controlling the acoustical mode. Moreover, the control process is carried out in two global phases: the first part is via nonlinear interactions between oscillators and second part which is similar to the energy reduction by classical damped systems. Analytical developments are also carried out showing that the system can be attracted by periodic [7] or modulated [8] regimes. Results are collected in [6].

Conclusions

It is shown that via changing the geometry of the classical resonator, the emergence of the nonlinear behaviours of the resonator will be accelerated. Moreover, via coupling this resonator to an acoustical mode, it is possible to create a noise control via exploiting nonlinear interactions between oscillators. There is an ongoing work which deals with creation of nonlinearities via electric circuits for acceleration of noise control.

On the determination of high energy output operation ranges of a piezoelectric bistable energy harvesting system by parallel computing

Nils Gräßner*, Lukas Lentz* and Utz von Wagner*

*Technische Universität Berlin, Chair of Mechatronics and Machine Dynamics

Summary. Nonlinearities in energy harvesting (EH) systems are introduced by intention to broaden the range of operation parameters with high energy output. Nevertheless, as multiple solutions occur due to these nonlinearities, the determination of optimal operation conditions is a challenging task. A method based on parallel computing with numerical time integration is presented to determine these optimal operational parameters in the case of a bistable piezoelectric energy harvesting system under harmonic excitation, where excitation frequency and excitation amplitude are considered. Therefore the basins of attraction are taken into account to get a measure for the occurrence of multiple solutions.

Introduction

Bistable systems have the potential for efficient EH, due to their ability to undergo so called interwell solutions with large displacements around both stable equilibrium positions and therefore high energy output in a wide range of excitation frequencies [1]. The challenge is that also intrawell solutions, i.e. solutions with small displacements around one stable equilibrium or chaotic solutions may coexist for the same parameter set. Which one of these solutions occurs is determined by the initial conditions which are in a real world EH application neither known nor controllable. To find parameter sets with likely high energy output, the probability of each solution is determined in the following. Therefore, the model of a bistable EH system first introduced by Erturk [2] in 2009 and extensively analyzed in [3] is used. It contains one mechanical degree of freedom with a cubic nonlinearity and a coupling with an electric circuit. It is given by the nondimensional equations

$$x''(\tau) + dx'(\tau) + \frac{1}{2}(-x(\tau) + x(\tau)^3) + \theta_1 U(\tau) = f \cos(\eta\tau), \quad (1)$$

$$-\frac{\theta_2}{c_p} x'(\tau) + U'(\tau) + \frac{1}{R c_p} U(\tau) = 0, \quad (2)$$

where f (normalized excitation amplitude) and η (normalized excitation frequency) are considered as the operational parameters in the following. The state variable x , depending on the normalized time τ , is proportional to the displacement of a beam, which is discretized in space by the first eigenfunction. U characterizes the voltage at the piezos. The numeric values for the dimensionless parameters are given by $d = 0.01$, $\theta_1 = 0.13$, $\theta_2/c_p = 0.24$, $1/Rc_p = 0.55$ and $R = 1$. For more detailed information see [3]. The goal is to determine harmonic excitations given by η and f , for which the system has a high probability to undergo interwell solutions.

General behavior of the bistable magnetoelastic energy harvesting system

Figure 1a shows the steady state solutions and their basins of attraction of the EH system in the case $f = 0.1$ and $\eta = 0.5$. The results are computed by numerical time integration using the standard Runge-Kutta method (RK4).

Figure 1a: Phase trajectories of intrawell solution around negative equilibrium position (blue), intrawell around positive equilibrium position (red) and interwell solution (black). The red, blue and black areas indicate initial conditions resulting in the respective solution, i.e. basins of attraction.

Figure 1b: Maximal and minimal values of the displacement for each stationary solution as function of the normalized excitation frequency η for $f = 0.1$.

The type of the solution is classified by its color, where black indicates an interwell solution and blue and red describe intrawell solutions around negative and positive equilibrium positions respectively. In figure 1b all stationary solutions for a fixed excitation amplitude of $f = 0.1$ are shown with respect to the normalized excitation frequency η between 0.2 and 1.8. Each solution is represented by its maximum and minimum value of the state variable x . The same color code as before is applied with the addition that the gray areas indicate that there also chaotic solutions occur. It is noticeable, that for every η , where an interwell solution exists, also intrawell or chaotic solutions coexist. At this point it is so far unknown which of the coexisting solutions is most likely to occur in a real world application and therefore it is difficult to determine an operational parameter range where the energy output of the EH system is high.

Determination of high energy output operational parameter ranges

To identify operation ranges with high energy output it must be considered that each solution occurs with a different probability depending on the probability of the corresponding initial conditions, if multiple asymptotically stable solutions coexist. Therefore the corresponding basin of attraction must be taken into account. When the basin of attraction is known, it is possible to predict which solution will occur for each set of initial conditions. However, in a real world EH application the initial conditions are unknown. In this paper the probability density function $p(x_0, x'_0)$ of the initial conditions is assumed as the addition of two normal distributions around both equilibrium position with a standard deviation of 0.3. If $p(x_0, x'_0)$ is known, the probability P of a specific solution is

$$P = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} p(x_0, x'_0) b(x_0, x'_0) dx_0 dx'_0,$$

where $b(x_0, x'_0)$ is an indicator function which is 1 if the specific initial conditions (x_0, x'_0) are in the basin of attraction of the considered solution and 0 otherwise. To determine $b(x_0, x'_0)$ using numerical integration the investigated area is limited and discretized. In our case x_0 is considered between -2.0 and 2.0 and x'_0 between -1.0 and 1.0. The step size in both directions is $d = 0.008$. To compute a discretized version of the function $b(x_0, x'_0)$ a numerical time integration with every possible combination of x_{0i} and x'_{0k} must be performed. The integration time for each integration must be long enough that the steady state solution is reached. By comparing each steady state solution with the specific one, $b(x_{0i}, x'_{0k})$ can be set for all investigated initial conditions. Finally the probability of the specific solution can be determined by

$$P = \sum_{i=1}^{500} \sum_{k=1}^{250} p(x_{0i}, x'_{0k}) b(x_{0i}, x'_{0k}) d^2.$$

The results are shown in Figure 2a which is an extension of figure 1b since it additionally contains the information about the probability of each solution. The probability is visualized by the intensity of each color. For instance the interwell solution is visualized by different gray shades where white indicates a probability of 0.0 and black a probability of 1.0. It can be seen that for η in a range from 0.6 to 0.7 (green box) the probability that the system shows a high energy interwell solution is large. Hence this indicates that for a given f , η should preferably be in this area for high energy output. To achieve these results it is necessary to carry out a large number of numerical time integrations, since for each considered η (160 different values) it is required to compute the individual basin of attraction, which is generally time consuming ($500 \cdot 250 \cdot 160 = 20,000,000$ integrations). This can only be done by using a computing technique on a graphics processing unit. Therefore the time integration method (RK4) is implemented as a CUDA kernel by using the PYTHON package NUMBA. By reducing the resolution of the computed basins of attraction from $d = 0.008$ to $d = 0.08$ this approach also enables to consider further parameter variations, for example different excitation amplitudes. A corresponding result is shown in Figure 2b where the probability of the interwell solution is visualized over the normalized excitation frequency and the normalized excitation amplitude. The information in this Figure clearly demonstrates the optimal operational range of the parameters η and f for which the probability is large, that we have a high energy output.

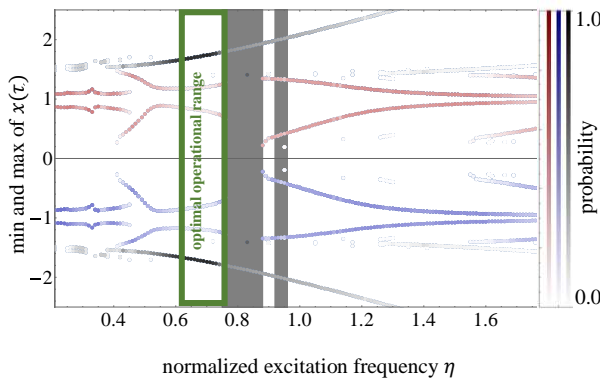

Figure 2a: Absolute maximal and absolute minimal value of x for each stationary solution with respect to η for $f = 0.1$. The opacity of each color indicates the probability of each specific solution.

Figure 2b: Appearance probability of the interwell solution with respect to η and f . Dark black indicates a high probability for the interwell solution. Therefore dark areas indicate beneficial operation values for η and f .

Targeted energy transfer between a linear oscillator and a time-dependent nonlinear systems

Aur lie Labetoulle*, Emmanuel Gourdon* and Alireza Ture Savadkoohi*

*Univ Lyon, ENTPE, CNRS UMR5513, LTDS, France

Summary. Targeted energy transfer between two weakly and linearly coupled oscillators is studied. One of oscillators possesses time-dependent damping and nonlinear restoring forcing terms. Thanks to the detection of different system dynamics, its phase-dependent characteristics are clarified leading to having finer vision about energy channelling between such oscillators. The developments prepare design tools for tuning parameters of the time-dependent oscillator leading to the design of energy channelling between two oscillators.

We would like to design the targeted energy transfer [1] between a linear and a time-dependent nonlinear oscillator. Our considered system is composed by a linear oscillator weakly coupled to an absorber with a time-dependent cubic rigidity [2] and damping (see Fig. 1). The considered system can correspond to an acoustical mode which is linearly coupled to an adaptative acoustical resonator in nonlinear domains. The studying of such resonators with fixed parameters have been already articulated in [3, 4, 5] for membrane and Helmholtz resonators and has been programed for a loudspeaker in [6].

Figure 1: System with time-dependent cubic rigidity and damping

To study the behaviour of this system around a 1 : 1 resonance, we consider the nondimensioned governing equations. Then, to have the envelope of the response of the system we introduce the complex variables of Manevitch [7]. To detect the different dynamics of the system, the multiple scales method [8] is used. Hence, we introduce fast and slow time scales. We keep only the first harmonics of the system via truncating other harmonics.

From the study of the fast dynamics of the system we can define the equation of the slow invariant manifold (SIM) which corresponds to the energy of the first linear oscillator (N_1) as functions of that of the absorber (N_2) and also the phase (δ_2). Moreover, we can detect the local extrema of the SIM. Introducing the perturbation in the complex variables of Manevitch, the unstable zone of the SIM can be clarified.

From the study of the slow dynamics of the system, we are able to define the equilibrium, singular points and the backbone curve of the system. These developments permit to predict different possible periodic or non-periodic regimes as functions of excitation amplitude and frequency.

For the system with time dependent rigidity and damping, we represent in Fig. 2 the SIM with its unstable zone accompanied by results obtained from direct numerical integration of the governing equations of the system without external excitation but under initial conditions. We notice that the SIM depends on three parameters: the energy of the linear oscillator (N_1), the energy of the nonlinear oscillator (N_2) and its phase (δ_2) contrary to the case with constant parameters where the SIM only depends on N_1 and N_2 . Moreover we can observe in the Fig. 2b that the numerical integration follows the SIM and therefore the analytical predictions. The Fig. 3 represents different views of the equilibrium points of this system and the unstable zone of the SIM. We observe that, there are two branches: a main branch (i) and an isola (ii).

Depending of progress of the work, some experimental results will be probably presented.

Summary. This abstract presents a method for fault detection and isolation (FDI) in nonlinear uncertain systems. The proposed method has two stages: first, an offline training of a static map to capture the unstructured uncertainty; second, an online fault detection, isolation, and estimation scheme. A nonlinear mechanical benchmark system is used to illustrate the performance of the scheme.

Introduction

The reliable functioning of high-tech systems can only be achieved through predictive maintenance, for which techniques for fault detection (is a fault occurring?) and fault isolation (what is the fault source?) are essential prerequisites [1]. We aim to develop a hybrid (physics-learning) fault detection and isolation (FDI) scheme that provides superior monitoring performance by leveraging cutting-edge machine learning (ML) algorithms and first-principles physics-based models. This abstract is organized as follows. First, the problem formulation is elaborated. Then, the proposed methodology is briefly presented. Next, the proposed method is evaluated by a benchmark FDI problem using simulation results. Finally, concluding remarks are discussed.

Problem Formulation

Consider a nonlinear dynamical system of the form:

$$\begin{cases} \dot{x}(t) = g(x(t), u(t)) + \eta(x(t), u(t)) + \omega(t) + \phi(x(t), u(t), t), \\ y(t) = x(t) + \nu(t), \end{cases} \quad (1)$$

where $t \in \mathbb{R}^+$, $x \in \mathbb{R}^{n_x}$, $y \in \mathbb{R}^{n_y}$, $u \in \mathbb{R}^{n_u}$ are time, state, measured output, and known input vectors, respectively, and $n_x, n_u \in \mathbb{N}$. Function $g : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \mapsto \mathbb{R}^{n_x}$ is a known nonlinear function. Function $\eta : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \mapsto \mathbb{R}^{n_x}$ represents unknown model uncertainty. Functions $\omega, \nu : \mathbb{R}^+ \mapsto \mathbb{R}^{n_x}$ are unknown disturbances, and function $\phi : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \times \mathbb{R}^+ \mapsto \mathbb{R}^{n_x}$ is the unknown process fault.

Methodology

The proposed methodology has two stages: 1. offline uncertainty learning, and 2. online FDI scheme (see Fig. 1). First, in the offline learning stage, a static map for unstructured uncertainty is trained on the basis of the healthy system input and output data (i.e., for the system with $\phi = 0$). We use a supervised method (i.e., linear regression in this abstract) to find the static map from system input and output to uncertainty in the training phase. Labeled data for the supervised learning of the model uncertainty is obtained using the known part of the system dynamics and healthy system input and output historical data. Then, in the online stage, we estimate the fault by matching the faulty model and the approximately known model of the healthy system (which is constituted by a physics-based model and the trained uncertainty model). Based on the estimated fault signal, the fault can be detected and isolated using the CUSUM-based procedure [3] as a change detection method.

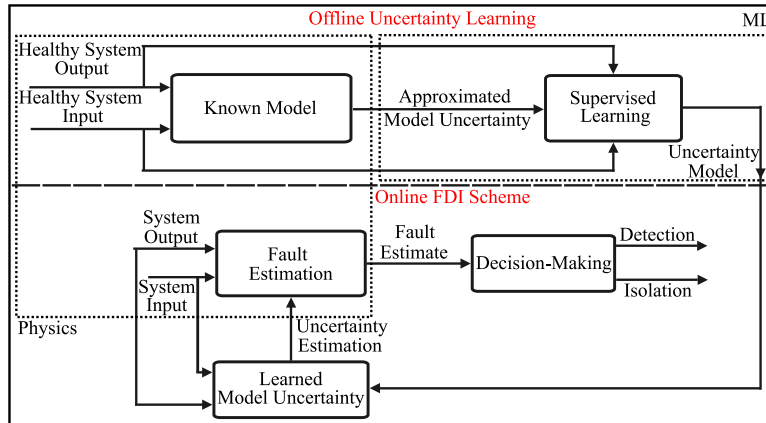

Figure 1: Offline uncertainty learning and online FDI scheme block diagrams.

Figure 2: The nonlinear benchmark schematic.

Figure 3: The CUSUM sequences and the thresholds.

Simulation Results

In what follows, the methodology is applied to a nonlinear benchmark system (a single-link robotic arm with a revolute elastic joint, see schematic in Fig. 2) [2]. This system has the structure introduced in (1) and four states, $x(t) = [x_1(t), x_2(t), x_3(t), x_4(t)]^T$. In the simulation, a fault is induced in the third equation of the right-hand side of (1). The fault, which reduces the link mass, occurs abruptly at 225 seconds. The CUSUM-based thresholds and sequences for each state are depicted in Fig. 3. The CUSUM sequence is a cumulative sum of the estimated fault, which is compared to the CUSUM threshold for fault detection. It is clear from the left-down plot of the figure that the fault can be detected by the proposed method since the CUSUM sequence exceeds the threshold after the fault occurrence. Furthermore, to indicate the capability of the proposed method, it is compared with a linear conventional observer-based FDI method to detect a small fault (Fig. 4). This small fault is the same as the previous fault. However, its magnitude is one-fifth of the previous one. It can be seen in the figure, unlike the proposed method, the linear method cannot detect the fault due to ignoring the nonlinearity and uncertainty.

Conclusions

The proposed methodology for FDI of nonlinear systems has improved fault detectability compared to conventional methods in the presence of nonlinearity and uncertainty for the benchmark system.

Subcritical Hopf bifurcation in the dynamics of a pressure relief valve

Fanni Kádár[†] and Gabor Stepan[†]

[†]*Department of Applied Mechanics, Budapest University of Technology and Economics, Budapest, Hungary*

Summary. The direct spring operated pressure relief valves are prone to harmful vibrations, which endanger the protected system under pressure. The studied mathematical model describes a system consisting of a vessel and of a pressure relief valve mounted on the vessel. The mathematical model with the state variables of valve lift, valve disk velocity and vessel pressure shows strong asymmetric nonlinearities. Our adapted numerical simulation is appropriate to produce bifurcation diagrams with the bifurcation parameter of the inlet flow rate, and also to draw the phase portrait. At the certain range of parameter combinations the equilibrium state loses the stability through subcritical Hopf bifurcation. In the case of dense parameter sweep in the phase space an unstable limit cycle appears between the trajectories. This unstable limit cycle can be calculated analytically by executing the Hopf bifurcation calculation. In comparison with the numerical unstable limit cycle, we studied the effect of the asymmetry of the nonlinearities on the analytically calculated unstable limit cycle. Global bifurcation diagram is constructed to trace the dynamical behaviour of the system 'outside' the unstable limit cycle, which includes impacts with the valve seat.

Introduction

The mathematical model of the direct spring operated pressure relief valve (see Fig. 1a) can be derived from the Newtonian equation of the valve disk and from the mass balance equation of the vessel [1]:

$$y_1' = y_2, \quad (1)$$

$$y_2' = -\kappa y_2 - (y_1 + \delta) + y_3, \quad (2)$$

$$y_3' = \beta (q - \sqrt{y_3} y_1), \quad (3)$$

where the dimensionless coordinates $y_{1,2,3}$ represent the valve lift, the valve disk velocity and the overpressure in the vessel, respectively. The dimensionless parameters are the inlet flow rate q , the damping coefficient κ , the opening pressure δ , and stiffness β of the fluid, which are obtained from the physical parameters in Fig. 1a according to the following formulas:

$$q = \frac{Q_{in}}{\frac{A p_0}{k} D \pi C_d \sqrt{\frac{2 p_0}{\rho}}}, \quad \kappa = \frac{b}{m} \sqrt{\frac{m}{k}}, \quad \delta = \frac{k x_0}{A p_0} = \frac{p_{open}}{p_0}, \quad \beta = \sqrt{\frac{m}{k}} \frac{E}{V} \frac{A D \pi}{k} \sqrt{\frac{2 p_0}{\rho}}.$$

During operation, only the flow rate q can change, which is chosen as bifurcation parameter. The volume V of the vessel is inversely proportional to the β , and it has an essential influence on the stability of the equilibrium state and also on the type of stability loss. Figure 2a shows a stability diagram of the equilibrium in the plane of the parameters q and β . It can be seen that the system is stable for small and large β values. We study the loss of stability at $\beta = 10$, which belongs to the small vessel volume. For this data the bifurcation diagram is shown in Figure 2b. The analytically calculated and numerically checked critical flow rate value at the Hopf bifurcation is $q_{cr} = 5.930$.

(c) Bifurcation diagram for $\beta = 10$

Figure 1: Modelling, stability and bifurcations of the pressure relief valve

Nonlinear analysis

The 3rd degree approximation of the system (1-3) around the equilibrium y_{10}, y_{20}, y_{30} has the form:

$$\begin{bmatrix} \xi_1' \\ \xi_2' \\ \xi_3' \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 \\ -1 & -\kappa & 1 \\ -\beta\sqrt{y_{30}} & 0 & -\beta\frac{y_{10}}{2\sqrt{y_{30}}} \end{bmatrix} \begin{bmatrix} \xi_1 \\ \xi_2 \\ \xi_3 \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ \beta \left(-\frac{1}{2\sqrt{y_{30}}} \xi_1 \xi_3 + \frac{y_{10}}{8\sqrt{y_{30}^3}} \xi_3^2 + \frac{1}{8\sqrt{y_{30}^3}} \xi_1 \xi_3^2 - \frac{y_{10}}{16\sqrt{y_{30}^5}} \xi_3^3 \right) \end{bmatrix} \quad (4)$$

At the bifurcation point, the linear part has the eigenvalues $\lambda_{1,2} = \pm i\omega, \lambda_3 := \lambda \in \mathbb{R}^-$. Since the nonlinearity is strongly asymmetric, there are 2nd degree terms in Eq. (4). Consequently, the system has to be reduced to the centre manifold that is approximated by 2nd degree terms, too. The centre manifold can be calculated in the eigenbasis of coordinates (u_1, u_2, u_3) , and it is tangent to the plane spanned by the complex conjugate eigenvectors. The lengthy algebraic calculation involves also the Near Identity transformation:

$$\begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \mathbf{I} \begin{bmatrix} v_1 \\ v_2 \end{bmatrix} + \begin{bmatrix} \sum_{j+k=\{2,3\}} \varphi_{jk}(\mu) v_1^j v_2^k \\ \sum_{j+k=\{2,3\}} \psi_{jk}(\mu) v_1^j v_2^k \end{bmatrix}, \quad (5)$$

which leads to the 3rd order normal form for (v_1, v_2) . This way, we obtain the Poincare-Lyapunov constant $\Delta = 0.028 > 0$, which refers to subcritical Hopf bifurcation. The emerging unstable limit cycle has the amplitude:

$$r = \sqrt{-\frac{\text{Re}\lambda'_{1,2}|_{q=q_{cr}}}{\Delta} (q - q_{cr})}, \quad (6)$$

where the root tendency $\text{Re}\lambda'_{1,2} = -0.046 < 0$ can be calculated from the characteristic equation by implicit derivation with respect to the bifurcation parameter q . Through a polar coordinate transformation $v_1 = r \cos(\omega\tau), v_2 = r \sin(\omega\tau)$. Transforming back only the linear part of Eq. (5) to the original phase space makes the calculation easier, and has a sufficient result for symmetric systems [2], but Fig. 2b shows with dashed red line how this treatment effects the location of the limit cycle for this strongly asymmetric case. The limit cycle can fit better to the numeric unstable limit cycle when the 2nd degree terms are transformed back, too. After the polar coordinate transformation, the second degree terms result in constant and $\sin(2\omega\tau), \cos(2\omega\tau)$ terms multiplied by r^2 . If the linear system is shifted with this constant only, then the unstable limit cycle is shown by red continuous line in Fig. 2b. The trace of the unstable limit cycle fits best by transforming back also the 2nd degree terms, which is represented with red dots in Fig. 2b.

(a) Centre manifold (yellow), tangent plane (green), two numerical trajectories (black), analytical limit cycle (red) (b) A stable and an unstable numerical trajectories (black) embracing the unstable limit cycle (white) and analytical limit cycles with 3 different approximations (red)

Figure 2: Numerical and analytical results presented in the phase space of pressure relief valve

The global dynamics of the system 'outside' the unstable limit cycle is determined by the impacts of the valve disk and the seat. This is characterized by the numerical bifurcation diagram in Fig. 1c, which fits perfectly to the analytically predicted unstable limit cycle.

Summary. In this study, oscillations of a vertical flexible structure with pinned-pinned ends in uniform flow are modelled and compared with the responses of a horizontal structure. Wake oscillator approach is adopted to simulate vortex-induced forces in the in-line and cross-flow directions and multi-mode approximation of the structural response is developed. Differences in the observed multi-mode lock-in behaviour and hysteretic responses for vertical and horizontal configurations are discussed for the case previously considered in experiments [1].

Introduction

Wake oscillator method allows simplifying calculations of the fluid forces acting on the slender structure vibrating in the fluid flow so that complex phenomenon of vortex-induced vibrations (VIVs) for a variety of structures and case parameters could be investigated with limited computational efforts. In the current study, analysis of vertical pipe vibrations is performed based on the previous investigations of a flexible structure in 1D [2] for the wake oscillators presented in [3].

Flexible riser model

Initially in straight configuration, flexible structure with pinned-pinned ends is considered vibrating in uniform current in 2 dimensions, accounting for the in-line and cross-flow displacements that varies along the length, L . The pipe is modelled as an Euler–Bernoulli beam whereas external fluid forces are described using nonlinear wake oscillator equations. Here, the Krenk-Nielsen oscillator [4] with the frequency doubling coefficients is selected to predict the drag force fluctuations based on the study [3] where the effect of phenomenological oscillators on the performance of the flexible riser model for the horizontal configuration were considered. The obtained coupled system of nonlinear partial differential equations is simplified employing Galerkin–type discretisation to create reduced order model. The resulting ordinary differential equations are solved numerically providing multi-mode approximations of the structure displacements and non-dimensional fluid force coefficients. The obtained model is applicable for both horizontal and vertical configurations and can be written in non-dimensional form for i th mode as:

$$\begin{aligned}
 \ddot{X}_i + 2a\Omega_R\dot{X}_i + \omega_{ni}^2 X_i &= \frac{W_w}{Lm_*\omega_0^2} \sum_{n=1}^N X_n \Phi_{ni} + \frac{a\Omega_R^2}{i\pi^2 St} (1 - \cos(i\pi)) + \frac{b\Omega_R^2}{4\pi St} w_i - b\Omega_R \sum_{n=1}^N \sum_{m=1}^N w_n \dot{X}_m \Pi_{nmi} \\
 &+ \frac{c\Omega_R}{2} \sum_{n=1}^N \sum_{m=1}^N q_n \dot{Y}_m \Pi_{nmi} + 2\pi a St \sum_{n=1}^N \sum_{m=1}^N \dot{X}_n \dot{X}_m \Pi_{nmi} + \pi a St \sum_{n=1}^N \sum_{m=1}^N \dot{Y}_n \dot{Y}_m \Pi_{nmi}, \\
 \ddot{Y}_i + a\Omega_R\dot{Y}_i + \omega_{ni}^2 Y_i &= \frac{W_w}{Lm_*\omega_0^2} \sum_{n=1}^N Y_n \Phi_{ni} - \frac{b}{2}\Omega_R \sum_{n=1}^N \sum_{m=1}^N w_n \dot{Y}_m \Pi_{nmi} + \\
 &+ \frac{c}{4\pi St} \Omega_R^2 q_i - c\Omega_R \sum_{n=1}^N \sum_{m=1}^N q_n \dot{X}_m \Pi_{nmi} + 2\pi a St \sum_{n=1}^N \sum_{m=1}^N \dot{X}_n \dot{Y}_m \Pi_{nmi}, \\
 \ddot{w}_i - 2\varepsilon_{x1}\Omega_R\dot{w}_i + 2\varepsilon_{x2}\Omega_R \sum_{n=1}^N \sum_{m=1}^N \sum_{l=1}^N (\dot{w}_n w_m w_l \Psi_{nml}) &+ 2\frac{\varepsilon_{x3}}{\Omega_R} \sum_{n=1}^N \sum_{m=1}^N \sum_{l=1}^N (\dot{w}_n \dot{w}_m \dot{w}_l \Psi_{nml}) + 4\Omega_R^2 w_i = A_x \ddot{X}_i, \\
 \ddot{q}_i - \varepsilon_y \Omega_R \dot{q}_i + \varepsilon_y \Omega_R \sum_{n=1}^N \sum_{m=1}^N \sum_{l=1}^N (q_n q_m q_l \Psi_{nml}) &+ \Omega_R^2 q_i = A_y \ddot{Y}_i,
 \end{aligned}$$

where X_i and Y_i are in-line and cross-flow displacements multipliers, w_i and q_i are wake coefficients multipliers, Ω_R is vortex shedding frequency, St is Strouhal number, $\varepsilon_{x1}, \varepsilon_{x2}, \varepsilon_{x3}, \varepsilon_y$ are dimensionless wake oscillator damping coefficients, A_x, A_y are empirical coupling coefficients, Φ_{ni}, Π_{nmi} and Ψ_{nml} are dimensionless coefficients obtained during the discretisation procedure due to the mode interaction, a, b, c are dimensionless coefficients depending on the initial drag, fluctuating drag and lift coefficients respectively, N is total number of modes considered, ω_{ni} is the i th natural frequency, ω_0 is reference frequency, m_* is mass per unit length (including structural mass and fluid added mass), W_w is weight of structure per unit length. Then the displacements and wake coefficients are calculated as

$$X(\zeta, \tau) = \sum_{n=1}^N X_n(\tau) \tilde{X}_n(\zeta); \quad Y(\zeta, \tau) = \sum_{n=1}^N Y_n(\tau) \tilde{Y}_n(\zeta); \quad w(\zeta, \tau) = \sum_{n=1}^N w_n(\tau) \tilde{w}_n(\zeta); \quad q(\zeta, \tau) = \sum_{n=1}^N q_n(\tau) \tilde{q}_n(\zeta).$$

where τ is non-dimensional time and the sinusoidal functions $\tilde{X}_n(\zeta), \tilde{Y}_n(\zeta), \tilde{w}_n(\zeta), \tilde{q}_n(\zeta)$ depending on the location along the beam $\zeta = \frac{z}{L}$ are used. Here, z is the longitudinal coordinate, and $z = 0$ indicates the bottom for the vertical configuration.

For our analysis, the configuration of the riser was selected to match the case experimentally investigated in [1] where a flexible tube with internal fluid with the weight of 2.97 N/m , length of 2.92 m , diameter of 0.018 m , and applied tension of 147 N was considered in the Reynolds number range from around 1780 to 14800. The other relevant parameters were the mass ratio of 1.17 and damping ratio of 0.025.

Results

Comparison of the lock-in curves calculated for in-line and cross-flow displacement amplitudes for the independent velocity points and under decreasing and increasing flow velocity is performed in this study for the horizontal and vertical risers, as illustrated in Figs 1a and 1b. Hysteretic behaviour is observed in the valleys between the lock-in peaks. The co-existing solutions obtained with decreasing and increasing velocities indicate significant differences in the displacement magnitudes. Figures 1c and 1d demonstrate displacement amplitudes of three co-existing solutions along the riser length for a chosen value of the reduced velocity of $U_R = 10.48$. Analysis of the obtained responses reveal a different number of modes observed in the in-line and cross-flow directions. An apparent asymmetry towards higher amplitudes in the response of the vertical structure is noticeable below $\zeta = 0.50$.

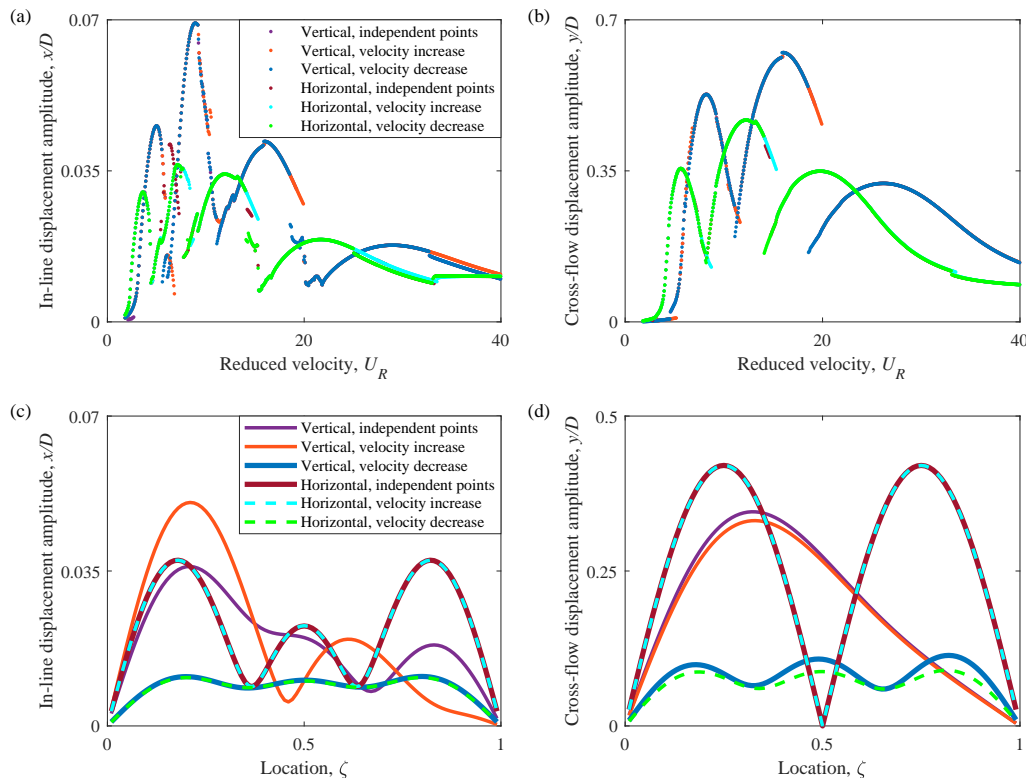

Figure 1: Dynamics of a vertical and horizontal flexible riser for the range of reduced velocity predicted by the 3 mode approximation: (a) in-line and (b) cross-flow displacement multi-mode lock-in at $\zeta = 0.25$; (c) in-line and (d) cross-flow displacement amplitude variation along the riser length at the reduced velocity of $U_R = 10.48$.

Conclusions

This study investigates the differences in the predicted behaviour of a flexible structure in uniform flow for vertical and horizontal configurations under increasing and decreasing flow velocity, and also in the limited case, when the structure starts oscillating from zero initial conditions for each flow velocity. Vertical model shows the higher amplitudes of displacement from the initial position than the horizontal structure in general. Vertical structure also demonstrates a large asymmetry of the response, a more notable contribution of the nearby modes at the nodal points and a slight delay in the peak occurrence in the reduced velocity range, compared to the horizontally positioned one.

Summary. This paper investigates the dynamic behaviour of a geometrically nonlinear nanobeam resting on the fractional visco-Pasternak foundation and subjected to dynamic axial and transverse loads. The fractional-order governing equation of the system is derived and then discretized by using the single-mode Galerkin discretization. Corresponding forced Mathieu-Duffing equation is solved by using the incremental harmonic balance (IHB) method for the strong nonlinear case. Methodology and results are validated against the solution via multiple scales method for the weakly nonlinear case. A parametric study is performed for order two and three superharmonic resonance conditions and for primary resonance case. The results demonstrated a significant influence of fractional-order and damping parameter of the visco-Pasternak foundation as well as the nonlocal parameter and external excitation load on frequency response of the system.

Introduction

A special class of beam models is so-called nonlocal beams, where the nonlocal elasticity constitutive equation is employed to consider the small-scale effects [1]. Such nonlocal beams are usually referred to in the literature as nanobeams due to the nano-scale dimensions of structures. The incremental harmonic balance method is used to study nonlinear dynamic behaviour of beam structures by many authors, e.g. see [2]. The main advantage of harmonic balance techniques is that they can be employed to find the periodic solutions of strongly nonlinear systems without introducing a small parameter like in perturbation techniques [3]. Shen et al. [4] investigated the Mathieu-Duffing oscillator by the incremental harmonic balance (IHB) method and determined the stability of the periodic solution using the Floquet theory. Later, this method was extended to study the nonlinear Duffing [5] and forced Mathieu-Duffing type [6] fractional-order differential equations, where the fractional derivative term was approximated through the Galerkin procedure. This study aims to employ the incremental harmonic balance techniques to study the frequency response of a nanobeam system resting on the fractional visco-Pasternak type foundation. Pasternak elastic foundation model is usually used for materials which besides normal deflection contain shearing distortion. It should be noted that, under certain assumptions, a nonlocal beam model could represent nanostructures such as carbon nanotubes. In that case, boundary conditions to analyze the free or forced vibration of a nanobeam structure can be prescribed based on the end conditions in a carbon nanotube i.e. a number of layers of fixed atoms in the lattice (e.g. see [7]). If only one layer of atoms is fixed at both ends of carbon nanotube, we can use simply supported (S-S) boundary conditions in the mechanical model, and if several layers of atoms are fixed, we can use boundary conditions of clamped-clamped (C-C) nanobeam. The single-mode Galerkin method is used to discretize the governing equation and obtain the nonlinear response for the fractional-order forced Mathieu-Duffing equation. The results are verified by the comparison of amplitude-frequency curves from the multiple scales and incremental harmonic balance methods obtained for the superharmonic resonance conditions of order two and three and a primary resonance case.

Problem definition

The governing equation for the forced vibration of a nanobeam resting on the fractional visco-Pasternak foundation is derived based on the model presented in Fig.1. Following parameters are used: L is the length of the nanobeam, ρ is the density, A is the cross-sectional area of homogenous nanobeam, δ and \bar{G}_p are the coefficients of the fractional visco-Pasternak foundation, D^α is the operator of the Caputo fractional-order derivative, \bar{F}_0 is the amplitude of static load while \bar{F}_1 is the amplitude of the dynamic force of the frequency Ω_1 .

Figure 1: Nanobeam on fractional visco-Pasternak foundation a) physical and b) mechanical model

Based on the Euler-Bernoulli beam theory and von Kármán nonlinear deformation, nonlocal constitutive equation and the Newton's second law for the elementary part of the nanobeam, the following nonlinear fractional-order partial differential equation of motion of the nanobeam resting on the fractional visco-Pasternak foundation can be derived

$$\begin{aligned} & \rho A \frac{\partial^2 w}{\partial t^2} + D^\alpha w \bar{\delta} + D^\alpha \left(\frac{\partial^2 w}{\partial x^2} \right) \bar{G}_p + (\bar{F}_0 + \bar{F}_1 \cos \Omega_1 t) \frac{\partial^2 w}{\partial x^2} \\ & - \frac{EA}{2L} \frac{\partial^2 w}{\partial x^2} \int_0^L \frac{1}{2} \left(\frac{\partial w}{\partial x} \right)^2 dx + EI \frac{\partial^4 w}{\partial x^4} - \mu \left[\rho A \frac{\partial^4 w}{\partial t^2 \partial x^2} + D^\alpha \frac{\partial^2 w}{\partial x^2} \bar{\delta} + D^\alpha \left(\frac{\partial^4 w}{\partial x^4} \right) \bar{G}_p \right. \\ & \left. + (\bar{F}_0 + \bar{F}_1 \cos \Omega_1 t) \frac{\partial^4 w}{\partial x^4} - \frac{EA}{2L} \frac{\partial^4 w}{\partial x^4} \int_0^L \frac{1}{2} \left(\frac{\partial w}{\partial x} \right)^2 dx \right] = \bar{F}_2 \cos \Omega_2 t. \end{aligned} \quad (1)$$

Solution procedures

The partial differential equation (1) is nondimensionalized and after introducing a new time scale $\bar{\tau} = \bar{\Omega} \tau$ and we assume the solution of nondimensional version of Eq.(1) as $\bar{w}(\bar{x}, \bar{\tau}) = \phi(\bar{x})q(\bar{\tau})$, nonlinear fractional-order forced Mathieu-Duffing equation is obtained in the following form

$$\bar{\Omega}^2 q'' + \varepsilon \gamma_{12} \bar{\Omega}^\alpha D_{\bar{\tau}}^\alpha q + (\omega_n^2 - \varepsilon \gamma_3 F_1 \cos \bar{\tau}) q + \varepsilon \gamma_4 q^3 = \bar{f} \cos \bar{\tau}, \quad (2)$$

For some initial guess q_0 of the steady-state modal amplitude, a neighbouring state of motion can be expressed in the form $q = q_0 + \Delta q$, $\bar{\Omega} = \bar{\Omega}_0 + \Delta \bar{\Omega}$, where q_0 and Δq can be represented as sums of trigonometric functions and corresponding weighting coefficients. Based on Galerkin procedure as described in papers [5, 6], Eq. (2) is discretised and Newton-Rapson method is applied to solve for increments of amplitude when $\Delta \bar{\Omega} = 0$.

Numerical results

Here, we show the numerical results obtained by the presented incremental harmonic balance (IHB) method for finding the frequency response of the system. We verify the results by comparing the steady-state frequency responses for the superharmonic resonance case $2\bar{\Omega} \approx \omega_n$ obtained by the IHB and the multiple scales method (MS), as given in Fig. 2a. Influence of the fractional-order derivative parameter for weak nonlinearity and the nonlocal parameter for strong nonlinearity on the amplitude-frequency responses are given in Fig. 2b and Fig. 2c, respectively.

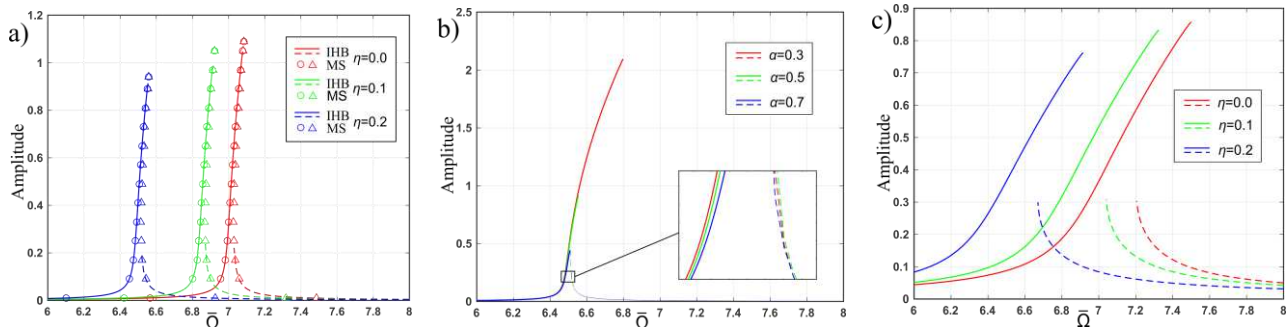

Figure 2: Frequency response for the superharmonic resonance case $2\bar{\Omega} \approx \omega_n$: a) weak nonlinearity, changes of nonlocal parameter, IHB vs MS, b) weak nonlinearity, changes of order of fractional derivative, c) strong nonlinearity, changes of nonlocal parameter.

Conclusions

From the validation study, it is revealed that the incremental harmonic balance method is in good agreement with the multiple scales analysis for the weakly nonlinear case. The advantage of the incremental harmonic balance method lies in the fact that it does not require the introduction of small parameter and thus strong nonlinearity cases can be observed. It has been demonstrated that introduction of the incremental harmonic balance method in the analysis of nonlocal structures can possibly lead to more reliable analysis of strongly nonlinear nano-scale systems.

Nonlinear Vibrations of Long Slender Continua Coupled with Discrete Inertia Elements Moving Vertically in a Tall Structure

Stefan Kaczmarczyk*

**Engineering Dept, Faculty of Arts, Science and Technology, University of Northampton, Northampton, UK*

Summary. A nonlinear mathematical model of axially moving long slender continua coupled with discrete inertia elements deployed in a tall structure is developed. In engineering applications such a system represents a vertical transportation system (high-rise lift/elevator). The longitudinal motion of the discrete masses that represent the car, counterweight and compensating sheave assembly are constrained by a nonlinear damping device. Numerical simulation techniques are then used to predict a range of complex dynamic interactions and resonance phenomena which in turn informs the development of vibration control strategies.

Introduction

Tall buildings and structures are subjected to sway motions of large amplitude and low frequency due to resonance conditions induced by wind loads and long-period seismic excitations [1,2]. These sources of excitation affect the performance of vertical transportation systems (VTS; high-rise lift/elevator systems) deployed in buildings [3]. The fundamental natural frequencies of tall buildings fall within the frequency range of the wind and seismic excitations and the sway motions form a base motion excitation mechanism which acts upon the components of VTS [4]. Particularly affected are long slender continua (LSC) such as suspension ropes, compensating and travelling cables. The lengths of these elements vary when the VTS moves vertically within the host structure. The lateral motions of the LSC are coupled with the vertical motions of discrete masses installed in the hoisway, such as the car, counterweight of the compensating sheave assembly (CSA).

Complex resonance interactions arise in the system when the frequency of the base excitation is tuned to one (or more) natural frequencies of the system. Substantial research efforts has been devoted to the issue of mitigating the effects of the dynamic responses that might occur. In the first instance the masses and geometry of the system can be adjusted to change the resonance frequencies to shift the resonance regions. However, in most cases the structural constraints and design limitations do not leave much space for the changes to be effective. Active vibration control strategies involving boundary lateral motions and/or longitudinal motions (such as active stiffness control [4]) can be considered to mitigate the effects of resonances. However, these approaches involve the application of expensive and sophisticated actuator control algorithms and often passive methods are preferred to be used. For example, the industrial practice to mitigate the effects of dynamic interactions in a high-rise elevator system involves the application of a hydraulic tie-down device attached at the CSA. The damping force is then a nonlinear function of the CSA's velocity. The aim of this study is to develop a numerical simulation model to predict and to analyse the nonlinear vibrational interactions in the system under resonance conditions. The characteristics of the damping device can then be optimised and adjusted to minimize the effects of adverse dynamic responses of the system.

Nonlinear dynamics model

Figure 1 shows a VTS system mounted within a vertical cantilever host structure subject to ground motions $s_r(t)$, $r = 1, 2$ in the in-plane and out-of-plane directions, respectively. The structure undergoes bending elastic deformations with the in-plane and out-of-plane displacements at the top end ($z = z_0$) denoted as $w_{r0}(t)$, respectively. The fundamental modal responses of the structure can be defined by the following equation

$$\ddot{W}_r(t) + 2\zeta_r \omega_r \dot{W}_r(t) + \omega_r^2 W_r(t) = -\frac{\ddot{s}_r(t)}{m_r} \int_0^{z_0} m_s(z) \Psi_r(z) dz \quad (1)$$

where $r = 1, 2$ and W_r represent the modal coordinates. The natural frequencies of the structure are denoted as ω_r , ζ_r represent the modal damping ratios, $\Psi_r(z)$ are the eigenfunctions (mode shape functions) of the structure. In this

formulation $0 \leq z \leq z_0$, $m_s(z)$ is the linear mass density of the structure and $m_r = \int_0^{z_0} m_s(z) \Psi_r^2(z) dz$. The deflections at the top of the structure are then be determined as $w_{r0} = \Psi_r(z_0) W_r(t)$, $r = 1, 2$. The equations of motion of the LSC treated as continua with small bending stiffness are given as

$$\begin{aligned} m_i \bar{v}_{iit} + E_i J_i \bar{v}_{ixxxx} - \left\{ T_i - m_i \left[V^2 + (g - a_i) x_i \right] + E_i A_i e_i \right\} \bar{v}_{ixx} + m_i g \bar{v}_{ix} + 2m_i V \bar{v}_{ixt} &= F_i^v \left[t, L_i(t) \right], \quad i = 1, \dots, 4, \\ m_i \bar{w}_{iit} + E_i J_i \bar{w}_{ixxxx} - \left\{ T_i - m_i \left[V^2 + (g - a_i) x_i \right] + E_i A_i e_i \right\} \bar{w}_{ixx} + m_i g \bar{w}_{ix} + 2m_i V \bar{w}_{ixt} &= F_i^w \left[t, L_i(t) \right], \quad i = 1, \dots, 4. \end{aligned} \quad (2)$$

The response of discrete masses are described by following equations

$$\begin{aligned} M_1 \ddot{q}_1 - E_1 A_1 e_1 + E_2 A_2 e_3 &= 0; \quad M_2 \ddot{q}_2 - E_1 A_1 e_4 + E_2 A_2 e_2 = 0, \\ M_3 \ddot{q}_3 + E_1 A_1 e_1 + E_1 A_1 e_4 + c_3 |\dot{q}_3|^{\alpha-1} \dot{q}_3 &= 0; \quad I_3 \ddot{\theta}_3 - R E_1 A_1 e_1 + R E_1 A_1 e_4 = 0 \end{aligned} \quad (3)$$

Figure 1: Greatest figure of all time

where $\bar{v}_i(x_i, t), \bar{w}_i(x_i, t)$, $i = 1, 2, \dots, 4$, represent the dynamic displacements of the LSC, F_i^v, F_i^w are the excitation terms, E_i, A_i, J_i, m_i and E_2, A_2, J_2, m_2 are the modulus elasticity, cross-sectional effective area, second moment of area, and mass per unit length of the compensating ropes and the suspension ropes, respectively. The compensating ropes are of length L_1 at the car side and the suspension ropes are of length L_2 at the counterweight side, respectively. The length of the suspension rope at the car side and the compensating rope at the counterweight side are denoted as L_3 and L_4 , respectively. The lengths of suspension ropes and compensating cables are time-varying so that $L_i = L_i(t)$, $i = 1, \dots, 4$. The masses and dynamic displacements of the car, counterweight and the compensating sheave assembly are represented by M_1, M_2 and M_3 , q_1, q_2 and q_3 , respectively. The speed and acceleration/ deceleration of the car are denoted by V and a , respectively, and T_i denote the rope quasi-static tensions. In this model the quantities e_i are the quasi-static axial strains in the LSC system. The kinematic constraint equation to be used in equations (2-3) is expressed as $Y \equiv 2q_3 - u_1(L_1, t) - u_4(L_4, t) = 0$.

Results and conclusions

The model is solved numerically and the results demonstrate the resonance behaviour of the system. The resonance frequencies of the LSC components can be shifted / changed by the use of different masses of the CSA. The frequencies of the suspension ropes depend on the mass of the car (and the corresponding mass of the counterweight) as well as on the car loading conditions. The characteristics of the hydraulic tie-down / damping device can be optimised and adjusted to minimize the effects of adverse dynamic interactions taking place in the system. It should be noted that the nature of the dynamic conditions present in high-rise building systems is such that small changes of the natural frequencies of the structure might result in large changes of the resonance conditions that arise in the installation.

Summary. It is well-known that perturbation analysis of reduced-order models (ROMs) of nonlinear structures produced by classical Galerkin truncation (using single or finite linear modes) might lead to erroneous results. At least three different approaches were proposed for resolving this issue in the literature, besides increasing retained modes (thus obtaining not a minimal ROM), namely, perturbation by directly attacking the continuous partial differential equations (PDEs), rectified Galerkin truncation, and nonlinear normal modes. The latter two give their ROMs but the first does not, although all the three lead to notably improved nonlinear responses. The three should be equivalent to each other in the sense of improved characterization of structure's nonlinearity, although at first glance they are quite different in their formulations. Our key observation is that the underlying essential similarity of the three resolutions is that the structure's dominant nonlinearity effects are always well captured *before* mode truncations (in distinct and subtle manners). Inspired by this similarity, we propose a new reduced-order modelling approach based upon dominant spectrum decomposition idea, with also comparisons of the above three existing methods being discussed. Explicitly, the key dominant dynamic patterns/features (indicated by their associated spectrum) inherent with nonlinear structures are captured before mode truncation. These dynamic patterns include not only the directly excited structural modes (always retained in classical Galerkin truncation), but also those dominant passive patterns which are slaved to the quadratic nonlinearity, sub-(super) harmonic excitations, or hard non-zero boundary conditions.

Basic formulation

Three typical one-dimensional scenarios in weakly nonlinear dynamics are discussed [1, 2], explicitly

(a) Hard sub-(super) harmonic excitation problem denoted by

$$\ddot{w}(x, t) + L[w] = F(x) \cos \Omega t + \varepsilon N_3[w] - 2\varepsilon \mu \dot{w} \quad (1)$$

with boundary conditions $w(0, t) = w(1, t) = 0$. Here $L[\cdot]$, $N_3[\cdot]$ are the structure's linear and geometric cubic-nonlinear operators, $F \sim O(1)$, $\Omega = 3\omega_m + \varepsilon\sigma$ are the amplitude and frequency of a hard sub-harmonic external excitation, with ε being a small parameter for proper perturbation analysis, and σ a detuning parameter.

(b) Quadratic (and cubic) nonlinearity problem governed by

$$\ddot{w}(x, t) + L[w] = N_2[w] + N_3[w] + F \cos \Omega t - 2\mu \dot{w} \quad (2)$$

with $w(0, t) = w(1, t) = 0$. Here $w(x, t) \sim O(\varepsilon)$ is the structure's displacement, and $L[\cdot]$, $N_2[\cdot]$, and $N_3[\cdot]$ are the linear, quadratic and cubic (spatial) operators, respectively. $F \sim O(\varepsilon^3)$ is the excitation, with $\Omega = \omega_m + \varepsilon^2\sigma$.

(c) Hard sub-(super) harmonic moving boundary problem represented by

$$\ddot{w}(x, t) + L[w] = \varepsilon N_3(w, t) - 2\varepsilon \mu \dot{w}, \quad w(0, t) = 0, w(1, t) = s(t) = S_0 \cos \Omega t \quad (3)$$

where the boundary motion $s(t) = S_0 \cos \Omega t$ is a hard sub-harmonic kinematic excitation with $S_0 \sim O(1)$, $\Omega = 3\omega_m + \varepsilon\sigma$. Here S_0 , Ω are amplitude and frequency of boundary motion, respectively.

For the three problems above we point out that, essentially, one single structural mode, i.e., the m -th mode (ω_m, ϕ_m) , is directly excited and will thus survive in the corresponding ROMs in the absence of internal resonance, meaning that it is possible to use a single-mode Galerkin truncation like $w(x, t) \approx \phi_m q_m(t)$ for Eqs. (1) and (2) and $w(x, t) \approx \phi_m q_m(t) + \psi_0(x)s(t)$ for Eq.(3), where a shape function $\psi_0(x)$ is introduced for satisfying the non-zero boundary motion $s(t)$, with $\psi_0(0) = 0$, $\psi_0(1) = 1$. However, it turns out that the induced perturbation results do not agree with the direct perturbation outcomes (regarded as the most accurate), indicating that the single-mode truncation is incorrect and that more structural modes should be retained in the Galerkin truncation.

Error source analysis

Our observation is that, although only the m -th structural mode is directly excited, there are possibly other passive dominant dynamic patterns which should be captured. For example, if only the m -th mode is retained in the low-order Galerkin-reduced model, all the following response components, i.e., q_j , $j \neq m$, will be completely neglected [1, 2]

$$q_1 = B_1 e^{i\omega_1 T_0} + \hat{c}_1 e^{i\Omega T_0} + cc., \quad q_2 = B_2 e^{i\omega_2 T_0} + \hat{c}_2 e^{i\Omega T_0} + cc., \dots, q_j = B_j e^{i\omega_j T_0} + \hat{c}_j e^{i\Omega T_0} + cc., \dots \quad (4)$$

The key subtle point is that, although the free structural modal amplitudes $B_j \rightarrow 0$, $j \neq m$ will vanish eventually (not being directly or indirectly excited), certain forced components $p_j = \hat{c}_j e^{i\Omega T_0} + cc.$, $j \neq m$ might be non-trivial (say, be

of comparable amount with respect to the retained components q_m and p_m). These non-trivial forced components $p_j = \hat{c}_j e^{i\Omega_j t} + cc.$ are exactly what we meant by dominant passive dynamic patterns besides the retained (ω_m, ϕ_m) , which could be caused by hard secondary excitations, quadratic nonlinearity and hard boundary motion. Explicitly,

$$F \cos \Omega t \text{ for Eq.(1), } N_2[\phi_m, \phi_m] q_m^2 \text{ for Eq.(2), } -(-\Omega^2 I + L)\psi_0(x) S_0 \cos \Omega t \text{ for Eq.(3)} \quad (5)$$

are the (non-secular) sources inducing non-trivial passive dynamic patterns, and should be fully captured. If single-mode truncation is used, only the m -th projected component of the terms in Eq.(5) will be considered. This is the error source ensuing from the perturbation analysis when using single-mode based ROMs.

Dominant spectrum decomposition and minimal ROMs [2]

We propose the following single-mode truncation corrected by the dominant spectral decomposition, i.e.,

$$w(x, t) = \phi_m(x) \cdot q_m(t) + \sum \Phi_{\Omega_i}(x) \cdot p_{\Omega_i}(t) \quad (6)$$

where $(\phi_m, q_m \sim e^{i\omega_m t})$ is the directly excited structural mode, and $(\Phi_{\Omega_i}, p_{\Omega_i} \sim e^{i\Omega_i t})$ are the i -th forced components or passive dynamic patterns due to various sources denoted by Eq.(5) above, with $\{\Omega_1, \Omega_2, \dots\}$ being the set of frequencies of these dynamic patterns, entering explicitly the low-order equation of motion as

$$(\partial^2 / \partial t^2 + L) \sum \Phi_{\Omega_i}(x) \cdot p_{\Omega_i}(t) = \text{source terms in Eq.(5)} \quad (7)$$

Therefore, using Eqs. (6) and (7), we derive the new ROMs of the nonlinear structure denoted by

$$(\partial^2 / \partial t^2 + L) \phi_m q_m(t) = \underbrace{0}_{\text{source terms in Eq.(5) eliminated}} + \varepsilon RT[\phi_m, q_m, \Phi_{\Omega_i}, p_{\Omega_i}] + \text{NST} \quad (8)$$

Perturbation analysis using ROMs in Eq.(8) agrees with the direct perturbations, as illustrated in Fig.1 below for the moving boundary problem in Eq.(3), where κ_{S2} is one key parameter of the modulation equations. Here RT and NST are short for resonant and non-secular terms, respectively. Note that discrete-1 uses $w(x, t) \approx \phi_m q_m(t) + \psi_0(x) s(t)$, with partially projected passive dynamic pattern captured, while discrete-2 uses $w(x, t) = \phi_m q_m(t) + \psi_0 s(t) + \Phi_{\Omega}(x) p_{\Omega}(t)$ with passive dynamic patterns fully captured, where $s(t) = p_{\Omega}(t)$, $\psi_0 + \Phi_{\Omega} = \Lambda_{B1}[g_{\Omega}(x, \xi)]$ and g_{Ω} is the steady Green's function [1,2]. Results will also be discussed by comparing with those based upon rectified Galerkin method [3] and nonlinear normal modes (NNMs) [4].

Note that the dominant spectrum decomposition technique above can be essentially used for reduced-order modelling of more general (strong/weak) nonlinear systems, if passive dynamic patterns can be explicitly obtained (numerical simulations might be employed for detections), although in this presentation we focus on approximate analytical passive patterns which can be derived in a perturbation formulation.

Summary. This paper deals with cyclic systems, such as for instance turboengines, in the presence of random mistuning and geometrical nonlinearities. A new methodology based on cyclic components is proposed to create a nonlinear reduced-order model. It is applied on a simplified bladed-disk with a cubic nonlinearity for both tuned and mistuned cases. Internal resonances in which several modes of a system exchange energy are recovered. A comparison of the amplification factor due to mistuning between the linear and nonlinear structures is given.

1 Introduction

This paper studies the dynamics of cyclic structures such as turboengines. For perfectly tuned linear systems, Valid and Ohayon [1] proved that their model could be written in terms of cyclic components. As underlined in [2, 3], the full system of equations, controlling the dynamics of the structure, can thus be split into multiples much smaller cyclic systems. The modes associated with these cyclic components, also called nodal diameters, form a modal basis of the equations of motion. The thorough review given by Mitra and Epureanu [4] presents the properties of cyclic structures and underlines two ongoing problematics for such systems: the nonlinear and the mistuning effects.

In this paper, geometrical nonlinearities are investigated. As the bypath ratio of turboengines is getting larger, effects due to large deformation are getting more pronounced in recent practical applications. Such nonlinearities couple the different nodal diameters of the system. Consequently the size of the cyclic system becomes equal to the one of the full system and applying cyclic symmetric properties loses its advantages. However combining the specific cyclic geometry of the structure and nonlinear effects reveals some interesting complex phenomena. These have been widely studied by the scientific community. Vakakis [5] studied the nonlinear characteristics (similar modes, localization, energy transfer) of a simplified tuned cyclic structure and compared his result with experimental ones [6]. Georgiades et al. [7] studied modal interactions occurring in cyclic structures. Sarrouy et al. [8] proposed a methodology to determine the multiple periodic solutions of a tuned cyclic structure. Internal resonances [9], transfer of energy from one mode to another, were investigated in these papers. More recently Grolet et al. [10] and Fontanela et al. [11] studied the phenomenon of dark solitons in cyclic structures. All of these papers solved the full system of equation which is time-consuming. Recently, we propose in [12] a methodology to determine which nodal diameter gets coupled in a tuned cyclic structure. This allows to decrease significantly the size of the problem and to express the nonlinearity in the cyclic domain. With this strategy, employing the cyclic symmetry property gets again more computationally interesting.

Random mistuning corresponds to the presence of small imperfection in the cyclic structure, due to manufacturing tolerances for instance. This theoretically breaks the cyclic symmetry property and the entire system must be solved to capture exactly the whole dynamics. In terms of modal properties, the mistuning leads to a split of frequencies of the degenerated modes as explained in [4, 5]. Methodologies [13, 14] that use cyclic symmetric properties have been developed to reduce the size of the linear system of equations. They assume that the motion of the system is mostly controlled by the tuned modes. In a series of papers, Bladh et al. [15, 16, 17] proposed a new methodology to create a reduced-order model (ROM) in order to perform many simulations for multiple random mistuning patterns. This probability study has provided an amplification factor curve with respect to the level of mistuning. This amplification factor is defined as the ratio of the maximal displacement of the mistuned structure over the tuned one. Such analysis is time-consuming, even for linear problems, but the concept of amplification factor is extremely interesting for engines manufacturers. Studies [18] have shown that intentional mistuning patterns (large and controlled difference between the sectors) reduce the impact of random mistuning on the response amplitude and thus allow a better prediction of the system dynamics.

In this paper, both random mistuning and geometrical nonlinearity are considered. The objective is to present a new methodology to create non-linear ROMs that can be used to predict amplification factor of nonlinear mistuned structures. Section 2 presents how mistuning and nonlinearities can be taken into account in a cyclic formulation. Section 3 details the new ROM methodology that is based on these cyclic components. The simplified bladed-disk (blisk) used as test-case will be presented in Section 4. Finally, a probability approach will then be conducted in Section 5 to determine the amplification factor for the linear and nonlinear blisk systems.

2 Cyclic symmetry formulation

This section first recalls the cyclic symmetric properties of a linear system before introducing nonlinearities and mistuning.

2.1 Linear cyclic symmetric systems

Let consider a cyclic structure composed of N identical sectors (tuned system), such as the one illustrated in Figure 1. The dynamics of the entire structure is described with the equation:

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{C}\dot{\mathbf{u}} + \mathbf{K}\mathbf{u} = \mathbf{f}_{\text{ext}}, \quad (1)$$

where \mathbf{M} , \mathbf{C} and \mathbf{K} represent the mass, damping and stiffness matrices. The vectors \mathbf{u} and \mathbf{f}_{ext} denote the displacement and the external forces associated with the entire structure. As detailed in [3, 12] the cyclic symmetry property only requires to model a single sector (whose mass, damping and stiffness matrices will be noted \mathbf{M}_0 , \mathbf{C}_0 and \mathbf{K}_0). Applying the spectral Fourier matrix \mathbf{F} (normalized by a factor \sqrt{N}) and the matrix $(\mathbf{B}_k)_{k \in \llbracket 0, K \rrbracket}$ (where $K = \frac{N}{2}$ if N is even and $\frac{N-1}{2}$ otherwise) which relates to a phase change function of the nodal diameter considered between the left and right boundaries of a sector, one obtains the following decoupled equation of motion in the cyclic domain for each nodal diameter k ,

$$\tilde{\mathbf{M}}_k \ddot{\tilde{\mathbf{u}}}_k + \tilde{\mathbf{C}}_k \dot{\tilde{\mathbf{u}}}_k + \tilde{\mathbf{K}}_k \tilde{\mathbf{u}}_k = \tilde{\mathbf{f}}_k, \quad (2)$$

where $\tilde{\mathbf{M}}_k = \bar{\mathbf{B}}_k^T \bar{\mathbf{F}} \mathbf{M}_0 \mathbf{F} \mathbf{B}_k$ and similarly for the damping and stiffness matrices. The operators \cdot^T and $\bar{\cdot}$ denote respectively the transpose of a vector or matrix and the complex conjugate. The vectors $\tilde{\mathbf{u}}_k$ and $\tilde{\mathbf{f}}_k$ represent the cyclic component of the displacement and the external forces associated with the nodal diameter k . The initial problem (Equation (1)) contains $N \times N_{\text{dof}}$ unknowns (with N_{dof} the number of degrees of freedom of one sector). It is transformed into N independent problems with N_{dof} unknowns each (corresponding to Equation (2) applied $\forall k \in \llbracket 0, K \rrbracket$).

In turboengines application, one stage of blisk usually gets excited by another stage. This creates an excitation force with specific properties: in most cases the excitation either follows a traveling or a standing wave pattern. The associated wave number of the excitation force will be noted h_{ex} [19]. As a consequence, Equation (2) needs only to be solved for this specific nodal diameter h_{ex} as the remaining nodal diameters are not excited and therefore do not respond.

Figure 1: General cyclic structure. The cyclic symmetry property requires to model only a single sector such as the one illustrated in grey color.

2.2 Nonlinear cyclic symmetric systems

In the presence of internal nonlinearities (the cyclic boundaries are assumed to be free of nonlinear forces), the system (2) gets coupled from the nonlinear terms and needs to be solved for all k simultaneously. The equation of motion in the cyclic domain becomes:

$$\tilde{\mathbf{M}}_k \ddot{\tilde{\mathbf{u}}}_k + \tilde{\mathbf{C}}_k \dot{\tilde{\mathbf{u}}}_k + \tilde{\mathbf{K}}_k \tilde{\mathbf{u}}_k + \tilde{\mathbf{f}}_{\text{nl},k}(\tilde{\mathbf{u}}) = \tilde{\mathbf{f}}_k, \quad \forall k \in \llbracket 0, K \rrbracket, \quad (3)$$

where $\tilde{\mathbf{f}}_{\text{nl},k}(\tilde{\mathbf{u}})$ are the cyclic nonlinear forces for the k -th nodal diameter. Those are function of the displacement written here in terms of cyclic components such that $\tilde{\mathbf{u}} = [\tilde{\mathbf{u}}_0^T, \dots, \tilde{\mathbf{u}}_K^T]^T$. The components $\tilde{\mathbf{u}}_k$ for the degenerated diameters ($k \in \llbracket 1, K-1 \rrbracket$ if N is even and $k \in \llbracket 1, K \rrbracket$ if N is odd) are complex values. The nonlinear terms couple a priori all nodal diameters. Therefore the system (3) has the same size as (1).

In some of our recent work [12], we showed how to identify which nodal diameter get coupled for a given excitation when the structure exhibits polynomial nonlinearities. Applying this methodology reduces the system (3) to the following

$$\tilde{\mathbf{M}}_k \ddot{\mathbf{u}}_k + \tilde{\mathbf{C}}_k \dot{\mathbf{u}}_k + \tilde{\mathbf{K}}_k \mathbf{u}_k + \tilde{\mathbf{f}}_{nl,k}(\mathbf{u}) = \tilde{\mathbf{f}}_k, \quad \forall k \in (k_m), \quad (4)$$

where k_m is a reduced set of the interacting nodal diameters found by the methodology explained in [12]. In practice the nonlinear term $\tilde{\mathbf{f}}_{nl,k}$ can be either obtained by calculating the nonlinear forces in the physical domain (function of the displacement and using Fourier transforms back and forth) or by computing them directly in the cyclic domain (see the method proposed in [12]).

2.3 Nonlinear mistuned cyclic symmetric systems

Only random mistuning (small variations between sectors) is considered in this work. Stiffness variations are assumed but the method can be easily extended for mass or damping mistuning. Consider the cyclic system illustrated in Figure 1 and assume that each sector shows a slight variation in its stiffness matrix such that, for a sector j , its stiffness is defined with

$$\mathbf{K}_j = \mathbf{K}_0 + \Delta\mathbf{K}_j, \quad (5)$$

where $\Delta\mathbf{K}_j$ denotes the mistuned part of sector j . In order to get the general equation of motion in the cyclic domain, one applies the same cyclic symmetric procedure (the same projections) as explained above despite the fact that the sectors are not necessarily all identical. The system of equations becomes

$$\tilde{\mathbf{M}}_k \ddot{\mathbf{u}}_k + \tilde{\mathbf{C}}_k \dot{\mathbf{u}}_k + \tilde{\mathbf{K}}_k \mathbf{u}_k + \Delta\tilde{\mathbf{K}}_{k,a} \tilde{\mathbf{u}} + \Delta\tilde{\mathbf{K}}_{k,b} \bar{\tilde{\mathbf{u}}} + \tilde{\mathbf{f}}_{nl,k}(\tilde{\mathbf{u}}) = \tilde{\mathbf{f}}_{ext,k}, \quad \forall k \in \llbracket 0, K \rrbracket, \quad (6)$$

When applying the Fourier matrix, the physical mistuned matrix gets split into $\Delta\tilde{\mathbf{K}}_a$ and $\Delta\tilde{\mathbf{K}}_b$. They are respectively multiplied by $\tilde{\mathbf{u}}$ and its complex conjugate. In (6), $\Delta\tilde{\mathbf{K}}_{k,a}$ and $\Delta\tilde{\mathbf{K}}_{k,b}$ represent these mistuned parts impacting the k -th nodal diameter. The construction of these matrices follows standard linear algebra from the cyclic symmetric properties and are not detailed here for brevity. As highlighted in (6), the mistuning effect also creates coupling between the cyclic components (the whole $\tilde{\mathbf{u}}$ vector is present) and thus the system must be solved for all nodal diameters simultaneously.

For better readability, the different equations (6) for all k are concatenated using block diagonal matrices and it gives

$$\tilde{\mathbf{M}} \ddot{\mathbf{u}} + \tilde{\mathbf{C}} \dot{\mathbf{u}} + \tilde{\mathbf{K}} \mathbf{u} + \Delta\tilde{\mathbf{K}}_a \tilde{\mathbf{u}} + \Delta\tilde{\mathbf{K}}_b \bar{\tilde{\mathbf{u}}} + \tilde{\mathbf{f}}_{nl}(\tilde{\mathbf{u}}) = \tilde{\mathbf{f}}_{ext} \quad (7)$$

The purpose of the new methodology presented in this study is to compute a nonlinear reduced-order model (ROM) of system (7).

3 Methodology to create a nonlinear ROM

The following methodology is based on the theory of normal nonlinear mode (NNM) developed by Rosenberg [21] and the synthesis procedure of Szemplinsky [22].

3.1 Evaluation of the NNMs

The first step of the proposed ROM creation is to compute the NNMs associated with the k -th cyclic component of the underlying perfect cyclic symmetric system. They are defined as the solutions of the following autonomous and conservative system associated with (4) in which only the nodal diameter k is taken into account in the nonlinear term (the system is thus decoupled),

$$\tilde{\mathbf{M}}_k \ddot{\mathbf{u}}_k + \tilde{\mathbf{K}}_k \mathbf{u}_k + \tilde{\mathbf{f}}_{nl,k}(\mathbf{u}_k) = \mathbf{0}. \quad (8)$$

The NNMs are computed with the Harmonic Balance Method (HBM) with a pseudo arc-length procedure [20]. The solution of (8) is supposed periodic of fundamental frequency ω and sought as

$$\tilde{\mathbf{u}}_k = \sum_{n=-N_h}^{N_h} \tilde{\mathbf{c}}_{k,n} e^{in\omega t}. \quad (9)$$

where N_h is the maximum number of harmonics retained and $\tilde{\mathbf{c}}_{k,n}$ are the harmonics coefficients of the k -nodal diameter. For a degenerated diameter, each harmonic coefficient is independent as $\tilde{\mathbf{u}}_k$ is a complex vector; however for non-degenerated diameters, one has $\tilde{\mathbf{c}}_{n,k} = \bar{\tilde{\mathbf{c}}}_{n,-k}$ and thus a real vector is obtained. Substituting (9) in (8) and projecting the system on the exponential basis with the scalar product,

$$\langle f, g \rangle = \frac{1}{T} \int_0^T f(t) \bar{g}(t) dt, \quad (10)$$

one retrieves the HBM system of equations to solve with $\tilde{\mathbf{c}}_{k,n}$ and ω as unknowns. The nonlinear forces are evaluated with the Alternating Frequency Time (AFT) procedure [23]. In practice, for an initialization on mode i , we only retrieve for each nodal diameter the harmonics coefficients -1 and 1 : $\tilde{\mathbf{c}}_{i,k,\pm 1}$. These are then normalized by a control coordinate and are used to form the vector denoted later $\phi_{i,\pm 1}^{\text{nl}}$, which provides the shape of the displacement for all DOFs parametrized by the control coordinate.

3.2 Synthesis procedure

The second step is to build a nonlinear reduction basis. The solution of (7) is sought after in the form of (11) for each nodal diameter (index k). The cyclic displacement of each of these nodal diameters is defined with multiple nonlinear modes (index i up to I) whose calculation is explained in Section 3.1, supplemented by multiple linear modes (index m up to M).

$$\begin{aligned} \tilde{\mathbf{u}}_k = & \sum_{i=1}^I \left[\phi_{i,1}^{\text{nl}} \left(|\alpha_{i,n>0}^{\text{nl}}| \right) \left(\sum_{n=1}^{N_h} \alpha_{i,n}^{\text{nl}} e^{in\omega t} \right) + \phi_{i,-1}^{\text{nl}} \left(|\alpha_{i,n<0}^{\text{nl}}| \right) \left(\sum_{n=-1}^{-N_h} \alpha_{i,n}^{\text{nl}} e^{in\omega t} \right) \right] \\ & + \sum_{m=1}^M \left[\phi_m^{\text{lin}} \left(\alpha_{m,1}^{\text{lin}} e^{i\omega t} + \alpha_{m,-1}^{\text{lin}} e^{-i\omega t} \right) \right] \quad \forall k \in \llbracket 0, K \rrbracket. \end{aligned} \quad (11)$$

The generalized coordinates associated with the NNMs are approximated with a Fourier expansion (of order N_h) whose coefficients are $\alpha_{i,n}^{\text{nl}}$. As explained in [21], $\phi_{i,\pm 1}^{\text{nl}}(|\alpha_i^{\text{nl}}|)$ depends on the amplitude of the generalized coordinates and is thus evaluated via an interpolation process at every solver iteration. Linear modes can also be added to the synthesis procedure if necessary and those are represented by mode shapes ϕ_m^{lin} and generalized coordinates $\alpha_{m,1}^{\text{lin}}$ and $\alpha_{m,-1}^{\text{lin}}$. Equation (11) is the synthesis associated with a degenerated nodal diameter: each NNM is split into two parts (the positive and negative harmonic coefficients) to respect the eigenvalue multiplicity. For a non-degenerated diameter, the cyclic component is only controlled with its positive harmonic (its negative counterpart is its complex conjugate). Mathematically the reduction (11) can also be written as

$$\tilde{\mathbf{u}}_k = \sum_{n=-N_h}^{N_h} \tilde{\mathbf{c}}_{k,n} e^{in\omega t}, \quad \forall k \in \llbracket 0, K \rrbracket, \quad (12)$$

where the harmonic coefficients are sought after as

$$\begin{pmatrix} \tilde{\mathbf{c}}_{-N_h} \\ \vdots \\ \tilde{\mathbf{c}}_n \\ \vdots \\ \tilde{\mathbf{c}}_{N_h} \end{pmatrix} = \underbrace{(\phi^{\text{nl}}(|\alpha^{\text{nl}}|) \quad \phi^{\text{lin}})}_{\Phi} \underbrace{\begin{pmatrix} \alpha^{\text{nl}} \\ \alpha_1^{\text{lin}} \\ \alpha_{-1}^{\text{lin}} \end{pmatrix}}_{\alpha}, \quad (13)$$

where $\tilde{\mathbf{c}}_n = [\tilde{\mathbf{c}}_{0,n}, \dots, \tilde{\mathbf{c}}_{K,n}]^T$ gathers the n -th harmonic coefficients of all nodal diameters and α^{nl} is the concatenation of $(\alpha_{i,n}^{\text{nl}})_{(i,n) \in \llbracket 1, I \rrbracket \times \llbracket -N_h, N_h \rrbracket}$. Similarly, the unknowns $\alpha_{\pm 1}^{\text{lin}}$ contains the generalized coordinates for the different linear modes. The matrix Φ is created by combining appropriately the different basis: the NNMs and the linear modes. The solution (12) is substituted in (7) and the system is then projected in the exponential basis (see Equation (10)). This gives:

$$\begin{pmatrix} \tilde{\mathbf{Z}}_{-N_h} & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \tilde{\mathbf{Z}}_{N_h} \end{pmatrix} \begin{pmatrix} \tilde{\mathbf{c}}_{-N_h} \\ \vdots \\ \tilde{\mathbf{c}}_{N_h} \end{pmatrix} + \begin{pmatrix} 0 & \cdots & \Delta \tilde{\mathbf{K}}_b \\ \vdots & \ddots & \vdots \\ \Delta \tilde{\mathbf{K}}_b & \cdots & 0 \end{pmatrix} \begin{pmatrix} \tilde{\mathbf{c}}_{-N_h} \\ \vdots \\ \tilde{\mathbf{c}}_{N_h} \end{pmatrix} + \begin{pmatrix} \tilde{\mathbf{c}}_{\text{f}_{\text{nl}}, -N_h} \\ \vdots \\ \tilde{\mathbf{c}}_{\text{f}_{\text{nl}}, N_h} \end{pmatrix} = \begin{pmatrix} \tilde{\mathbf{c}}_{\text{f}_{\text{ext}}, -N_h} \\ \vdots \\ \tilde{\mathbf{c}}_{\text{f}_{\text{ext}}, N_h} \end{pmatrix} \quad (14)$$

where $\tilde{\mathbf{Z}}_n = (in\omega) \tilde{\mathbf{M}} + (in\omega) \tilde{\mathbf{C}} + \tilde{\mathbf{K}} + \Delta \tilde{\mathbf{K}}_a$ is the dynamical rigidity matrix associated with the harmonic $n \in \llbracket -N_h, N_h \rrbracket$. The vectors $\tilde{\mathbf{c}}_{\text{f}_{\text{nl}}, n}$ and $\tilde{\mathbf{c}}_{\text{f}_{\text{ext}}, n}$ gather the n -th harmonic coefficients of all nodal diameters for the nonlinear and external forces. The nonlinear forces are evaluated with the same procedure as the one explained in Section 3.1. The harmonic coefficients in (14) are then substituted by (13). Finally, the last stage of the ROM creation is premultiplying this equation by Φ^T ,

$$(\Phi^T \tilde{\mathbf{Z}} \Phi) \alpha + (\Phi^T (\mathbf{J}_{1+2N_h} \otimes \Delta \tilde{\mathbf{K}}_b) \Phi) \bar{\alpha} + \Phi^T \tilde{\mathbf{c}}_{\text{f}_{\text{nl}}} = \Phi^T \tilde{\mathbf{c}}_{\text{f}_{\text{ext}}}, \quad (15)$$

where $\tilde{\mathbf{Z}}$ is a block diagonal matrix containing $(\tilde{\mathbf{Z}}_n)_{n \in \llbracket -N_h, N_h \rrbracket}$. The vectors α , $\tilde{\mathbf{c}}_{\text{f}_{\text{nl}}}$ and $\tilde{\mathbf{c}}_{\text{f}_{\text{ext}}}$ are vertically concatenated. The matrix \mathbf{J}_{1+2N_h} is the exchange matrix $(\mathbf{J}_{1+2N_h, i, j} = \delta_{2N_h+2-i, j})$. To couple the different modes, the nonlinear forces (term $\tilde{\mathbf{c}}_{\text{f}_{\text{nl}}}$) are evaluated with the AFT procedure while solving (15).

Even though the notation suggests that the same expansion is performed for each nodal diameter, the new methodology can be adjusted and each nodal diameter written with different modal basis and harmonic expansion.

This formulation is different from the synthesis proposed by Krack et al. [24] for the following reasons: the reduced Equation (15) uses cyclic components, a multi-harmonic expansion and a reevaluation of the nonlinear forces (once with the NNM evaluation and once with the synthesis stage).

In practice, the unknowns of system (15), α , are solved with a Newton-Raphson solver. For better efficiency, the semi-analytical jacobian of this system is provided to the solver. The work of Joannin et al. [25] provides insights on how to compute the jacobian in a similar problem.

3.3 Choice of nodal diameters and modes

The methodology proposed is efficient if the user chooses wisely the NNMs to compute, the linear modes and the HBM expansion order. As explained in Section 2, turboengines are usually excited by a specific excitation force with a given wave number h_{ex} . Moreover only random mistuning is accounted in this paper which induces an assumed slight variation around the tuned response of the system.

As a consequence, only NNMs of the nodal diameters that interact in the tuned system (see [12]) are evaluated. In the case of a mistuned structure, corrections are made possible by taking into account the linear modes of the remaining nodal diameters.

The selection of which modes to compute depends on the probability of the appearance of internal resonances and thus on the spectral repartition of the natural frequencies of the system.

4 Application for a tuned and a mistuned blisks

The purpose of this Section is to validate the methodology explained in Section 3. The reference solution used for validation is the HBM employed on the full system with $N_h = 3$ harmonics. Comparison of computation time between the reference solution and the ROM procedure is provided in Section 4.4.

4.1 Simplified model and ROM creation

The proposed methodology is tested on a simplified blisk composed of $N = 24$ sectors, one of which is illustrated in Figure 2. A cubic nonlinearity is applied at the tip of the blade to model symmetric large displacement. This test case was already used in [12] to study a perfectly tuned structure. The mass, damping and stiffness values can be found in Tables 1 and 2 of the aforementioned article. Figure 3 represents the natural frequencies of the underlying linear tuned system. In the remaining of the article, an external force with $h_{ex} = 3$ is applied and is set to excite the first mode of the nodal diameter 3 of the system. Based on [12], we know that the third and ninth nodal diameters will be coupled. Moreover, Figure 3 allows to see that the first and third modes of the nodal diameter 3 are almost commensurable, and similarly for the first and second modes of the ninth nodal diameter. As a consequence 1:3 internal resonances may occur. The NNMs computed will therefore be those associated with these 4 natural frequencies (depicted by red circles in Figure 3). In the rest of this section, the reduction basis used is composed of these 4 NNMs, expanded with the HBM up to $N_h = 3$, associated with more or less linear modes depending on the situation.

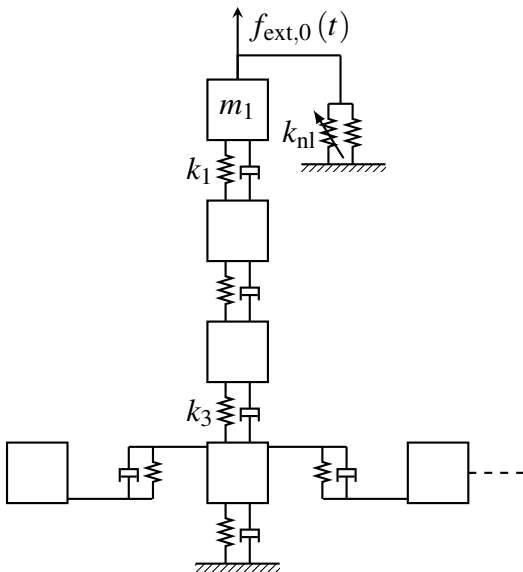

Figure 2: Description of the simplified blisk.

Figure 3: Natural frequencies for each nodal diameter.

The tuned system is first studied in Section 4.2. Section 4.3 focuses on mistuning and a random mistuning pattern is introduced on top of the spring stiffness values k_1 and k_3 , see Figure 2. The new stiffnesses are defined as

$$k_{m,i} = k_i(1 + \varepsilon\xi_i), \quad i \in \{1, 3\} \quad (16)$$

where $k_{m,i}$ is the mistuned stiffness value used instead of k_i ($i = 1$ ou 3). The parameters ε and ξ_i are the mistuning parameters: ε controls the level of mistuning ($\varepsilon \in [0, 1]$) and ξ_i is a random value taken from an uniform law in $[-0.1, 0.1]$. Table 1 provides the random mistuning pattern used in this section.

Sectors	S1	S2	S3	S4	S5	S6	S7	S8
ξ_1 (in%)	0.0094	-8.8	-9.2	0.43	6.4	4.4	3.2	9.5

	-1.4	9.7	-7.9	-6	-3.2	8.4	4.8	-1.5

Table 1: Numerical values used for ξ .

For each simulation, a bifurcation analysis [26] and branch switching algorithms [27] are performed. Solving (15) provides the generalized coordinates which can then be employed to recover the displacement of the entire structure. In the following section, the results illustrated are the displacement amplitude of the mass m_1 for the third and ninth nodal diameters. Those are noted respectively \tilde{u}_3 and \tilde{u}_9 .

4.2 Results for the tuned structure

First the ROM procedure is validated for the tuned model. The external force is applied on mass m_1 , and is defined as:

$$\tilde{f}_{\text{ext},3} = 25(e^{-i\omega t} + e^{i\omega t}). \quad (17)$$

This high amplitude force was chosen to exhibit multiple nonlinear phenomena for the tuned case and thus to verify the accuracy of the ROM for these complex situations.

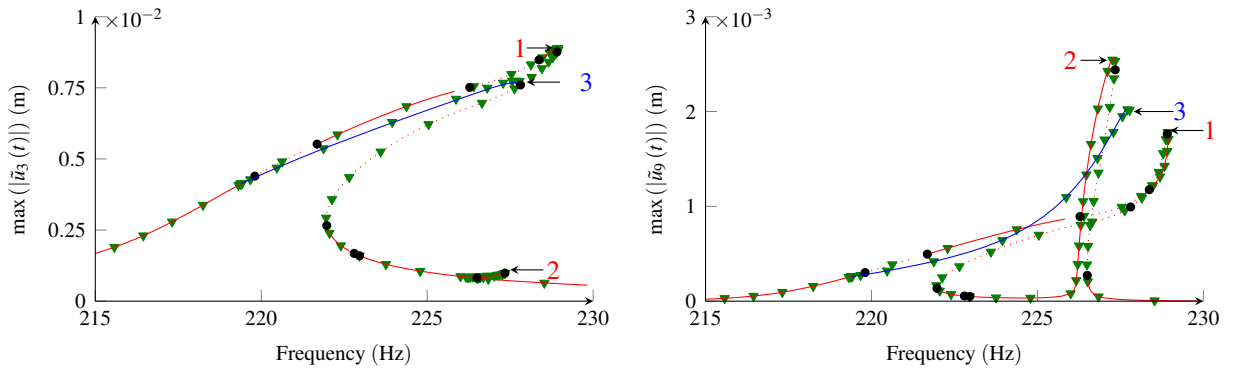

Figure 4: Frequency forced response for the tuned system. (∇): reference solution; ($-$): ROM solution for the stable main branch; (\cdots): ROM solution for the unstable main branch; ($-$): ROM solution for the bifurcated branch; (\bullet): bifurcation points.

The results obtained with the ROM procedure and the reference solution are provided in Figure 4. Two branches are represented: the main branch of solution and a bifurcated branch initiated from a symmetry-breaking bifurcation (only the stable part of this branch is represented in Figure 4). The ROM solution perfectly matches the reference solution with a huge computational time saving as detailed in Table 2. Multiple internal resonances are obtained in Figure 4. They are highlighted by arrows and number and the harmonics coefficients of the response at these points are represented in Figure 5. For the peak numbered 1, on the main branch, \tilde{u}_3 mainly responds with its first harmonic (see Figure 5a); however \tilde{u}_9 responds both on its first and third harmonics. It shows that a 1:1 and 1:3 internal resonances have taken place. For the peak numbered 2, still located on the main branch, the amplitude of \tilde{u}_9 is higher than \tilde{u}_3 (see Figure 5b) and is mainly due to

its first harmonic. An 1:1 internal resonance is occurring. Notice that for both of these peaks, the solution has a standing wave form similar to the external force (because $\tilde{c}_{k,n} = -\tilde{c}_{k,-n}$). For the peak numbered 3 located on the bifurcated branch, the solution has a forward traveling wave shape (because $\tilde{c}_{k,n<0} \neq 0$ and $\tilde{c}_{k,n>0} = 0$). Moreover Figure 5c shows a 1:3 internal resonance.

Figure 5: Amplitude of the harmonics coefficients of the response at the three peaks mentioned in Figure 4. (—): $\tilde{c}_{3,n}$; (—): $\tilde{c}_{9,n}$. The second harmonic is not represented as it is exactly equal to 0.

The same model was used in [12] with a different reduction procedure and similar results were obtained. Overall, this example has shown that the proposed ROM is perfectly able to recover complex phenomena such as internal resonances and branch switching for a tuned system.

4.3 Results for the mistuned structure

The random mistuning pattern given in Table 1 is now introduced in the system. Three values of ε are studied: 0.01, 0.1 and 1, corresponding respectively to a deviation of 0.1%, 1% and 10% between the tuned and mistuned systems. A traveling wave excitation is applied on m_1 such that

$$\tilde{f}_{\text{ext},3} = 2.5e^{-i\omega t}. \quad (18)$$

This force is 10 times smaller than the standing wave force used for the tuned case and its amplitude is more typical of turboengines applications.

For $\varepsilon = 0.01$ and $\varepsilon = 0.1$, the nonlinear basis is supplemented with all the linear modes below the threshold 1 of Figure 3 (represented by the dashed green line T1) that are used to take into account the other nodal diameters. For $\varepsilon = 1$, the system is largely mistuned (10% deviation) and the first three modes of each nodal diameter are included in the reduction basis (represented by the dashed green line T2 in Figure 3). For this system, all nodal diameters are coupled and respond; however only the third and ninth nodal diameters will be represented as they control the main dynamics. The stability of the response was not studied as the main purpose of the article is to validate the accuracy of the ROM with respect to the reference solution.

Figure 6 represents the forced response for the three values of ε . For these different configurations, no bifurcated branch was obtained. As ε increases, the amplitude of \tilde{u}_3 and \tilde{u}_9 decreases. The energy initially contained in these two nodal diameters is gradually transferred to the rest of the nodal diameters due to the mistuning effect. Moreover, we can observe the appearance of multiple linear resonances for the third and ninth nodal diameters. This is expected as frequency splitting occurs [28]. The new methodology perfectly matches the result of the reference solution.

In mistuned systems, detecting internal resonances is an arduous task as all nodal diameters are expected to respond. Figure 7 represents the harmonic coefficients of \tilde{u}_3 and \tilde{u}_9 for the peaks represented in Figure 6. For peak 1 of Figure 6a ($\varepsilon = 0.01$), the solution shows a traveling shape and the third harmonic of \tilde{u}_9 is dominant. It gives evidence to a 1:3 internal resonance (see Figures 7a). Similar results are obtained for peak 3 of Figure 6b ($\varepsilon = 0.1$) as shown in Figures 7b. The peaks 2 and 4 for the $\varepsilon = 0.01$ and $\varepsilon = 0.1$ are associated with a standing wave solution as depicted in Figures 7d and 7e for instance. For both peaks of Figure 6c ($\varepsilon = 1$), the solution has a standing wave shape and only the first harmonic responds for \tilde{u}_3 and \tilde{u}_9 .

Obtaining a standing wave solution, even though the excitation is defined with a traveling form, was expected for mistuned system [28]. However Figure 7 presents an interesting trend: as ε increases, the internal resonances progressively disappear. Studying successively Figure 7a, 7b and 7c (increase of ε), one can observe that the amplitude of the third harmonic of \tilde{u}_9 diminishes in aid of the first harmonic. As a consequence, it is expected that large mistuning would remove internal resonances. In order to make a definitive statement, further studies should be conducted but these are beyond the scope of this paper

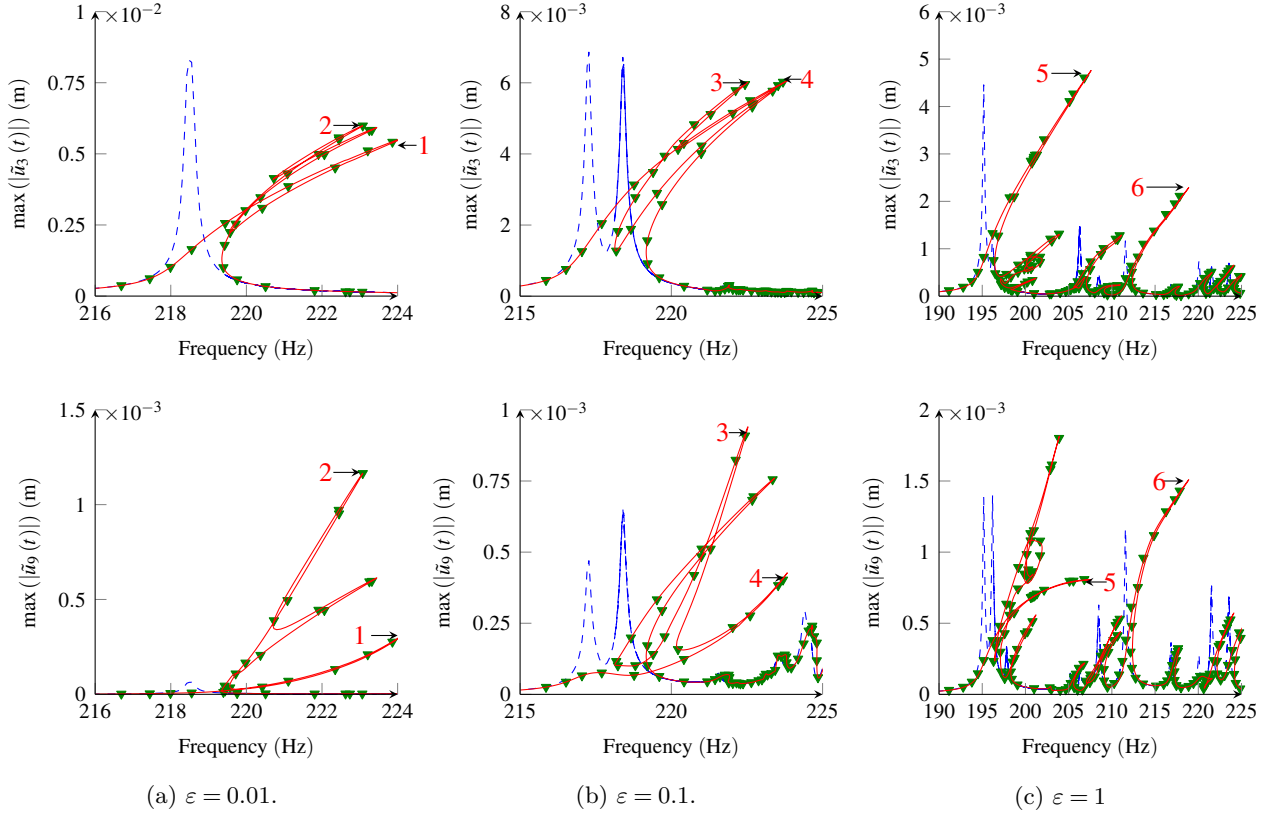

Figure 6: Frequency response function for different levels of mistuning. (—): linear response; the rest of the legend matches the one of Figure 4.

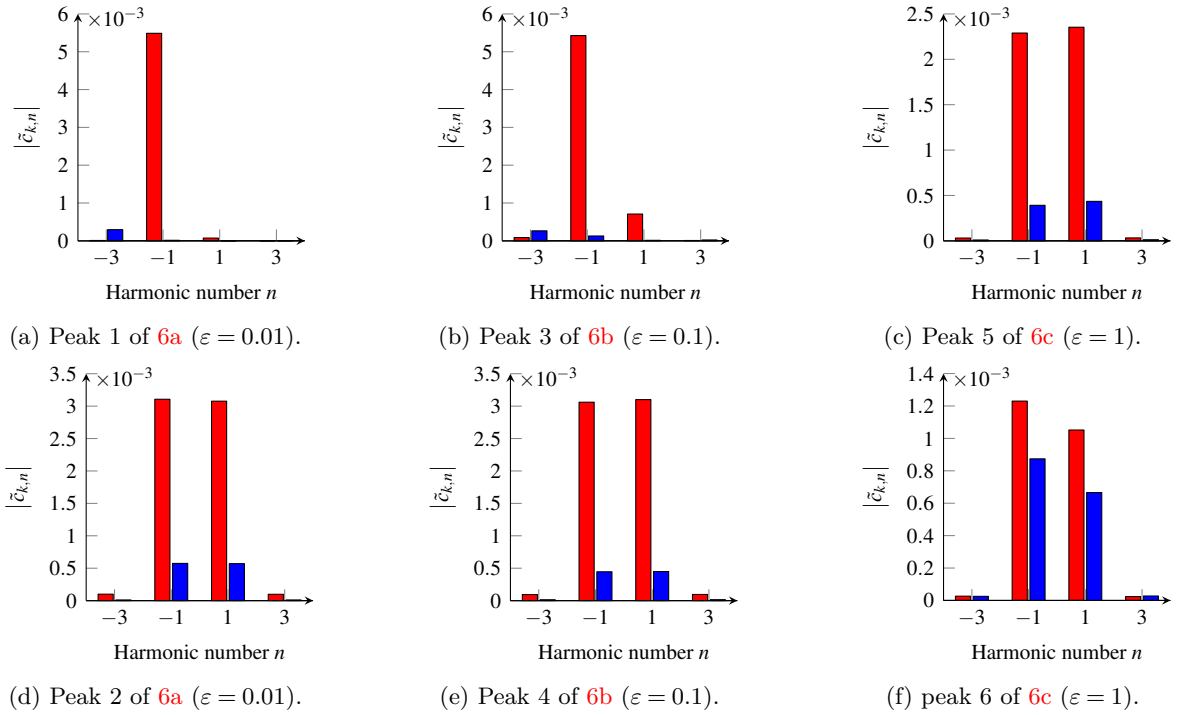

Figure 7: Harmonics content for the response on the six peaks of Figure 6. The legend matches the one of Figure 5.

4.4 Computation time comparison

For both tuned and mistuned systems, the proposed ROM has shown great accuracy and enables to recover complex nonlinear phenomena. Table 2 compares the computation time between the ROM and the reference solutions.

Test case	Method	Number of unknowns	Computation time (min)
Tuned system	Reference	720	24
	ROM	48	3
Mistuned system ($\varepsilon = 0.01$)	Reference	720	59
	ROM	108	24
Mistuned system ($\varepsilon = 0.1$)	Reference	720	145
	ROM	108	43
Mistuned system ($\varepsilon = 1$)	Reference	720	202
	ROM	186	81

Table 2: Computation time for the different test cases and methodologies. The simulations were run on a standard computer with Intel Core i7 2.30GHz 8Go.

The computation time of the new methodology is greatly reduced compared to the reference solution (2 to 8 times faster). The computation time of the NNMs is not taken into account in Table 2 as it is negligible (below 20s and needs to be computed only once for all simulations).

5 Amplification factor

When considering mistuned systems, turboengineers are used to study the maximal amplitude of the (physical) displacement obtained over all sectors. The amplification factor (AF) is defined as the ratio between this maximum amplitude and the amplitude of the (single) peak obtained in a perfectly tuned system. This is illustrated in Figure 8 for the linear case. We propose a similar definition in the presence of nonlinearity, see Figure 9. Both of these Figures are obtained on the test case of Figure 2 with a 2.5N traveling wave excitation and $h_{ex} = 3$. The mistuning pattern is the one presented in Table 1 with $\varepsilon = 0.1$.

Figure 8: Tuned (---) and mistuned (—) linear frequency forced responses.

Figure 9: Tuned (---) (respectively ∇) and mistuned (—) (respectively \blacktriangle) nonlinear frequency forced responses obtained with the ROM (respectively the reference solution).

The amplification factor relates to the amplification of the response due to the mistuning. In practice, one must generate a large number of random mistuning patterns to determine the overall behaviour of the AF. Extended studies have performed such tasks [17, 29] for linear systems. For instance, to determine accurately the 95th AF threshold (corresponding to 95% of mistuned blisks below this AF), one way is to launch a Monte Carlo simulation with a large number of samples. The simulation consists in randomly picking a large number of mistuning patterns (for a given law), and sweep the excitation frequency for each of them to determine the associated maximal amplitude. If one wants to reach a given accuracy, then the larger the AF-threshold, the

more simulations must be run. These calculations are time-consuming but it was shown, for instance in [17], that the distribution of the AF law was a three-parameter Weibull law, and this allows to reduce greatly the number of simulations needed. In the following, we have used a Weibull law reconstructed with only 50 simulations. We have run these simulations for a 2.5N traveling force and $h_{ex} = 3$. The mistuning definition follows Equation (16) with $\varepsilon = 1$ and ξ is taken within a uniform law with 15 different standard deviations (from 1% to 15% with a step of 1%). Figure 10a represents the AF with respect to the standard deviation for the linear system. Figure 10b provides the same information for the nonlinear system. For both of these Figures, the 95th, 50th and 5th percentiles (percentage of systems below the threshold) are represented. The maximum AF is obtained for $\varepsilon_{max} \approx 3\%$ for the linear system and $\varepsilon_{max} \approx 9\%$ for the nonlinear one. The value of the maximum AF is close to 1.9 for the linear system and 1.8 for the nonlinear one. Beyond this value of ε_{max} , the AF decreases. This behaviour has already been observed, in [29] for instance. The ROM solution matches well the reference solution with a significant computational time saving: the trend is correctly captured and errors are below 7% for a high level of mistuning.

Notice that the results were obtained with a specific excitation force. While Figure 10a remains valid for other levels of excitation (at h_{ex} fixed), the nonlinear results of Figure 10b are expected to vary. For a complete map of the influence of the mistuning, one must run these computations for all values of h_{ex} as well as for different force amplitudes.

(a) Linear Solution.

(b) Nonlinear solution for the ROM/reference procedures.

Figure 10: Amplification factor with respect to the deviation of the random mistuned pattern. (—+): 95th percentile; (—■): 50th percentile; (—●): 5th percentile. The blue, red and green colors denote respectively the linear case, the ROM and the reference solutions for the nonlinear case.

6 Conclusion

This paper presented a new reduced-order model methodology based on the computation of cyclic normal nonlinear modes. It is able to handle randomly mistuned cyclic structures while exhibiting complex nonlinear behaviour such as internal resonances. The method has been validated for a simplified blisk and has shown great accuracy while reducing significantly the computation time.

A probabilist study was conducted to study the impact of both the nonlinearity and the mistuning on the amplification factor of the system. For both linear and nonlinear systems, mistuning may lead to an amplification of 90% in the response. This maximum is however reached for different values of standard deviation. For both systems a plateau is reached after a relatively large value of standard deviation.

This new methodology is expected to be applicable and efficient for finite-element models of engineered structures. It thus offers probabilist opportunities which, at this date, could not be achieved. However, applying the same procedure to intentional mistuned structures (large discrepancies between the blades) is expected to be less efficient because the system is no longer close to its tuned counterpart.

Summary. Projection-based Model Order Reduction (MOR) aims at reducing the computational cost associated with the solution of large-scale dynamical systems to be used in many-query settings such as optimization and control. For nonlinear systems, significant cost reduction is only possible through an additional approximation of the nonlinear terms to reduce the computational effort of the Reduced-Order Model (ROM). These hyper-reduction techniques often lead to instability when the nonlinear terms are not approximated with a high accuracy. Increasing the accuracy of the nonlinearity approximation increases the complexity of the ROM and will question the original motivation behind MOR to obtain a faster simulator and a system with lower number of states for controller design. In this study, a non-intrusive (data-based without the need for the physical model) Reduced Basis (RB) method is proposed for a highly nonlinear model, called the Drift Flux Model (DFM), to simulate multi-phase flow inside a pipe. A set of RB functions are extracted from a collection of high-fidelity solutions by changing the input signals of the system via a Proper Orthogonal Decomposition (POD). The solution of the ROM is obtained through a linear combination of these RB functions with coefficients obtained by a Residual Recurrent Neural Network (RRNN). The RRNN approximates the map between the input signals and the increment of projection coefficients of the high-fidelity solution onto the reduced space. The generation of the RB functions and the training of the RRNN are performed during the offline phase, while the RB solution of a new input signal can be recovered via the outputs of the RRNN in the online phase. The proposed method decouples the offline and the online phases, and provides fast and reliable solutions of the original DFM.

Problem description

One of the widely accepted models to simulate multi-phase flow is the DFM [1], a highly nonlinear set of conservation laws described as below:

$$\left\{ \begin{array}{l} \frac{\partial}{\partial t}(\alpha_l \rho_l) + \frac{\partial}{\partial x}(\alpha_l \rho_l v_l) = 0, \\ \frac{\partial}{\partial t}(\alpha_g \rho_g) + \frac{\partial}{\partial x}(\alpha_g \rho_g v_g) = 0, \\ \frac{\partial}{\partial t}(\alpha_l \rho_l v_l + \alpha_g \rho_g v_g) + \frac{\partial}{\partial x}(\alpha_l \rho_l v_l^2 + \alpha_g \rho_g v_g^2 + p) = F + G, \end{array} \right. \quad t \in [0, T], x \in [0, L], \quad \left\{ \begin{array}{l} 1 = \alpha_l + \alpha_g, \\ v_g = K(\alpha_l v_l + \alpha_g v_g) + S, \\ p = (\rho - \rho_0)c_i^2 + p_0, \\ p = \rho_g c_g^2, \end{array} \right. \quad (1)$$

where $\alpha_i(t, x)$, $\rho_i(t, x)$, $v_i(t, x)$, $p(t, x)$ represent volume fraction, density and velocity of phase i and the common pressure, respectively. The subscript $i \in \{l, g\}$ denotes the liquid and gas phase with c_i the sound velocity in the medium of phase i , K and S two constants implying the flow regime and p_0 and ρ_0 the reference pressure and density. Here, t represents time and T is the time horizon of the simulation. In addition, x denotes the spatial coordinate and L is the length of the spatial domain. Finally, $F(t, x)$ and $G(t, x)$, respectively, denote the frictional and gravitational terms, which add extra nonlinearity to (1).

Highly nonlinear finite-volume schemes are developed to solve (1) [1], rendering the discretized system of equations even more complex. Therefore, real-time simulations cannot be achieved unless powerful computational resources are available. Moreover, control design for such a complex system is generally infeasible. Hence, MOR should be applied.

Reduced-order model

Intrusive (projection-based) MOR of (1) leads to an unstable system unless the nonlinear parts are approximated with a high accuracy. To circumvent this issue, a non-intrusive (data-based) MOR is applied in this study, which in addition resolves the need to access the physical model and enables the use of highly nonlinear and accurate finite-volume schemes. The algorithm introduced in [3] is used here together with an RRNN structure as shown in Figure 1. The variables W and b are, respectively, the weight coefficients and the bias values of each node in the hidden layer, to be specified during the training. It is well-known that recurrent neural networks trained on the residual values (variation of states over each time step) have a higher capability in approximating dynamical systems [4].

The RRNN structure takes the input signals of the system and gives the temporal variation of the coefficients of the RB functions as an output. Since we are dealing with a dynamical system, the coefficients of the RB functions in the previous time step are also fed as an input to the RRNN.

Results

In the simulations for the RRNN, we have used one hidden layer consisting of 20 nodes with one time-step delay ($0 : 1$ in the delay layer means both $u(t)$ and $u(t - 1)$ are considered as the training inputs). The delay in the recurrent structure

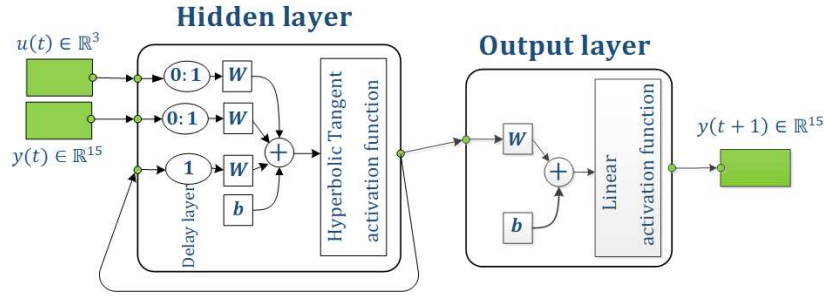

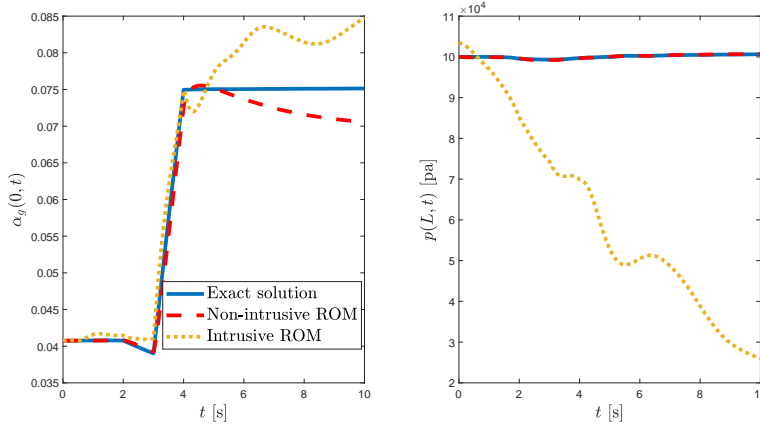

Figure 1: The nonlinear autoregressive network with exogenous inputs combined with RRNN.

 Figure 2: Comparison of the approximation of $\alpha_g(0, t)$ and $p(L, t)$.

is also set to one. The inputs to the system ($u(t)$ in Figure 1) are liquid and gas mass flow rates at the left boundary and the valve opening at the right boundary (3 inputs in total, $u(t) \in \mathbb{R}^3$). We have considered three independent variables α_g , v_l and p in (1) and assigned 5 RB functions for each (15 outputs in total, $y(t) \in \mathbb{R}^{15}$). To train the RRNN, five different samples of inputs $u(t)$ are fed into the structure and the coefficients of the hidden layer (W and b) are regulated to minimize the mean-squared error between the RRNN outputs and the temporal variations of the coefficients of the RB functions obtained after applying POD to the snapshots.

To test the RRNN generalization, a new input is provided for the network and the comparison of the state variables has been performed. The evolution of the state variables α_g at the inlet of the computational domain and the pressure p at the outlet of the computational domain is shown in Figure 2 for the actual solution, the intrusive and the non-intrusive ROMs. The intrusive method gives unbounded and unstable solution over time although the nonlinear terms are approximated by 10 collateral basis functions using the Empirical Interpolation Method [5]; two times more accurate than the linear terms. On the other hand, the non-intrusive one gives reasonably accurate results and is much faster than the full-order model. The speedup (obtained by dividing the CPU time of solving the full-order model to the CPU time of solving the ROM) for the non-intrusive method is 71.1 while for the intrusive one is only 2.05. To increase the accuracy in approximating the gas volume fraction, the number of the RB functions should be increased; however, as the approximation of pressure is of higher importance, we are satisfied with the performance of the non-intrusive ROM.

Conclusions

In this work, a non-intrusive MOR is applied to the DFM to reduce its corresponding computational time. Contrary to the projection-based MOR that develops an unstable system, the non-intrusive method provides an accurate and a stable reduced-order system, which is solved much faster compared to the original model.

Reduced-order Modeling from Experimental Data via Spectral Submanifolds

Mattia Cenedese, Joar Axås and George Haller
Institute for Mechanical Systems, ETH Zürich, Switzerland

Summary. Reduced-order modeling is among the leading theoretical and computational challenges for data concerning nonlinear systems in mechanics, ranging from structures and fluid flows, to their interaction and other multi-physics problems. Data-driven model reduction methods are well-established for linear dynamical systems, while available approaches for nonlinear systems often reveal to be sensitive in the identified parameters, and to be limited in prediction capabilities. With this contribution, we present an approach based on the theory of spectral submanifolds, which captures explicit nonlinear models from data. Without specific assumptions on the type of observables or the kind of measurements, our method identifies nonlinear models that exhibit the footprint of geometric nonlinearities or nonlinear damping in the observed dynamics. Our reduced-order models, which are trained on decaying vibrations data, are also capable to accurately predict forced-responses of the nonlinear dynamical system. We show the performances of our algorithm on measurement data of oscillations in structural or fluid dynamics.

Introduction

In the context of data-driven reduced order modeling, the most common approaches in the literature are Principal Orthogonal Decompositions (POD) followed by Galerkin projections [1] or Dynamic Mode Decomposition (DMD) [2]. The former method, however, needs the knowledge of the governing equations of motion to retrieve the reduced dynamics, while DMD is purely data-driven, but it cannot capture essentially nonlinear (or *non-linearizable*) dynamics [3], as, for example, transitions between equilibrium states or nonlinear frequency responses of structural vibrations. Available approaches from machine learning tend to not be robust or easy to handle for extrapolation or prediction [4]. In this contribution, we present an approach based on the recent theory of spectral submanifolds (SSMs) [5] that can extract reduced-order models from generic observables capitalizing on normal forms.

Results and discussion

Our method is a two-step procedure, whose details are described in [7]. After having embedded the data in a suitable observable space (either by using Whitney or Takens-type embedding, depending on available measurements), we perform data-driven dimensionality reduction by modeling the SSM geometry. Our reduced coordinates are the projection to the modal subspace tangent to the SSM at the equilibrium, and the nonlinearities are described via polynomials. From these arbitrary coordinates, we then seek the reduced dynamics in normal form by minimizing the conjugacy error among data, and, for oscillatory problems, the general normal form related to m linearized modes of the system reads

$$\begin{aligned}\dot{\rho}_j &= -\alpha_j(\boldsymbol{\rho}, \boldsymbol{\theta})\rho_j, & j = 1, 2, \dots, m, & \quad m \geq 1, & \quad \boldsymbol{\rho} = (\rho_1, \rho_2, \dots, \rho_m), & \quad \boldsymbol{\theta} = (\theta_1, \theta_2, \dots, \theta_m). \\ \dot{\theta}_j &= \omega_j(\boldsymbol{\rho}, \boldsymbol{\theta}),\end{aligned}\tag{1}$$

The maps α_j and ω_j are the nonlinear continuations of linearized frequency and damping, identifying how dissipation and frequency change with respect to the normal form modal amplitudes $\boldsymbol{\rho}$ and eventually phases $\boldsymbol{\theta}$, whose latter dependence is only showing up in internally resonant systems. We also remark that our modeling approach when related to multiple non-resonant modes do not assume the modes to be uncoupled. We use (1) to study the dynamics and make predictions for eventual forced responses, and afterwards, using the SSM geometry, we can trace back normal form amplitudes to physical observed quantities. To show the performance of our method in capturing the nonlinear behavior in systems with different physics, we consider an example in fluid-structure interaction and one featuring structural vibrations.

We first consider the liquid sloshing example from [6, 7] depicted in Fig. 1(a), where measurements are carried out via a laser system and the excitation is provided by moving the platform onto which the tank sits. We set our observable to be horizontal position of the water center of mass and we focus on the slowest system mode. We train our SSM-based model from the resonance decay data shown in Fig. 1(b) using cubic nonlinearities, showing already good accuracy in reconstructing test trajectories. The model identifies the nonlinear backbone curves, characterizing damping $\alpha(\rho)$ and frequency $\omega(\rho)$, and is then used to compute frequency responses, which follows the reduced dynamics

$$\dot{\rho} = -\alpha_0\rho - \beta\rho^3 + f\sin(\psi), \quad \dot{\psi} = \omega_0 + \gamma\rho^2 - \Omega + \frac{f}{\rho}\cos(\psi),\tag{2}$$

where Ω is the forcing frequency, f the forcing amplitude and $\psi = \theta - \Omega t$ the phase lag. Forced periodic solutions can be sought in closed form from eq. (2). In Fig. 1(c), we show these forced responses, where the dots are experimental measurements for different forcing frequency and forcing amplitude values, while solid lines are predictions from (2), after proper calibration for finding the normal form forcing amplitude f . Even though our model has been trained only on unforced data, it exhibits great accuracy in predicting forced responses (thanks to our detailed modeling of softening and of nonlinear damping), also for amplitudes being higher with respect to those of training data.

Another example is the two-beam system of Fig. 1(d). The first two modes of this assembly feature a 1 : 2 internal resonance and system nonlinearities are due to weak frictional contact happening at the joint between the inner beam and

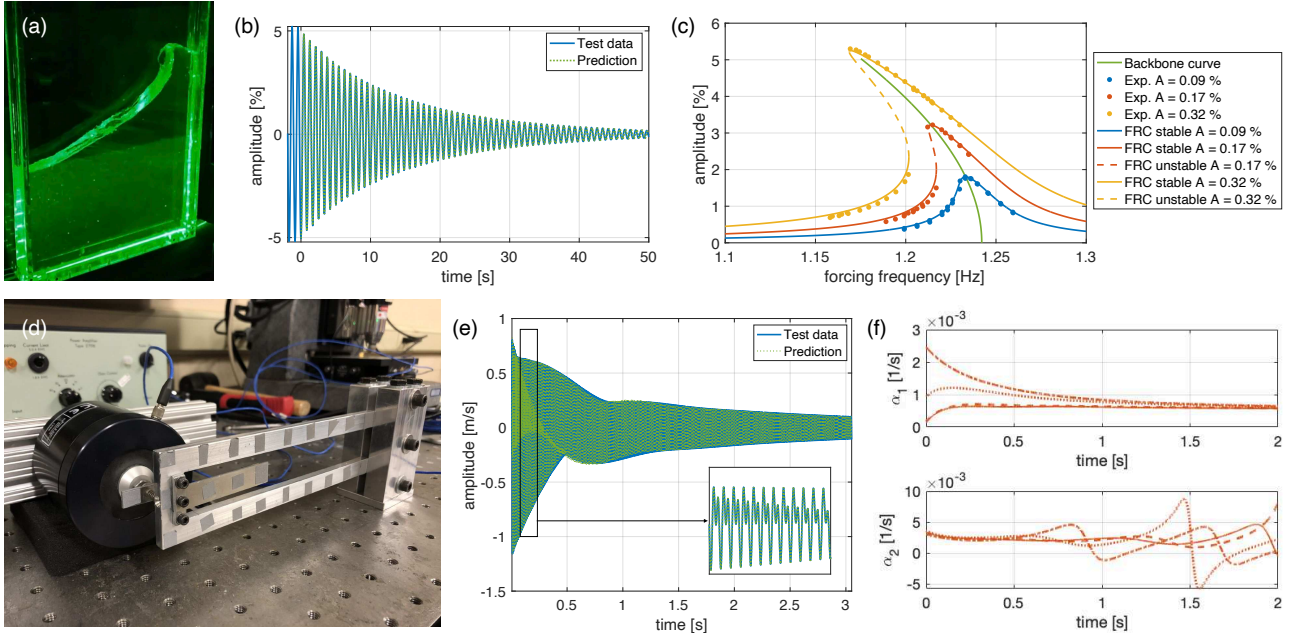

Figure 1: (a) Photo of measurements of liquid sloshing in a tank. (b) Decaying oscillations released from resonant quadrature forcing with model predictions. The amplitude is the horizontal displacement of the center of mass of the water inside the tank, expressed in percentage after normalization with respect to the tank width. (c) Analytical Forced Response Curves (FRCs), the damped backbone curve (blue solid line) and experimental measurements for different forcing amplitudes and frequencies. (d) Picture of the resonant tester structure. (e) Decaying resonant oscillations excited via hammer impact of the inner beam along with model predictions. The amplitude is the velocity of the inner beam tip. (f) Nonlinear damping trends for the slow α_1 and fast α_2 modes along some decaying trajectories.

the external one, which is clamped to the ground on the other side. Decaying vibrations are excited using hammer impacts on different locations of the inner beam and our observable is the inner tip velocity measured via laser scanner vibrometry. Due to internal resonance, transients show two dominant frequencies, cf. Fig. 1(e), as they very quickly converge to the slow four-dimensional SSM, i.e., related to the two slow system modes. In this case, our method automatically detects the internal resonance from data and it identifies a cubic order model with the specific form

$$\begin{aligned}
 \dot{\rho}_1 &= -\alpha_{0,1}\rho_1 - \beta_{11}\rho_1^3 - \beta_{12}\rho_2^2\rho_1 - \rho_1\rho_2(\sigma_{11}\cos\psi - \sigma_{12}\sin\psi), \\
 \dot{\rho}_2 &= -\alpha_{0,2}\rho_2 - \beta_{21}\rho_1^2\rho_2 - \beta_{22}\rho_2^3 - \rho_1^2(\sigma_{21}\cos\psi + \sigma_{22}\sin\psi), \\
 \rho_1\dot{\theta}_1 &= +\omega_{0,1}\rho_1 + \gamma_{11}\rho_1^3 + \gamma_{12}\rho_2^2\rho_1 + \rho_1\rho_2(\sigma_{11}\sin\psi + \sigma_{12}\cos\psi), \\
 \rho_2\dot{\theta}_2 &= +\omega_{0,2} + \gamma_{21}\rho_1^2\rho_2 + \gamma_{22}\rho_2^3 + \rho_1^2(\sigma_{22}\cos\psi - \sigma_{21}\sin\psi),
 \end{aligned} \tag{3}$$

where $\psi = \theta_2 - 2\theta_1$ is the internal phase shift. Our data-driven model is able to reconstruct trajectories test with an average 1.2 % error, as in the example of Fig. 1(e). In particular, the damping of the fast mode undergoes consistent variation as shown in Fig. 1(f), becoming also negative for some times, since the fast mode tries to absorb energy from the slow mode. Additional details of this example are reported in [8].

Our data-driven approach is implemented on the open-source MATLAB® package SSMLearn, which is to be released soon. Other than the source code, the repository contains the data sets discussed in this contribution and the live-scripts with their analysis, and also additional worked examples.

Summary. This abstract proposes an approach for parametric system identification for a class of continuous-time Lur'e-type systems. To overcome the computational drawbacks of numerical forward integration, the Mixed-Time-Frequency (MTF) algorithm is used to compute model responses in a fast way. These model responses are required to evaluate the cost function, which quantifies the mismatch between the measured and simulated steady-state output response. Furthermore, we show that the gradient of the cost function with respect to the model parameters can also be computed using the MTF algorithm. Hence, the MTF algorithm facilitates efficient use of global and local optimization methods to minimize the cost function, which yields the identified parameter set. Finally, by enforcing the identified model to be inside the set of convergent models, we certify a stability property of the identified model, which allows for safe generalization to other inputs than those used to train the model. The proposed approach is successfully applied in mechanical ventilation, where parameters of a first-principle model are identified. This case study highlights the benefits of the proposed approach.

Identification Problem

A practically relevant class of nonlinear systems is the class of Lur'e-type systems, see Figure 1. In such systems, the linear time-invariant (LTI) dynamics are captured in an LTI block and all the nonlinearities are captured in a static nonlinear block placed in the feedback loop. We consider the problem of parametric identification of so-called continuous-time *convergent* Lur'e-type systems. Convergent systems are systems that, for any bounded input, have a unique, globally asymptotically stable (GAS) steady-state solution that is bounded on the whole time axis [3]. For the class of Lur'e-type system, sufficient conditions for exponential convergence exist [5]. Our goal is to find parameters of the Lur'e type system that ensures the closest fit between the steady-state model response and the measured steady-state output response, while also ensuring that the identified model is convergent. We consider the case where both the input $w(t)$ and output $z(t)$ are scalar. The feedback signals $y(t)$ and $u(t)$ are considered *not measured*.

A property of convergent systems is that for T -periodic input $w(t)$, the steady-state output $z(t)$ is also T -periodic, facilitating the use of only steady-state data for the purpose of identification. The considered cost function, measuring the squared identification error, is given by

$$J(\theta) = \frac{1}{N} \sum_{k=0}^{N-1} \epsilon(t_k, \theta)^2 := \frac{1}{N} \sum_{k=0}^{N-1} (z_{\text{simulated}}(t_k, \theta) - z_{\text{measured}}(t_k))^2 \quad (1)$$

with θ being the model parameter vector, parameterizing the LTI system matrices and the nonlinearity in Figure 1, N the number of samples in one period, t_k the sampling times (uniformly spaced) and $z_{\text{simulated}}(t, \theta)$, $z_{\text{measured}}(t)$, the simulated and measured steady-state response, respectively. Next, we define Θ as the set of parameters θ which renders the considered Lur'e-type model convergent. The objective is to minimize $J(\theta)$ in (1) while ensuring convergence by guaranteeing $\theta \in \Theta$. We consider the state dimension to be known and the model parametrization to be given by the user. The identification problem can now be formulated as follows:

$$\hat{\theta} = \arg \min_{\theta \in \Theta} J(\theta). \quad (2)$$

Cost Function Minimization

The constrained optimization problem (2) is solved in a two-step fashion. In the first step, initial parameter estimates are obtained. If the model is derived from first-principle modeling, then the user could provide initial parameter estimates based on physical insights. Otherwise, the best linear approximation [4] can be used, which yields a *linear* initial model in a fast way. Alternatively, any global parameter search algorithm [1] can be used, which results in a full *nonlinear* initial model, however, at the expense of computational time.

In the second step, a gradient-based search is used to optimize all parameters of the full nonlinear model. In order to evaluate the cost function (1), computation of the model response is required. Doing this using numerical forward

Figure 1: Considered Lur'e-type system.

Figure 2: Experimental setup of mechanical ventilation.

Figure 3: Realistic breathing pattern.

Figure 4: Measured response and remaining errors as defined in (1).

integration is a computationally expensive task. Therefore, for the class of convergent Lur'e-type systems, [3] developed the so-called Mixed-Time-Frequency (MTF) algorithm. This algorithm computes iteratively the response of the LTI block in frequency-domain and the response of the static nonlinearity in time-domain, which are both computationally efficient steps. It can be shown that for convergent Lur'e-type systems, this iterative computational approach is guaranteed to converge, ensuring the accurate and fast computation of the 'true' steady-state model response.

Besides the steady-state model response, also the gradient of the cost function (1) with respect to the model parameters is required in any gradient-based optimization approach to minimize the cost function in (1). One of our main contributions of this work is to show that this gradient can be obtained by simulation of a *parameter sensitivity system*, which is again a *convergent Lur'e-type system*. Hence, again the MTF algorithm can be used as a means of fast and accurate computation of the output response of this sensitivity system to obtain the gradient of the cost function. Using well-established optimization routines [2], the constrained optimization problem (2) can then be solved in a fast way by exploiting the computational benefits of the MTF algorithm.

Experimental Case Study in Mechanical Ventilation

The proposed approach is applied to find the parameters of a first-principles model of the mechanical ventilation setup schematically depicted in Figure 2. Mechanical ventilation is used in intensive care units to assist or stimulate respiration of patients who are unable to breathe on their own. The blower realizes the pressure p_{blower} by an internal control-loop which tracks the target breathing cycle p_{target} , both depicted in Figure 3. The measured pressure p_{blower} is considered as the input of the system. Air flows through a hose into the lungs of the patient, where at the patient-side of the hose the airway pressure p_{airway} is measured and considered as the output of the system. Also an intentional leakage component with known characteristics is present in order to refresh the air to the patient. Using first-principles modeling, a Lur'e-type model characterized by five parameters can be derived. The static nonlinearity in the model stems from the nonlinear pressure-flow characteristic of the hose, being characterized by a linear and quadratic resistance. Rather than using humans in these experiments, the ASL5000 breathing simulator is used, which simulates the lung behavior of patients, being characterized by a resistance and compliance parameter. The fifth parameter is the resistance of the leakage component, which is known by means of calibration. The case where the patient is fully sedated is considered, which implies no breathing activity from the patient.

A one minute experiment is performed where 15 periods of the 4 seconds periodic input depicted in Figure 3 are applied to the system. The average of the last 12 periods of p_{blower} and p_{airway} are used as *steady-state* input and output data, respectively, for the purpose of identification. Such a short experiment time is of crucial importance in this application as time is extremely costly in such medical settings. Parameters of an 'average' patient model are used to initialize a gradient-based exterior-point optimization algorithm to minimize the cost function in (1).

The measured steady-state output p_{airway} is depicted in Figure 4, together with the error obtained by the initial model $\epsilon_{Initial}$ (this is a model with *average* patient-hose parameters) and the model obtained after the gradient-based search ϵ_{Final} . For comparison, also the error of an identified *linear* model (using subspace techniques) is plotted in Figure 4. In this figure, the benefits of identifying a nonlinear model are clearly visible as it yields a much smaller error than the initial and linear model. This is also confirmed by the yielded cost (1), which is 2.55 for the initial model, 2.40 for the linear model and 0.17 for the final model. Furthermore, as we performed *parametric* system identification, the parameters of the model represent physical quantities that reveal important medical information on the patient and medical ventilation equipment, which are useful for medical personnel. To illustrate the computationally efficiency, a total of 1530 model responses were computed in *only* 13 seconds in the gradient-based search. The obtained model is guaranteed to exhibit the *convergence* property, which is highly instrumental for prediction purposes in controller design in mechanical ventilation.

Summary. Dry friction laws like the Coulomb law and many of its extensions predict forces that are discontinuous functions of slip velocity. In state space, this discontinuity occurs along discontinuity manifolds corresponding to sticking of the physical contacts. Previous works studied the dynamics induced by these models when the discontinuity manifold is codimension-one (Coulomb law in 2 dimensions) or codimension-two (Coulomb friction in 3 dimensions). Here we investigate the dynamics in more general contact models, which leads to higher codimension discontinuity manifolds. In particular, we analyse in details the Coulomb-Contensou friction model describing the friction forces and torques at a finite-sized contact area. Among others we show that the direction of slip velocity as well as the ratio between the spinning angular velocity and the slip velocity have predictable values at each transition between slip and stick.

Dynamics induced by discontinuous friction models

If completely rigid bodies are assumed with a single-point contact, the Coulomb friction law describes the friction force as a nonsmooth function of slip velocity. Namely,

$$\vec{\lambda}_f = -\mu\lambda_n \frac{\vec{s}}{|\vec{s}|}, \quad (1)$$

where $\lambda_n > 0$ is the normal force between the surfaces, $\vec{\lambda}_f$ is the tangential (friction) force, \vec{s} is the relative velocity between the surfaces at the contact point, and μ is the friction coefficient. This model involves a discontinuity when $|\vec{s}| = 0$. In the case of planar (two-dimensional) friction problems with Coulomb friction, the discontinuity occurs along a codimension-1 manifold in phase space [1]. Such systems belong to the class of Filippov systems, for which a well-established theory describes when and how systems converge to discontinuity manifold and how they continue to evolve after that point.

When a planar model involves several point contacts, each of them induces a codimension-1 discontinuity manifold. These manifolds may intersect giving rise to secondary discontinuity manifolds of higher codimension, and a hierarchical system of discontinuities. The theory of Filippov systems was extended to such systems in [2] and [3].

A qualitatively different scenario occurs in the case of spatial (three-dimensional) friction problems. In that case, the Coulomb law gives rise to a discontinuity along an isolated codimension-2 manifold where both components of the slip velocity \vec{s} vanish simultaneously. This lead to the recent introduction of the concept of *extended Filippov systems*, and the development of theory describing how systems behave in the neighbourhood of such discontinuities [4]. Among others, special features of slip-stick transitions, and the conditions of persistent stick motion were developed.

The Coulomb friction law requires refinement and extension where the stiffness of the contacting bodies is not large enough. Then, the local normal deformations have to be considered which creates a finite contact area. The Coulomb friction can be applied *locally* between the tangential and normal force distributions. By integration over the contact area, the resultant friction force $\vec{\lambda}_f$ and the friction torque τ_f can be computed with respect to a reference point of the contact area. This calculation can be found in the literature by using appropriate series expansion and closed form analytical approximations [5, 6]. It was found that the relative *slipping velocity* \vec{s} and the *spinning angular velocity* ω are coupled in the tangential force $\vec{\lambda}_f$ and the drilling torque τ_f . According to those result in the literature, a simple phenomenological approximation of the friction law can be given as

$$\vec{\lambda}_f = -\mu_\lambda \lambda_n \frac{\vec{s}}{\sqrt{|\vec{s}|^2 + (c_\omega \omega)^2}}, \quad (2)$$

$$\tau_f = -\mu_\tau \lambda_n \frac{c_\omega \omega}{\sqrt{|\vec{s}|^2 + (c_\omega \omega)^2}}. \quad (3)$$

In (2)-(3), μ_λ , μ_τ are dimensionless coefficients proportional to the friction coefficient μ , and the model parameter c_ω characterises the interaction between the translational and rotational friction effects. As a limit case for very large local stiffness of the bodies, the contact area becomes a contact point, and these parameters are assumed to tend to $\mu_\lambda \rightarrow \mu$, $\mu_\tau \rightarrow 0$ and $c_\omega \rightarrow 0$. In this limit case, (2) leads to the Coulomb friction law (1) with a codimension-2 discontinuity. However, for a finite contact stiffness, the model has a discontinuity when $|\vec{s}| = 0$ and $\omega = 0$ at the same time. It means a codimension-3 discontinuity, but friction models including coupling between rolling and slipping (see e.g. [7]) are expected to initiate discontinuity manifolds up to the codimension-5 case. Currently there is no theory describing this class of non-smooth dynamical systems.

Figure 1: A projection of the 2-sphere with an example of the vector field representing fast dynamics of a slipping contact in the presence of the friction model (2)-(3). The curves represent nullclines of the dynamics. The field has 6 fixed points at the intersections of the nullclines.

Vector fields with higher codimension discontinuities

The recent theory of *extended Filippov systems* [4] addresses dynamics of a system with state variables \vec{x} in the neighborhood of a codimension-2 discontinuity manifold of state space that occurs at $\vec{u}(\vec{x}) = 0$ for some $\vec{u}(\vec{x}) \in \mathbb{R}^2$. The theory is based on the observation, that the variable \vec{u} can be replaced by polar variables $r = |\vec{u}|$, and $\phi = \arg(\vec{u})$ (i.e. the angle of \vec{u}). Then, for $r \ll 1$, ϕ evolves on a faster time-scale than r . The theory of smooth slow-fast dynamical systems offers an efficient tool to analyze the emerging dynamics. In most cases, ϕ rapidly converges to fixed points, and the slow dynamics of r is evaluated at those points.

Here, we apply the same technique to systems where a codimension n discontinuity occurs at $\vec{u} = 0$, $\vec{u} \in \mathbb{R}^n$. We again decompose \vec{u} to a slow variable $r \in \mathbb{R}$ and fast variables $\vec{\phi} \in \mathbb{S}^{n-1}$ over the $n-1$ sphere. In many cases, the fast dynamics converges to fixed points, where the one-dimensional slow dynamics can be analyzed easily.

Application to the dynamics of finite-sized contacts

Consider a rigid multi-body system with smooth behavior except for one single finite-sized contact area with dry friction. The state variable \vec{x} consists of the generalized coordinates \vec{q} and their time derivatives $\dot{\vec{q}}$. The equations of motion and kinematic constraints enable one to develop equations for the dynamics of the slip velocity \vec{s} and angular velocity of slip ω in the following form:

$$\dot{\vec{u}} := \begin{bmatrix} \dot{\vec{s}} \\ \dot{\omega} \end{bmatrix} = \mathbf{M}^{-1}(q) \begin{bmatrix} \vec{\lambda}_f \\ \tau_f \end{bmatrix} + \vec{b}(q, \dot{q}) \quad (4)$$

Here \vec{b} is the acceleration in the absence of frictional forces and \mathbf{M} is a 'local mass matrix' associated with the reference point of the contact region. One can combine this equation with a friction model like (2)-(3). Then, replacement of \vec{u} by the variables r and $\vec{\phi}$ as described above uncovers intriguing fast dynamics over the 2-sphere when $r \ll 1$ (Fig. 1). It appears that the limit sets of the fast dynamics are two to six fixed points. The slow dynamics is either convergence to or divergence from $r = 0$ (i.e. stick) at each of the fixed points. This observation implies that slip-stick and stick-slip transitions always occur through non-trivial combinations of rotational and translational motion at the contact surface. The analysis also hints at the possibility of ambiguous cases where persistence of stick is undecidable within the scope of rigid body theory.

Nonsmooth Modal Analysis of a Rectangular Plate in Unilateral Contact

David Urman and Mathias Legrand

Department of Mechanical Engineering, McGill University, Montreal, Canada

Summary. A scheme for the nonsmooth modal analysis of a rectangular plate in frictionless unilateral contact with a rigid foundation is demonstrated. Application of nonsmooth modal analysis requires finding periodic solutions to the Signorini problem. To this end, the nodal boundary method in the framework of the finite element method is used. It allows to approximate the solution through a system of nonsmooth ordinary differential equations in the internal displacements of the plate. The resulting system exhibits chattering-free periodic solutions numerically found via the harmonic balance method. Sequential continuation is used for detection of nonsmooth modes.

Introduction

Nonsmooth modal analysis (NMA) refers to the application of nonlinear modal analysis on structures for which the dynamics is governed by nonsmooth equations [7]. In the present work, the subject of analysis is a rectangular plate, with in-plane displacements, in unilateral contact with a rigid obstacle expressed via the usual Signorini complementarity conditions [1]. In essence, NMA requires the detection of families of periodic motions to the autonomous system [5, 7, 9]. Generally, NMA requires use of numerical techniques since closed-form solutions to the Signorini problem do not generally exist [7, 9]. In [9], the wave finite element method (WFEM) was used for NMA of the bar and has proven to provide accurate result for the case of the uniform-area bar. However, extension of this methodology to two-dimensional systems has failed due to high numerical energy dissipation effectively annihilating periodic solutions [9]. The finite element method (FEM) has also been commonly used to solve the Signorini problem numerically [3]. In the FEM framework, there exist several numerical schemes for treatment of the Signorini conditions. However, those were not used for NMA for various reasons. For example, schemes utilizing a fully elastic Newtonian impact law exhibit non-physical chattering [3, 7] while the penalty [3] and Nitsche [2] methods do not exactly enforce impenetrability with the obstacle in the discrete setting. The mass redistribution method (MRM) [4], while allowing for energy conservation and elimination of chattering, requires solving a constrained optimization problem in many variables to form the reduced mass matrix. However, the *Nodal Boundary Method* (NBM) eliminates chattering by reducing the mass and stiffness matrices via a series of linear operations on the mass matrix's rows and columns [8]. The ordinary differential equations (ODEs) resulting from NBM exhibit periodic solutions which can be found via the harmonic balance method (HBM) [8]. Continuous families of periodic solutions are then found via sequential continuation along different periods of the motion [5].

Boundary Value Problem for Periodic Motions with Unilateral Contact

Within the framework of two-dimensional in-plane elasticity, we investigate the problem of a thin and isotropic plate prone to unilateral contact with a rigid foundation. The equation governing the motion of the plate reads

$$\rho \bar{\mathbf{u}}_{tt}(\mathbf{x}, t) - \mathbf{div}(\boldsymbol{\sigma}(\bar{\mathbf{u}}(\mathbf{x}, t))) = \mathbf{0}, \quad (\mathbf{x}, t) \in \Omega \times [0, \infty) \quad (1)$$

where $\bar{\mathbf{u}}(\mathbf{x}, t) : \mathbb{R}^2 \times \mathbb{R}^+ \rightarrow \mathbb{R}$ and ρ describe the displacement field and density, respectively. The stress tensor $\boldsymbol{\sigma}(\bar{\mathbf{u}}(\mathbf{x}, t))$ is related to the displacements via a classical plane-stress assumption. Other than the classic Neumann and Dirichlet boundary conditions, a portion Γ_C of the plate's boundary is prone to the unilateral contact conditions

$$0 \leq g_0 - \bar{\mathbf{u}}(\mathbf{x}, t) \cdot \mathbf{n}, \quad \sigma_n \leq 0, \quad (g_0 - \bar{\mathbf{u}}(\mathbf{x}, t) \cdot \mathbf{n}) \sigma_n(\bar{\mathbf{u}}(\mathbf{x}, t)) = 0, \quad \mathbf{x} \in \Gamma_C \quad (2)$$

where g_0 defines the distance between the non-deformed boundary and the rigid obstacle. The contact pressure is captured by $\sigma_n(\bar{\mathbf{u}}(\mathbf{x}, t)) = \mathbf{n}^\top \boldsymbol{\sigma}(\bar{\mathbf{u}}(\mathbf{x}, t)) \mathbf{n}$ where \mathbf{n} is the outward normal to the contact boundary. For NMA, we search for solutions of period T such that $\bar{\mathbf{u}}(\mathbf{x}, 0) = \bar{\mathbf{u}}(\mathbf{x}, T)$ and $\bar{\mathbf{u}}_t(\mathbf{x}, 0) = \bar{\mathbf{u}}_t(\mathbf{x}, T)$.

Nodal Boundary Method

The NBM applies on the FEM formulation of the Signorini problem, stated in Equations (1) and (2), which takes the form

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{G}^\top \boldsymbol{\lambda}(t) \quad (3)$$

$$\boldsymbol{\lambda}(t) + \max(\mathbf{0}, \mathbf{g}\mathbf{1} - \mathbf{u}_C(t) - \boldsymbol{\lambda}(t)) = \mathbf{0} \quad (4)$$

where $\mathbf{u}(t) \in \mathbb{R}^N$ constitute the N nodal displacements approximating the displacement field $\bar{\mathbf{u}}(\mathbf{x}, t) \approx \mathbf{P}(\mathbf{x})\mathbf{u}(t)$ with $\mathbf{P}(\mathbf{x})$ denoting piecewise-Lagrangian shape functions. In the NBM, we distinguish between nodal displacements $\mathbf{u}_C(t)$ on Γ_C and the remainder of the nodal displacements $\mathbf{u}_O(t)$ such that $\mathbf{u}(t) = (\mathbf{u}_O(t) \ \mathbf{u}_C(t))^\top$. It is well known that formulation (3) and (4) form an ill-posed problem due to the existence of infinitely many values for $\boldsymbol{\lambda}$ at the moment of contact [1]. In the NBM, we attempt to resolve this ill-posedness by assigning $\boldsymbol{\lambda}$ a relationship with $\mathbf{u}(t)$ via the FEM

approximation of the boundary integral on Γ_C :

$$\mathbf{G}^T \boldsymbol{\lambda} \leftarrow \int_{\Gamma_C} \mathbf{P}^T(\mathbf{x}) \sigma_n(\mathbf{P}(\mathbf{x}) \mathbf{u}(t)) d\mathbf{x} = \mathbf{G}^T (\mathbf{N}_C \mathbf{u}_C(t) + \mathbf{N}_O \mathbf{u}_O(t)) \quad (5)$$

where \mathbf{N}_C and \mathbf{N}_O are constant matrices. Substitution of (5) into (4) results in an LCP in $\mathbf{u}_C(t)$ admitting a unique solution for given $\mathbf{u}_O(t)$ and g . This unique solution consists of piecewise constant matrix $\mathbf{A}(\mathbf{u}_O(t), g)$ and vector $\mathbf{d}(\mathbf{u}_O(t), g)$ such that $\mathbf{u}_C(t) = \mathbf{A}(\mathbf{u}_O(t), g) \mathbf{u}_O(t) + g \mathbf{d}(\mathbf{u}_O(t), g)$. The values of \mathbf{A} and \mathbf{d} can be found numerically by solving the LCP. From this expression, we construct the NBM approximation of the displacement which always satisfies (4) and (5) along with the FEM approximation of the Signorini conditions

$$\bar{\mathbf{u}}(\mathbf{x}, t) \approx \mathbf{P}(\mathbf{x}) (\mathbf{A}^*(\mathbf{u}_O, g) \mathbf{u}_O(t) + \mathbf{d}^*(\mathbf{u}_O, g)), \quad \mathbf{A}^*(\mathbf{u}_O, g) = \begin{bmatrix} \mathbf{I} \\ \mathbf{A}(\mathbf{u}_O, g) \end{bmatrix}, \quad \mathbf{d}^*(\mathbf{u}_O, g) = \begin{bmatrix} \mathbf{0} \\ \mathbf{d}(\mathbf{u}_O, g) \end{bmatrix}. \quad (6)$$

In the FEM framework, substitution of approximation (6) into (3) yields the system of ODEs

$$(\mathbf{A}^*(\mathbf{u}_O, g))^T (\mathbf{M} \mathbf{A}^*(\mathbf{u}_O, g) \ddot{\mathbf{u}}_O(t) + \mathbf{K} \mathbf{A}^*(\mathbf{u}_O, g) \mathbf{u}_O(t) + \mathbf{K} \mathbf{d}^*(\mathbf{u}_O, g)) = \mathbf{0} \quad (7)$$

which are nonsmooth ODEs (due to \mathbf{A}^* and \mathbf{d}^*) in $\mathbf{u}_O(t)$. Periodic solutions of the ODE can be found via the HBM [8]. Then, sequential continuation is used to determine families of periodic solutions of the plate in unilateral contact, in a similar fashion to [5].

Figure 1: Forced response of the plate for various damping coefficients ξ and backbone curves generated via NBM-HBM with varying number of harmonics N_h .

Figure 2: Solution at point A in Figure 1 at different times fractions of the period $T = 2\pi/1.87$. Color gradient represents $\|\mathbf{u}(\mathbf{x}, t)\|_2$

Conclusions

Under the NBM's formulation of the Signorini problem, NMA of the plate was conducted successfully. Indeed, this formulation may apply to more intricate structures prone to unilateral contact. Therefore, future work shall include expanding the NBM formulation to practical engineering cases. Also, comparison of NBM against Nitsche method for purposes of NMA is considered. While Nitsche applies the Signorini conditions in a weak sense, the NBM does so in a strong sense and it is of interest to compare the rates of convergence of both methods to the true solution.

Numerical Methods for Nonsmooth DAEs

Alexandre Rocca*, Vincent Acary* and Bernard Brogliato*

*University Grenoble-Alpes, Inria, CNRS, Grenoble INP, LJK, 3800 Grenoble, France (e-mail: firstname.surname@inria.fr)

Summary. In this work, we will discuss the various approaches to simulate hybrid differential algebraic equations (hybrid DAEs), i.e., dynamical systems with some algebraic constraints switching with respect to the state variables. Then, we will present our recent work on the simulation of such hybrid DAE through a reformulation as DAEs with non-smooth constraints. Finally, we show on some examples that numerical methods for non-smooth dynamical systems can be extended for the simulation of these non-smooth DAEs.

Hybrid DAEs are an increasing share of the simulated hybrid systems. They can be found in a large panel of engineering domains such as, but not limited to, chemical process engineering [15], electronics [1], for a long time in mechanical systems [4], and in numerous cyber-physical systems. In most of these domains, engineers rely on model-based design language such as Modelica [8] to define their dynamics in a piecewise manner using conditional statements. The resulting dynamical systems are of the form:

$$\begin{cases} \dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t), \mathbf{z}(t)) \\ 0 = \mathbf{g}_i(\mathbf{x}(t), \mathbf{z}(t)) \\ \forall (\mathbf{x}(t), \mathbf{z}(t)) \in \mathcal{X}_i. \end{cases} \quad (1)$$

The variables \mathbf{x}, \mathbf{z} are the differential and algebraic variables, respectively. The sets $\mathcal{X}_i = \{(\mathbf{x}, \mathbf{z}) \in \mathbb{R}^{n_1+n_2=n} \mid \mathbf{h}_i(\mathbf{x}, \mathbf{z}) > 0\}$ define a partition of \mathbb{R}^n such that: $\bigcup_i \mathcal{X}_i = \mathbb{R}^n$, $\text{int}(\mathcal{X}_i) \neq \emptyset$, for all i . In addition, let assume that $i \neq j$, $\partial\mathcal{X}_i \cap \partial\mathcal{X}_j = \emptyset$. Indeed, the definitions of the dynamics on the border of a partition are, in general, ambiguous.

Related Works

It is first worth to mention that some works, such as [14], have taken the approach of relaxing the non-smoothness inherent to the hybrid DAE using smooth versions of a step function such as the sigmoid function, Hill function, or the hyperbolic tangent. If these works enable a direct application of known numerical methods for non-linear DAEs, they, in general, worsen the numerical simulation efficiency due to the high stiffness, but also the numerical stability because of bad conditioning inherent to stiff systems. This was for example noted for the simulation of electronic systems with diodes [1].

Another approach, taken by V. Merhmann et al. [7, 11], is to use numerical methods defined for hybrid DAE structured as hybrid automata. Their implementation relies on event based numerical methods and explicit transition functions to correctly re-initialise the system after switching. It is noteworthy that they detect and simulate in some particular case sliding modes in a similar fashion to Filippov sliding motion [6] for ODEs. In particular, this concept of continuous solutions for hybrid DAE as been formalised and studied by I.V Matrosov [9, 10] in an unrelated work. The work of A. Benveniste et al. [3] uses non-standard analysis to construct well-defined transitions from one mode to another in the context of hybrid DAE even in presence of varying index. In particular, this work pairs well with [11] as the definition by the user of the DAE initialisation at switching is not needed anymore. It is also worth to mention the work of S. Trenn [16] that defines the solutions of hybrid DAE with exogenous switching. In particular, he introduces the notion of distributional solutions which can also be used to efficiently solve inconsistent initial conditions.

Outside of the hybrid automata approach, the hybrid DAE have also been studied as non-smooth dynamical systems. For example, differential variational inequalities (DVI) form a class of non-smooth DAEs which are studied in [12]. In particular, they give well-posedness results, and some numerical methods are analysed, for DVI with a structure similar to index-1 DAEs. K. Camlibel et al. [5] extend results of well-posedness of differential inclusions to differential algebraic inclusions with maximal monotone operators. In additions, they study the well-posedness of non-smooth linear DAEs with some passivity properties.

Analysis of Non-smooth DAEs

In a previous work [13], we proposed to relax the switching algebraic equations $\mathbf{g}_i(\mathbf{x}, \mathbf{z}) = 0$ from (1) by filling-in the graph of the constraints. This is achieved by using step-functions $s^+(\cdot)$ in a similar fashion to [2] in order to build a generalised constraint.

$$\mathbf{g}(\mathbf{x}, \mathbf{z}) = \sum_i \left(\prod_{j \neq i} (1 - s^+(h_j(\mathbf{x}, \mathbf{z}))) \right) s^+(h_i(\mathbf{x}, \mathbf{z})) \mathbf{g}_i(\mathbf{x}, \mathbf{z}) = 0. \quad (2)$$

The actual definition of $\mathbf{g}(\mathbf{x}, \mathbf{z})$ will depend of the choice of the step-function definition when $h_j(\mathbf{x}, \mathbf{z}) = 0$. Then, we studied the effect of such relaxation in (3), a particular 2-dimensional example (see Figure 1), and we have shown that the constraint (2) is relaxed as a generalised equation, whose well-posedness can be studied. We show that the system with

the generalised constraint (2) presents continuous sliding solutions that are not exhibited by the methods of [11] and [9].

$$\begin{cases} \dot{x}_1(t) = 1 + B_1 z(t) \\ \dot{x}_2(t) = B_2 z(t) \\ 0 \in \text{sign}(x_1(t) + |x_1(t)| - x_2(t)). \end{cases} \quad (3)$$

Then, by studying the well-posedness of the implicit Euler numerical discretization of this example (4), we conjecture an extension of the implicit Euler numerical scheme for simulation of such non-smooth DAEs. This improved Euler numerical scheme has proven to yield good results on our example (see convergence results on Fig. 2).

$$\begin{aligned} p_{k+1}^* &:= \min_{\mathbf{x}_{k+1}, \mathbf{z}_{k+1}, \lambda_{k+1}} \|\mathbf{x}_{k+1} - \mathbf{x}_k\|, \\ \text{s.t. } & x_{1,k+1} - x_{1,k} = h(1 + B_1 z_{k+1}) \\ & x_{2,k+1} - x_{2,k} = h B_2 z_{k+1} \\ & 0 \in \text{sign}(x_{1,k+1} + |x_{1,k+1}| - x_{2,k+1}), \end{aligned} \quad (4)$$

In this work, we will extend this analysis the more general class of hybrid DAEs that can be formulated as mixed linear complementarity systems. Indeed, in [13], we have seen the constraint (2) can be expressed as mixed linear complementarity problems. We show that such representation can be used for the numerical simulation of a wide variety of systems involving hybrid DAEs. We provide both a study of implicit Euler discretization, and numerical simulations of concrete case studies implemented with SICONOS a toolbox for the simulation of non-smooth dynamical systems.

Simulation of a Hall Flowmeter Funnel with a novel non-smooth numerical procedure for granular media

Paul Profizi* and Alexandre Charles*†

**Safran Tech, Modeling & Simulation, Rue des Jeunes Bois, Châteaufort, 78114 Magny-Les-Hameaux, France*

†*Université de Technologie de Troyes, 12 rue Marie Curie, CS 42060 10004 Troyes CEDEX*

Summary. Previous work proposed a new NSCD procedure fixing convergence issues for small dynamical systems. We demonstrate here the resulting improved implicit solver efficiency compared to the existing Jean-Moreau scheme, when applied to large systems such as granular media.

Introduction

The Discrete Element Method [Cuneda and Strack, 1979] has emerged from rock mechanics problems and is now applied to many other engineering problems. Besides DEM, the lesser known NonSmooth Contact Dynamics procedure [Jean, 1999] offers an alternative procedure for this type of problems. This latter scheme, essentially a stable backward Euler scheme in time, is mathematically more sounded [Moreau, 1999]. However, Alart and Renouf [Alart and Renouf, 2018] point out that the procedure is still hampered by non- or slow-convergence pathologies linked with its incremental solver. In a previous work [Charles et al., 2018], a new NSCD procedure was set up to fix convergence issues in small (dof) dynamical systems simulations. Since one cannot expect this convergence to be granted for larger systems, the procedure is applied to granular media simulation and shows a great improvement in solver efficiency for these problems compared to Jean-Moreau.

Numerical procedure

Differences and common points with respect to the original Jean-Moreau NSCD scheme are shown in Table 1. Both are Backward Euler schemes with a midpoint update rule. However, at step 5, Jean and Moreau solve at the same time impact and dry friction whereas we solve first the frictionless impact and only then friction in a staggered way. Jean and Moreau's way conveys a very direct implementation but challenges the convergence of the Nonlinear Gauss Seidel. This leads to drift-off in the simulation due to the necessary cut-off in convergence search after a given (high) number of iterations is reached. Jean notes that "The method has proven in applications to behave nicely as soon as the time step is small enough and the friction coefficient is lying in the range allowed" [Moreau, 1999, Jean, 1999]. One can object the subsequent error being only controlled by refining the time step, this somehow cancels the advantage of using an NSCD method versus a DEM. The presented procedure instead conveys a more intricate implementation and the necessity at step 3 to infer, from Coulomb law, a dry friction constitutive law in terms of Lagrange's generalized forces. We show next that the current method does however scale well and the gain is worth the pain in the case of a Hall Flowmeter Funnel simulation.

2D Simulation of a Hall Flowmeter Funnel

The increase in efficiency for solving the contact conditions using the novel procedure is illustrated with the simulation of the flow of a granular medium under gravity through a funnel, inspired by the Hall Flowmeter Funnel. In Figure 1 the initial state of the simulation is shown, along with the state of the granular medium at two subsequent moments during the flow. This case was chosen due to the compacting phase the granular medium has to go through and the resulting multiple self-equilibrated contact force networks usually causing convergence issues.

Figure 1: Illustration of the 2D Hall Flowmeter funnel with evolution of the granular medium configuration with time for the same 50 particles (the radii following a normal distribution of average $0.3mm$ and a deviation of 5%) for both procedures and here with a time step of $1e^{-4}s$. The difference in behaviour due to higher interpenetrations for Jean Moreau is clearly visible.

The simulation is run using both procedures for a total simulated time of $0.1s$. The results in terms of CPU time and cumulative penetration error when varying the time step are given in Figure 2. The penetration error is the sum of particle interpenetrations as well as residual penetration of particles in obstacles.

Figure 2: Influence of time step on CPU time and cumulative error for both procedures in the case depicted in Figure 1.

The source for this difference in computational efficiency can be traced to the time spent iterating during the solving of the contact conditions as depicted in Figure 3. One clearly sees the NLGS of the Jean-Moreau procedure maxing out its (unusually high) number of allowed iterations while the novel approach, thanks to its preconditioning and reformulation of the problem, converges very quickly (in less than 100 iterations) even though it has to go through two NLGS.

Figure 3: Total NLGS iterations for contact resolution at each time step in the case depicted in Figure 1.

Take aways

In the presentation, a novel nonsmooth procedure, until then limited to small archetypal problems, is upscaled to the case of granular media. The final outcome is a swift integration in time (3 orders of magnitude faster than the typical JM NSCD for an equivalent penetration error). The procedure is also illustrated on a selective laser melting powder bed spreading.

Tangencies in the phase space of mechanical systems with spatial Coulomb friction

Mate Antal

Department of Applied Mechanics, Budapest University of Technology and Ec., Budapest, Hungary

Summary. When modelling dry friction between rigid bodies, the Coulomb friction law leads to discontinuity surfaces in the phase space of the resulting dynamical system. This discontinuity is a codimension-1 subspace in the case of a planar (two-dimensional) contact and it is a codimension-2 subspace in the case of a spatial (three-dimensional) contact. The qualitative mathematical description of the trajectories is well-established in the literature for the former case, and some results have been recently added to the latter topic by the author. In this work, the tangency points are analysed, which points divide the discontinuity surface to 'sliding regions' and 'crossing regions'. These regions coincide to the existence or non-existence of rolling-sticking solutions, thus, tangencies as boundary points are strongly related to these physical phenomena. The qualitative analysis of tangencies at codimension-2 discontinuities are carried out by analytical methods and the results are demonstrated on mechanical problems with spatial Coulomb friction.

Tangencies in piecewise smooth vector fields

The mathematical concepts are presented in the simplest geometrical case in the phase space, but the formulation can easily be modified for more general situations. Consider a dynamical system in the form $\dot{x} = F(x)$, where $x = (x_1, \dots, x_m) \in \mathbb{R}^m$. We assume that the vector field F is smooth on \mathbb{R}^m except in a *discontinuity set* $\Sigma = \{x : x_1 = 0\}$. We call F a *piecewise smooth* vector field according to the two smooth regions $x_1 > 0$ and $x_1 < 0$. The set Σ has $m - 1$ dimensions, thus, we call it a codimension-1 discontinuity. Consider the normal vector $n = (1, 0, \dots, 0)$ of Σ at a chosen point $\tilde{x} \in \Sigma$. If the limits

$$\lim_{\varepsilon \rightarrow 0^+} F(\tilde{x} + \varepsilon n) = F^+(\tilde{x}), \quad \lim_{\varepsilon \rightarrow 0^+} F(\tilde{x} - \varepsilon n) = F^-(\tilde{x}), \quad (1)$$

exist and $F^+(\tilde{x}) \neq F^-(\tilde{x})$ for all $\tilde{x} \in \Sigma$ then F is called a *Filippov-system*. In the vicinity of the discontinuity set, two generic types of behaviour occur according to the first components F_1^+ and F_1^- of the limit vectors. The case $F_1^+ \cdot F_1^- > 0$ is called *crossing*, where the trajectories of F can be continued through the discontinuity. The case $F_1^+ \cdot F_1^- < 0$ is called *sliding*. In this case, the so-called *sliding dynamics* can be defined inside Σ by using the convex set generated by F^+ and F^- (for the details, see [1] or [2]).

The boundary between these two cases is when $F_1^+ = 0$ or $F_1^- = 0$, which is called a *tangency point* or simply a *tangency*, because the vector field is tangent to the discontinuity set from either side. Tangencies separate the crossing and sliding regions of the discontinuity set. Tangencies are often considered as singularities of the phase space; the analysis of these points gives qualitative information about the local behaviour of the vector field. The simplest tangencies are called *invisible fold* and *visible fold* (see Figure 1), more complicated cases can be found in the literature (see [3] and Chapter 6 of [4]).

Figure 1: Two basic types of tangencies in piecewise smooth systems. Left panel: invisible fold. The term 'invisible' expresses that although the vector field is tangent to the discontinuity set Σ , we can find no finite trajectory which is tangent to Σ . Right panel: visible fold. The term 'visible' expresses that there exists a trajectory which just touches Σ at the tangency point.

Analysis of tangencies at codimension-2 discontinuities

Let us now turn to the systems with codimension-2 discontinuities. Consider a system $\dot{x} = F(x)$ in the case when F is smooth everywhere except in the set $\Sigma = \{x : x_1 = x_2 = 0\}$. That is, Σ is now a codimension-2 discontinuity. Then, the continuously many normal directions to Σ can be parametrised by an angle ϕ as $n(\phi) = (\cos \phi, \sin \phi, 0, \dots, 0)$. We assume that for all $\tilde{x} \in \Sigma$, the limit

$$\lim_{\varepsilon \rightarrow 0^+} F(\tilde{x} + \varepsilon n(\phi)) = F^*(\tilde{x}, \phi) \quad (2)$$

exist for all angles $\phi \in [0, 2\pi)$. Then, we can call the vector field as an extended Filippov system. In such systems, the sliding and crossing regions can be defined by transforming to polar coordinates and using the concept of limit directions

[5]. We can define the concept of tangency points directly by requiring that the vector field is *tangent* to the discontinuity if both components F_1^* and F_2^* of the limit vector vanish in the normal plane to Σ . That is, we call \tilde{x} a tangency point if there exists a direction $\phi_1 \in [0, 2\pi]$ such that $F_1^*(\tilde{x}, \phi_1) = 0$ and $F_2^*(\tilde{x}, \phi_1) = 0$.

In this work, the tangencies can be analysed by similar tools those of the tangencies of codimension-1 discontinuities. However, these methods should be adjusted to the specialities of the codimension-2 discontinuity set. The vector field can be transformed to a truncated series form and by analytical tools, the local structure of the trajectories can be determined. The singularity conditions of the different types of the tangencies are investigated. Moreover, regularization is applied at the discontinuity, which provides a further insight into the problem.

Tangencies and mechanical problems with Coulomb friction

When Coulomb friction is assumed between rigid bodies, the two-dimensional contact problem usually leads to a piecewise smooth system where $x_1 = u$ is the relative velocity at the contact point. Then, the static (*sticking* or *rolling*) contact state corresponds to the sliding dynamics inside the discontinuity set while the *slipping* state occurs outside the discontinuity. The sliding region coincides with the region where the rolling/sticking state is permitted by the friction model. Similarly, the crossing region coincides to the region where the sticking state is not available due to slipping. It can be shown [6] that in the case of spatial Coulomb friction with a codimension-2 discontinuity, the same coincidence appears between these mathematical objects of the phase space and the mechanical phenomena.

In both the planar and spatial cases, the tangencies are located at the boundary where the rolling/sticking motion becomes realizable. Therefore, the local analysis of the vector field at the tangencies can be applied to explore the behaviour of bodies at the limit of slipping.

Figure 2: A three-dimensional mechanical model containing tangencies as important singularities at the boundary of slipping and sticking. Left panel: the sketch of the model. A block is pulled on a rough surface with a spring. The mass of the block is m , the stiffness of the spring is s , the friction coefficient on the surface is μ , and the end of the spring is pulled with a constant velocity v . The state space of the block can be described by $x = (u_x, u_y, \delta)$ where u_x and u_y are the components of the slipping velocity of the block and δ denotes the deformation of the spring. Right: the sketch of the phase space of the system with the projection of some typical trajectories onto the normal plane of the discontinuity. The blue and red half-lines denote the attracting and repelling limit directions, respectively.

The results are demonstrated on mechanical examples. For example, consider Figure 2, where we can see a block pulled by a spring on a rough surface. Analysis of the phase phase shows that there are two tangency points and one of them are a visible fold, the another is an invisible fold. It can be shown that although trajectories can reach the sliding region of the discontinuity, the only way to leave it is going through the *visible fold tangency*, that is, any solution containing sticking must go through the tangency point. In more complicated problems with a higher dimension of the phase space, the tangency point form boundary surfaces in the discontinuity. These surfaces behave as separatrices between the qualitatively different branches of solutions.

The hidden bridge between continuous and discontinuous worlds and why period 2 may imply chaos

Viktor Avrutin*, Mike Jeffrey†

**Institute for Systems Theory and Automatic Control, University of Stuttgart, Germany*

†*Department of Engineering Mathematics, University of Bristol, Ada Lovelace Building, Bristol UK*

Summary. We report a recently developed approach for the investigation of discontinuous maps. Using so-called hidden orbits, we demonstrate that several aspects of the dynamics well-known for continuous maps can also be transferred to discontinuous maps. Moreover, hidden orbits help us to understand the dynamics of maps with steep branches, which are known to be hard to investigate otherwise.

Motivation

Discontinuous maps appear naturally in many areas of nonlinear dynamics. In some situations, they act as approximate models of systems where the rules governing the dynamic behaviour undergo a fast (but continuous) change at some borders in the state space. In other situations, the change of the rules at the boundaries is in fact discontinuous.

It is well known that many properties of discontinuous maps differ quite significantly from the corresponding properties of continuous ones. For example, it is easy to show that the famous rule “period three implies chaos” applies to continuous maps and does not apply to their discontinuous counterparts where a 3-cycle may exist alone. Similarly, bifurcation diagrams one can observe in continuous maps are well organized: for instance, the branches corresponding to stable solutions appearing at (smooth or non-smooth) fold and flip bifurcations are typically connected via branches corresponding to unstable solutions which appear at the same bifurcations and determine the basin boundaries of coexisting attractors. In discontinuous maps, such unstable branches may be missing, the stable solutions may appear at border collision bifurcations “as if from nowhere”, and the basins may be separated not only by unstable orbits but also by the discontinuities and their preimages. Chaotic attractors in continuous maps are always cyclic, while in discontinuous maps they may be acyclic as well. Because of these – and many other – differences, it is indeed hard to believe that the two worlds can be unified, i.e., that it is possible to develop an approach dealing with discontinuous maps in such a way that several properties of continuous maps are restored as far as possible.

Approach

A novel approach for the investigation of discontinuous maps has been recently suggested in [1]. The key idea of the approach is to extend the definition of a discontinuous map in such a way that at the discontinuities, the function is considered to be *set-valued* (in particular, for 1D maps, *interval-valued*). It is worth emphasizing that following this approach, the orbits of the map remain single-valued. An orbit visiting a discontinuity is mapped to a point belonging to the corresponding set; if an orbit visits the discontinuity again, it may be mapped to the same or to a different point. Accordingly, in addition to all orbits existing in the original discontinuous map, every time an orbit of such an extended map (referred to as a map with vertical branches) visits a discontinuity, an infinite number of forward orbits (so-called *hidden orbits*) is created. By construction, a *hidden orbit* is an orbit including points inside the discontinuities, and if a hidden orbit $\{x_n \mid n = 1, 2, \dots\}$ satisfies $x_{n+p} = x_n$ for all n , the orbit forms a *hidden cycle* of period p . Clearly, each hidden cycle is repelling and can easily be computed, as its points are given by preimages of the corresponding discontinuity.

Results

There are several different application areas for the proposed approach.

- When dealing with all kinds of discontinuous maps, the corresponding maps with vertical branches simplify the bifurcation analysis by adding to the bifurcation diagrams the “missing” unstable branches given by hidden cycles. In this way, by the bifurcation structures in discontinuous maps can be described in terms well-known for continuous maps: for example, the border collision bifurcations at which a cycle appears “as if from nowhere” turn into the usual border collision flip and fold bifurcations [2]. Hidden orbits unify also the treatment of basin boundaries: if in a discontinuous map these boundaries are given by a discontinuity and its preimages, in a corresponding map with vertical branches there is a (repelling) hidden cycle at the basin boundary, similarly to continuous maps.
- A discontinuous map may act as a model of a system with a very fast but continuous switching process. In such cases, a more detailed modeling leads to maps with steep branches which are quite hard to deal with (from the numerical point of view, but also because the laws governing the fast switching process are not always known). Here, a map with vertical branches provides an approximation for dynamics involving steep branches. Clearly, a cycle including points on a steep branch is strongly repelling and hard to find numerically. By contrast, to calculate a corresponding hidden cycle is a simple task, as it is given by a sequence of preimages of the discontinuity.

- By definition, a map with vertical branches is discontinuous but connected. Several fundamental theorems have been proven for continuous maps and do not apply to discontinuous ones. However, one may ask whether the requirement for continuity of the function may be relaxed and whether the connectedness would be sufficient as well. This is the case for the Sharkovsky theorem (which implies, in particular, the well-known rule “period three implies chaos”): this theorem can be proven not only for continuous but also for maps with vertical branches [3]. In this way, hidden cycles restore the Sharkovsky ordering, providing all cycles which are missing in the usual discontinuous map (without vertical branches). On the other hand, if one can prove that a hidden cycle of a certain period does not exist in a map with vertical branches, then a non-hidden cycle of this period must exist in the corresponding discontinuous map.
- A striking property of hidden orbits is that the existence of two distinct hidden cycles implies that a countable number of other hidden cycles and an uncountable number of hidden aperiodic orbits exist as well. Although all these orbits may be located at a final number of points in the state space (the points of discontinuities and their preimages), their union can be seen as a hidden chaotic repeller. It is worth noting that under perturbation of a map with a vertical branch to a map with a steep branch, this chaotic repeller persists, becoming non-hidden.

In the simplest case, the existence of a hidden fixed point and a hidden 2-cycle implies the existence of hidden cycles of all periods, which can be interpreted as an unexpected form of the well-known rule, namely “periods one and two imply chaos” [4].

Non-smooth Reduced Interface Models for Co-simulation of Mechanical Systems

Ali Raoofian*, József Kövecses* and Marek Teichmann[†]

**Department of Mechanical Engineering and Centre for Intelligent Machines, McGill University, 817 Sherbrooke St. West, Montreal, QC H3A 0C3, Canada*

[†]*CM Labs Simulations, 645 Wellington, Montreal, QC H3C 1T2, Canada*

Summary. In a co-simulation setup, an entire system is divided into multiple subsystems modelled separately which may be simulated with different solvers and time scales suited to the subsystems. These subsystems are then interfaced and coupled in order to simulate the whole system. For interactive rates, the non-iterative coupling schemes are used which are prone to instability. This problem can become more challenging when non-smoothness is introduced into the modelling. In this work, an efficient model-based coupling approach is introduced which is able to account for contact state transmissions between the communication points, resulting in more stable and accurate results compared to other coupling methods. To further clarify the advantages of the proposed approach, an illustrative example is also presented.

Introduction

Co-simulation is generally used to simulate systems consisted of different sub-systems with different nature; like multi-body systems interacting with hydraulics, electronics or even other mechanical sub-systems which are modelled with different phenomena. The main challenges for modelling such complex systems are related to the interfacing of these sub-system components. One challenge will raise when contact interactions are included in the modelling which introduces non-smoothness to the dynamics and increases the complexity of the model. Contact interactions which are also known as unilateral constraints, transform the underlying dynamics problem by adding inequalities into the dynamic formulation and turn it to a linear or a non-linear complementarity problem. In real-time applications, efficiency of the simulation is also a requirement, where we are usually interested in non-iterative co-simulation because there is not enough time to go back in time and resolve for a time step. Stability is a key element in non-iterative co-simulation which is related to the size of the macro time step. To make a co-simulation more stable, we can estimate the subsystem variables between the communication points and couple the subsystems. One promising way to estimate these variables is to use model-based coupling in which the mechanical system is reduced into an interface model that emulates the dynamics of the mechanical system at the interface. However, there still exist some aspects in model-based co-simulation which can be further improved.

In this work, we are looking at non-smooth interface models. The idea is that to add some information about the unilateral contacts of the full model in the interface model. This information would help us to estimate contact state changes during macro time step using an interface model. As will be illustrated, this will enable us to successfully simulate some dynamic behaviours which cannot be captured otherwise.

Dynamic formulation of the interface model

Consider a multibody system subjected to unilateral and bilateral constraints where friction is also neglected. In a general form, the dynamic equations of a multibody system can be written in the impulse-momentum level as

$$\hat{\mathbf{M}}\mathbf{v}^+ + h\hat{\mathbf{c}} = \mathbf{M}\mathbf{v} + h\mathbf{f}_a + h(\mathbf{A}_i^T\boldsymbol{\lambda}_i^+ + \mathbf{A}_b^T\boldsymbol{\lambda}_b^+ + \mathbf{A}_u^T\boldsymbol{\lambda}_u^+) \quad (1)$$

where the contents of the *modified mass matrix* $\hat{\mathbf{M}}$, and *modified Coriolis and centrifugal terms* $\hat{\mathbf{c}}$ are determined with the time discretization method used [1]. $\mathbf{q} = \mathbf{q}(t_k)$ and $\mathbf{v} = \mathbf{v}(t_k)$ are the generalized coordinate and velocity of the system which are related by the transformation $\dot{\mathbf{q}} = \mathbf{N}\mathbf{v}$ and are known at the instant t_k . Moreover, \mathbf{f}_a and $\boldsymbol{\lambda}_i$ are the applied and interface forces and \mathbf{A}_i is the corresponding interface Jacobian matrix. Similarly, $\boldsymbol{\lambda}_b$ and $\boldsymbol{\lambda}_u$ are the bilateral and unilateral constraint forces and their corresponding Jacobian matrices are \mathbf{A}_b and \mathbf{A}_u . Then, considering a time step of size h , its configuration, velocity and unknown constraint forces in the next time-step are shown with $+$ sign. The constraint and the interface velocity arrays are related to the generalized velocity array \mathbf{v} as $\mathbf{w}_j = \mathbf{A}_j\mathbf{v}$ ($j \equiv i, b, u$), which can be discretized through time using the first-order Taylor series expansion as

$$\mathbf{w}_j^+ = \mathbf{A}_j\mathbf{v}^+ + h\dot{\mathbf{A}}_j\mathbf{v} \quad (2)$$

Knowing that $\mathbf{w}_b = \mathbf{0}$, Eqs. (1) and (2) can be cast into a single matrix form which alongside the complementarity condition of the unilateral constraints will form a *Mixed Linear Complementarity Problem* (MLCP) as,

$$\left\{ \begin{array}{l} \left[\begin{array}{cccc} \hat{\mathbf{M}} & -\mathbf{A}_b^T & -\mathbf{A}_u^T & -\mathbf{A}_i^T \\ \mathbf{A}_b & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{A}_u & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{A}_i & \mathbf{0} & \mathbf{0} & \mathbf{0} \end{array} \right] \left[\begin{array}{c} \mathbf{v}^+ \\ h\boldsymbol{\lambda}_b^+ \\ h\boldsymbol{\lambda}_u^+ \\ h\boldsymbol{\lambda}_i^+ \end{array} \right] + \left[\begin{array}{c} h(\hat{\mathbf{c}} - \mathbf{f}_a) - \mathbf{M}\mathbf{v} \\ h\dot{\mathbf{A}}_b\mathbf{v} \\ h\dot{\mathbf{A}}_u\mathbf{v} \\ h\dot{\mathbf{A}}_i\mathbf{v} \end{array} \right] = \left[\begin{array}{c} \mathbf{0} \\ \mathbf{0} \\ \mathbf{w}_u^+ \\ \mathbf{w}_i^+ \end{array} \right] \\ \mathbf{0} \leq \mathbf{w}_u^+ \perp \boldsymbol{\lambda}_u^+ \geq \mathbf{0} \end{array} \right. \quad (3)$$

Figure 1: The manoeuvre sequence of the multibody system using smooth and non-smooth RIMs.

Figure 2: Actuator force (left) and effective mass of the reduced model (right).

The final goal is to obtain a reduced interface model that represents dynamics of the mechanical system associated with interface degrees of freedom parameterized by \mathbf{w}_i . From the first and second rows in Eq. (3), the generalized velocities \mathbf{v}^+ and bilateral constraint impulse $h\lambda_b^+$ can be determined and be substituted into the third and forth rows. Then, the MLCP in Eq. (3) can be rewritten as

$$\begin{cases} \begin{bmatrix} \mathbf{H}_{uu} & \mathbf{H}_{ui} \\ \mathbf{H}_{ui}^T & \mathbf{H}_{ii} \end{bmatrix} \begin{bmatrix} h\lambda_u^+ \\ h\lambda_i^+ \end{bmatrix} + \begin{bmatrix} \mathbf{b}_u \\ \mathbf{b}_i \end{bmatrix} = \begin{bmatrix} \mathbf{w}_u^+ \\ \mathbf{w}_i^+ \end{bmatrix} \\ \mathbf{0} \leq \mathbf{w}_u^+ \perp \lambda_u^+ \geq \mathbf{0} \end{cases} \quad (4)$$

Eq. (4) is the *reduced interface model* (RIM) of non-smooth multibody systems which includes the complementarity condition and is able to capture the contact state transformation between the communication points. This reduced model may be referred to as *non-smooth RIM*. The advantages of this formulation will be demonstrated in the next section through numerical simulation.

Example and discussion

A planar model of a hydraulically actuated box with two bottom wedges connected to a disc through a revolute joint was used to illustrate the efficiency of the proposed RIM in a co-simulation setup. The hydraulic actuator is the first subsystem and set of the box and the disc are regarded as the second subsystem. Also, the box and the disc are allowed to slide without friction. In the manoeuvre shown in the Fig. 1, the box is initially a bit rotated around the right wedge. Then, the box will be pushed forward by the actuator under the effect of gravity. According to the reference solution (co-simulation using *zero order hold* setup with macro step size of $h = 0.2$ ms), as the multibody setup moves forward, the box rotates counterclockwise so that bot of its wedges touches the ground and the system continues to move forward horizontally. However, when the *smooth RIM* method introduced in [2] is used for model-based co-simulation, the contact points of the box are treated as bilateral constraints during the macro step which makes the system over-constrained when both wedges touch the ground. This can be also seen in Fig. 2 where the effective mass of the reduced model is depicted and, at the instances that both wedges are in contact with the ground, the effective mass shows a sudden rise in value due to the over-constraining. The over-constraining and the resulting high effective mass values will store excessive pressure in the hydraulic actuator and makes the system unstable so that in some instances, the box jumps off the ground and the whole simulation becomes unstable. The sudden rise in actuator force is also depicted in Fig. 2. However, by employing the proposed method, the contact detachment is taken into account in the reduced model and as it is evident from Fig. 2, the behaviour captured by the non-smooth RIM is similar to the reference solution. It should be mentioned that both model-based simulations were simulated with $h = 5$ ms.

Three-Link Snake Robot with a Single Control Input

Marat Dosaev, Liubov Klimina and Yury Selyutskiy

Institute of Mechanics, Lomonosov Moscow State University, Moscow, Russia

Summary. A three-link snake robot is proposed controlled by an internal flywheel installed at the first link. There are spiral springs installed in joints between links. These springs are non-deformed when angles between the links are zero. The robot performs plane-parallel motion over a rough surface. Each link contacts with the surface at a single point. Anisotropic dry friction acts at the contact points. The friction coefficient corresponding to the direction along the link direction is much smaller than that corresponding to the direction transversal to the link. The control torque is applied to the internal flywheel. Parameters of the mechanism and coefficients of the control law are adjusted to ensure irreversible propulsion of the robot along a prescribed direction.

Introduction

Snake robots can be used for works in aggressive areas. Such devices are widely discussed in the literature, and various schemes of construction and control are proposed for them, e.g. [1, 2]. Most of the research in this field assumes that there are motors which control angles between links in each joint. In the current work, we show that the presence of such motors is not necessary to obtain a snake-like motion of a link mechanism. We suppose that the only control applied to the system is associated with the rotation of a single inner flywheel installed at the leading link. Similar approach to the control of a three-link mechanism is applied in [3] for a swimming robot.

Description of the system, statement of the problem

The robot consists of three links AB , BD , DE located in OXY plane and connected to each other by cylindrical joints B and D (fig. 1). Spiral springs with the stiffness c are installed in joints. These springs are non-deformed when all links make a single straight line. The inner flywheel with the shaft A , the mass m_0 , and the central moment of inertia J_0 is installed at the first link. The point A is the center of mass of the first link; this link has the mass $(m_1 - m_0)$ and the central moment of inertia J_1 . Masses m_2 and m_3 of the links BD and DE are concentrated in the points C and E , respectively. The current position of the robot is described by coordinates x , y of the point A and angles φ_i , $i = 1, 2, 3$ between links and OX axis. The angle of orientation of the inner flywheel is a cyclic coordinate; ω_0 is the absolute angular speed of the flywheel.

Figure 1: The scheme of the snake robot controlled by a single internal flywheel

Each link contacts the supporting plane in a single point: A , C , E . Anisotropic dry friction \mathbf{F}_i is applied at each contact point; the corresponding friction model is taken from [4]. The friction coefficient $\mu_{i\xi}$ corresponding to the motion along the link is much smaller than $\mu_{i\eta}$ corresponding to the motion in the transversal direction. $V_{i\xi}, V_{i\eta}$ are projections of the speed \mathbf{V}_i of the contact point on the axis directed along the link and the axis orthogonal to it. The following relation holds:

$$\begin{pmatrix} F_{i\xi} \\ F_{i\eta} \end{pmatrix} = - \begin{pmatrix} \mu_{i\xi} & 0 \\ 0 & \mu_{i\eta} \end{pmatrix} \begin{pmatrix} V_{i\xi} \\ V_{i\eta} \end{pmatrix} \frac{m_i g}{V_i}.$$

The single control torque U is applied to the shaft of the flywheel. It is limited in the absolute value by the constant U_{\max} . The goal of the control is to ensure the existence of an attracting self-sustained irreversible mode of propulsion of the robot opposite to OX axis. This means that the projection V_x of the velocity \mathbf{V} of the center of mass on OX shouldn't change sign and the average value of projection V_y of \mathbf{V} on OY should be zero.

Methods and main results

Equations of motion are derived basing the Lagrange formalism. Generalized forces are associated with dry friction forces, corresponding generalized torques Q_i , and the control torque U applied to the flywheel:

$$\frac{d}{dt}\left(\frac{dK}{d\dot{x}}\right) = F_{1x} + F_{2x} + F_{3x}, \quad \frac{d}{dt}\left(\frac{dK}{d\dot{y}}\right) = F_{1y} + F_{2y} + F_{3y}, \quad \frac{d}{dt}\left(\frac{dK}{d\dot{\varphi}_i}\right) - \frac{dK}{d\varphi_i} + \frac{dP}{d\varphi_i} = Q_i \quad (i=1,2,3), \quad \frac{d}{dt}\left(\frac{dK}{d\dot{\omega}_0}\right) = U;$$

$$F_{ix} = F_{i\xi} \cos \varphi_i - F_{i\eta} \sin \varphi_i, \quad F_{iy} = F_{i\xi} \sin \varphi_i + F_{i\eta} \cos \varphi_i \quad (i=1,2,3);$$

$$Q_1 = r(F_{2y} + F_{3y}) \cos \varphi_1 - r(F_{2x} + F_{3x}) \sin \varphi_1, \quad Q_2 = r(F_{2y} + 2F_{3y}) \cos \varphi_2 - r(F_{2x} + 2F_{3x}) \sin \varphi_2, \quad Q_3 = r(F_{3y} \cos \varphi_3 - F_{3x} \sin \varphi_3).$$

Here K and P are kinetic and potential energies, respectively. The control torque U is as follows:

$$U = \begin{cases} U_p, & |U_p| \leq U_{\max}, \\ \text{signum}(U_p) \cdot U_{\max}, & |U_p| > U_{\max}, \end{cases} \quad U_p = -(a_0 \text{signum}(\sin(2\pi w_0 t)) - k_0 y - k_1 \varphi_1).$$

The first term of the U_p represents a periodic excitation aimed to ensure oscillations of the inner flywheel. The other two terms are required to ensure zero average shift of links from the axis OX during the self-sustained propulsion.

Analysis of motion equation was performed by direct numerical integration with different geometrical and mass parameters, coefficients of the control law and initial component $\dot{x}(0)$ of the velocity of the point A . Initial values of other variables were zero. The total mass of the system was supposed to be equal to 0.5 kg, moments of inertia: $J_0 = 0.0005 \text{ kgm}^2$, $J_1 = 0.002 \text{ kgm}^2$. Lengths of links were not varied: $AB=BC=CD=DE=0.05 \text{ m}$. The maximum value of the control torque was fixed: $U_{\max}=0.1 \text{ N}$. Friction coefficients were fixed: $\mu_{i\xi} = 0.03$, $\mu_{i\eta} = 0.9$ ($i=1,2,3$).

Parameter continuation was used to find the set of parameters providing higher speed of motion at the program mode.

It was shown that an attracting regime of irreversible propulsion exists in a rather wide range of parameters. In particular, high speed of propulsion is achieved for the following set: $m_1 = m_3 = 0.2 \text{ kg}$, $m_2 = 0.1 \text{ kg}$, $c = 0.15 \text{ kgm}^2\text{s}^{-2}$, $a_0 = 0.1 \text{ Nm}$, $w_0 = 1.2 \text{ s}^{-1}$, $k_0 = -0.1 \text{ N}$, $k_1 = 0.1 \text{ Nm}$. The transition process with initial value $\dot{x}(0) = 0.1 \text{ m/s}$ is shown in the fig. 2: initially robot was pushed in the direction opposite to the target direction; at first, the center of mass decelerates, then it starts accelerating and reaches the attracting self-sustained motion in the prescribed direction, i.e. against OX . At the attracting regime, the x -component V_x of the speed of the center of mass is always negative. Thus, the motion is irreversible. The average value $\langle V_x \rangle$ of the component V_x is about -0.37 m/s , and the average value of V_y is zero.

Figure 2: Components of the speed of the center of mass during the transition to the program mode (an example)

The control ensures transition of the system to the program regime of motion from a wide range of initial conditions. The program motion is irreversible with respect to the axis OX . It should be noticed, that the presence of springs in joints as well as the anisotropy of friction are necessary conditions for the existence of the desired irreversible mode of propulsion of the proposed robotic scheme.

Conclusions

A new scheme of the snake robot is proposed without any control inputs applied in inter-link joints. The only control is the torque applied to the inner flywheel installed at the first link. The robot performs a plane-parallel motion over a rough surface. An anisotropic dry friction acts in the points of contact between the robot and the supporting surface. The parameters of the construction and coefficients of the control law are adjusted to ensure existence of attracting propulsion mode of motion that is irreversible with respect to the preferable direction of propulsion.

Feedback Control for a Body Carrying a Chain of Oscillators

Igor Ananievski and Alexander Ovseevich
 Ishlinsky Institute for Problems in Mechanics RAS
 Prospekt Vernadskogo, 101-1, Moscow 119526 Russia

Summary. We study steering of a linear chain of point masses connected via springs to the equilibrium, by means of a bounded force applied to the first mass in the chain. In other words, we design an explicit feedback control that bring the system to a given terminal rest state in a finite time. Thus, we prove the complete controllability of the system, and describe explicitly the feedback control proposed. Then, we show its robustness with respect to unknown disturbances.

The chain of n oscillators: Problem statement

We consider a control problem for a system representing a solid body carrying a chain of n linear oscillators modelled by point masses connected via springs (Fig. 1). The whole system moves along a horizontal line under the action of a control force and an external disturbance applied to the carrying body.

Figure 1: A body carrying the chain of oscillators

Equations of motion have the form

$$\begin{aligned} m_0 \ddot{x}_0 &= -k_1 x_0 + k_1 x_1 + u + v \\ m_i \ddot{x}_i &= k_i x_{i-1} - (k_i + k_{i+1}) x_i + k_{i+1} x_{i+1}, \quad i = 1, \dots, n-1 \\ m_n \ddot{x}_n &= -k_n x_{n-1} + k_n x_n \end{aligned} \quad (1)$$

Here, we have the controllable mass m_0 , which is subject to control u , and disturbances v . Each mass $m_i, i = 0, \dots, n$ has coordinate x_i , and the Hooke law $F_i = k_i(x_i - x_{i-1})$ gives the force from mass m_{i-1} to m_i . Assuming $x = (x_0, x_1, \dots, x_n)$, we can write (1) in the Cauchy normal form

$$\dot{x} = A_1 x + \frac{1}{m_0} b(u + v)$$

where A and b are the block matrices

$$A_1 = \begin{pmatrix} 0 & I \\ A_0 & 0 \end{pmatrix}, \quad b = \begin{pmatrix} 0 \\ e \end{pmatrix}$$

$$A_0 = \begin{pmatrix} -\frac{k_1}{m_0} & \frac{k_1}{m_0} & 0 & \dots & 0 \\ \frac{k_1}{m_1} & -\frac{k_1 + k_2}{m_1} & \frac{k_2}{m_1} & \ddots & \vdots \\ 0 & \ddots & \ddots & \ddots & 0 \\ \vdots & \ddots & \frac{k_{n-1}}{m_{n-1}} & -\frac{k_{n-1} + k_n}{m_{n-1}} & \frac{k_n}{m_{n-1}} \\ 0 & \dots & 0 & \frac{k_n}{m_n} & -\frac{k_n}{m_n} \end{pmatrix}, \quad e = \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix}$$

and I is the unit matrix.

We assume that we know the current values x_0, \dot{x}_0, x_1 , while the other coordinates are not directly observable. Therefore, a measured output is

$$y = Dx, \quad D = \begin{pmatrix} 1 & 0 & 0 & 0 & \dots & 0 \\ 0 & 1 & 0 & 0 & \dots & 0 \\ 0 & 0 & 1 & 0 & \dots & 0 \end{pmatrix}$$

Theorem 1 Pair (A_1, b) is controllable and the pair (A_1, D) is observable.

Thus, we can in principle bring the system under consideration to any given state, at least if the disturbances are absent.

Control of canonical systems

The control problem stated can be reduced [1, 2] to the control problem for canonical system

$$\dot{z} = Az + B(u + v) \quad (2)$$

where

$$A = \begin{pmatrix} 0 & 0 & 0 & \cdots & 0 \\ -1 & 0 & 0 & \cdots & 0 \\ 0 & -2 & 0 & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & -2N-1 & 0 \end{pmatrix}, \quad B = \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{pmatrix}, \quad z, B \in \mathbf{R}^{2N+2} \quad (3)$$

We use matrices

$$q_{ij} = \int_0^1 x^{i+j-2}(1-x)dx = \frac{1}{(i+j)(i+j-1)}, \quad i, j = 1, \dots, 2N+2$$

$$Q = q^{-1}, \quad C = -\frac{1}{2}B^T Q, \quad \delta(T) = \text{diag}\{T^{-1}, T^{-2}, \dots, T^{-2N-2}\}$$

Note, that for the scalar control system (2),(3) the matrix C is a row-vector $C = (C_1, \dots, C_{2N+2})$. This allows to define the canonical feedback control by

$$u(z) = C\delta(T(z))z$$

which takes the form

$$u(z) = \frac{C_1}{T(z)}z_1 + \frac{C_2}{T^2(z)}z_2 + \cdots + \frac{C_{2N+2}}{T^{2N+2}(z)}z_{2N+2} \quad (4)$$

in the scalar control case. The function $T(z)$ is found from the equation

$$\langle Q\delta(T)z, \delta(T)z \rangle = 1 \quad (5)$$

Theorem 2 (see [2])

- A) Equation (5) define positive $T = T(z)$ uniquely.
- B) The control (4) is bounded: $|u| \leq \frac{1}{2}\sqrt{N(N+1)}$.
- C) If there are no disturbances, the control (4) brings state z to 0 in time $T(z)$.

Theorem 3 If disturbances v satisfy

$$|v| \leq c < \frac{1}{2\sqrt{N(N+1)}}$$

the derivative of T satisfies inequality

$$\dot{T} \leq -\sigma, \quad \sigma > 0$$

and control (4) brings state z to 0 in a finite time $T = O(T(z))$.

Swing Oscillations Generated by Sitting Human

Alexander Formalskii^{*}, Alejandro Jenkins^{**} and Liubov Klimina^{*}

^{*}*Institute of Mechanics, Lomonosov Moscow State University, Moscow, Russia*

^{**}*Universidad de Costa Rica, San José, Costa Rica*

Summary. Oscillations pumped by the human sitting on the swing are modeled. The model is represented by a three-link mechanism. Control torques are applied in the knee- and hip- joints. The control strategy is proposed that allows generation and maintaining of oscillations with large amplitude and also rotation around the suspension point. Control torques are designed as autonomous feedbacks depending on the angle and the angular speed of rotation of the swing. Numerical simulation is performed. The anthropomorphism of the proposed control is illustrated.

Introduction

Pumping of a swing is systematically discussed in the literature as a classical example of forced oscillations. This paper deals with the case of pumping a rigid swing by a sitting person. The paper provides the following novel results: it is shown that the anthropomorphic strategy of pumping is quasi-optimal one, the control strategy is proposed that can pump the swing to stationary rotation (not only to oscillations), the numerical simulation is performed for the three-link model of the system while usually only oscillations of a double-link model are discussed (see, for example, [1-5]).

Statement of the Problem

Three-link planar hinge mechanism models a human pumping a swing (see Fig. 1a). Link VP models a body, link PK – both thighs, and KF – both shins. Link PK is rigidly joined to the rod that corresponds to the swing. The rod is pivotally joined to the suspension point O that is the axis of rotation of the swing. The viscous friction torque with coefficient c acts at this axis. The angle of rotation of the swing is denoted as φ . One inter-link hinge K models two knee-joints, second hinge P – two hip-joints. Two limited control torques are applied at these two inter-link joints K and P . Thus, the system has three degrees of freedom, but only two control torques are applied. So, this system is under-actuated one. Angles α in joint K and β in joint P can be changed in limits $\alpha_{\min} \leq \alpha \leq \alpha_{\max}$ and $\beta_{\min} \leq \beta \leq \beta_{\max}$. Here $\alpha_{\min/\max}$, $\beta_{\min/\max}$ are given constants. The limitation upon these angles is modeled via relatively strong single-side spiral springs in joints K and P which practically ensures that angles α and β do not leave the prescribed domain. These springs model ligaments and tendons.

Figure 1: The schemes of the three-link and simplified double-link mechanisms

The goal of the control is to pump the swing as fast as possible and to the largest amplitude taking into account the restrictions imposed on the control. In this paper, the solution that is “close to optimal” is proposed.

Design of the control and simulation

As a preliminary step the quasi-optimal control is designed for the simplified double-link model in which a human is substituted by a single rigid body (see Fig. 1b) and the limited angle θ is a control input. This control strategy is represented by a relay-type function $\theta^*(\varphi, \dot{\varphi})$ that ensures pumping the swing to the large amplitude oscillations or even to stationary rotations (depending on parameters $\theta_{\min/\max}$ and friction coefficient c in the suspension joint):

$$\theta^*(\varphi, \dot{\varphi}) = \begin{cases} \theta_{\max}, & \text{if } \dot{\varphi} \cos \varphi \geq 0, \\ \theta_{\min}, & \text{if } \dot{\varphi} \cos \varphi < 0. \end{cases}$$

Function $\theta^*(\varphi, \dot{\varphi})$ is used as the program function in the initial problem for the three-link mechanism (with $\theta_{\min/\max}$ equal to $\alpha_{\min/\max}$ or $\beta_{\min/\max}$ correspondingly). Control torques are designed as combinations of linear feedbacks with respect to the differences between the current and program angles and their derivatives. Efficiency of this control strategy is illustrated by numerical simulation with parameters of the model similar to parameters of the human. This simulation shows that if friction coefficient c is rather large, then oscillations of the swing tend to a stationary oscillatory mode corresponding to a cycle in the configuration space (see Fig. 2). But if friction coefficient c is sufficiently small, then the swing is pumped to a stationary rotation corresponding to the cycle in the space $(\varphi \bmod 2\pi, \alpha, \beta)$. These cycles are attracting ones.

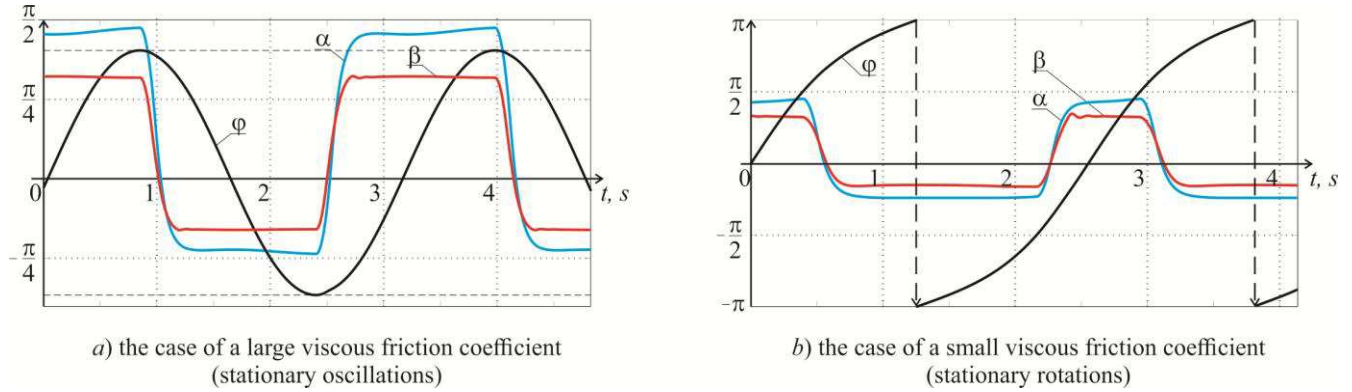

Figure 2: Illustration of stationary oscillations and rotations of the swing

Conclusion

The designed control allows maintaining oscillations in wide range of amplitudes as well as rotational motion with a constant period depending on the restrictions upon angles α , β and on the viscous friction coefficient c .

Dynamics of Interacting Populations in a Bounded Domain: Control and Estimation under Nonlinearity and Uncertainty

Tatiana F. Filippova

*Department of Optimal Control, Krasovskii Institute of Mathematics and Mechanics,
Ural Branch of Russian Academy of Sciences,
Ural Federal University, Ekaterinburg, Russian Federation*

Summary. The nonlinear control systems of Lotka - Volterra type which describe the dynamics of the interaction of predators and their preys are studied. It is assumed that the initial states of the system are not known precisely but belong to a given ellipsoid in the state space and there is no additional information (for example, probabilistic, statistical, etc.) on unknown values. We find the external ellipsoidal estimates of corresponding reachable sets for control systems under study. The considered models may describe the behavior of competing firms, population growth, environmental change, development of individual industries, etc. The results of modeling based on proposed methods are included to illustrate the main proposed ideas and presented estimation algorithms.

Introduction

The problem of state estimation for control systems under conditions of nonlinearity and uncertainty is studied. The case is investigated here when the probabilistic data of noise and possible errors is not available, and only some restriction on unknown parameters and functions are given. Models of this kind may be found in many applied problems including physics, economics, biology, ecology, etc. As one of the important and key idea to study such problems we use the so-called set-membership approach which was developed earlier [1, 2, 3, 4] to deal with a whole set of feasible parameters, consistent with the model structure, for systems with bounded uncertainty, with special types of measurements characterization etc.

The solutions of such classes of control and estimation problems with set-membership uncertainty are based on the construction and on the analysis of the corresponding reachable sets or their analogs. In this paper we study the procedures of upper estimating reachable sets for nonlinear control systems of Lotka-Volterra type. We use here the ideas and results of state estimation theory developed for nonlinear control systems which have a special quadratic dynamical structure [5, 6, 7, 8] and several new schemes of the problem solution are developed here. We prove here theoretical results and formulate related numerical algorithms for constructing external ellipsoidal estimates of reachable sets for nonlinear uncertain control systems of the studied type. Numerical examples and results of related simulations are included to illustrate the basic ideas and results.

Problem statement

The paper deals with the problems of control and state estimation for a dynamical control system

$$\dot{x}(t) = A(t)x(t) + f(x(t)) + G(t)u(t), \quad x \in R^n, \quad t_0 \leq t \leq T, \quad (1)$$

with unknown but bounded initial state

$$x(t_0) = x_0, \quad x_0 \in X_0, \quad X_0 \subset R^n, \quad (2)$$

and with control constraint

$$u(t) \in U, \quad U \subset R^m, \quad \text{for a.e. } t \in [t_0, T]. \quad (3)$$

Here matrices $A(t)$ and $G(t)$ (of dimensions $n \times n$ and $n \times m$, respectively) are assumed to be continuous on $t \in [t_0, T]$, X_0 and U are compact and convex. The nonlinear n -vector function $f(x)$ in (1) is assumed to be of quadratic type

$$f(x) = (f_1(x), \dots, f_n(x)), \quad f_i(x) = x' B_i x, \quad i = 1, \dots, n, \quad (4)$$

where B_i ($i = 1, \dots, n$) are constant $n \times n$ - matrices.

In previous studies [5, 6, 7, 8], it was taken as the main assumption that matrices B_i in (1)–(4) are positive definite; this additional condition simplified the analysis of nonlinearity in studying the structure and the properties of reachable sets of the control system (1)–(4).

As a particular kind of the above control problem we consider here the following Lotka-Volterra system which describes the classical ecological predator-prey (or parasite-host) model with additional control functions:

$$\begin{cases} \dot{x}_1(t) &= ax_1 - bx_1x_2 + u_1, \\ \dot{x}_2(t) &= -cx_2 + dx_1x_2 + u_2, \end{cases} \quad x(t_0) = x_0, \quad t_0 \leq t \leq T. \quad (5)$$

Here we assume that numbers $a, b, c, d > 0$ are given and initial vectors x_0 are unknown but bounded, that is we have the inclusion $x_0 \in X_0$, where X_0 is a given compact subset of R^2 . This assumption may be interpreted for example in such

a way that we do not know exactly the initial states (or amounts) of predators and prey. We assume also that controls $u(t)$ in (3)-(5) are taken measurable in Lebesgue on $[t_0, T]$, also the inclusion is true

$$u(t) \in U, \quad \text{a.e. } t \in [t_0, T], \quad (6)$$

where $U \in \text{comp}R^2$. The choice of a control can influence, in particular, the rate of change in amounts of predators and prey.

Basing on results of ellipsoidal calculus [1, 4] and estimation schemes described in [5, 6, 8] we present here the modified state estimation approaches which use the special structure of nonlinearity of studied control system (1)–(6) and combine advantages of estimating tools mentioned above. Numerical simulation schemes together with modeling examples are also included.

Main results

Note first that we have in the system (5)-(6) a bit more simple situation than in general case of the system (1)-(4), namely we have the equality $f(x)' = x_1 x_2 \cdot (-b, d)$. The idea used here in the analysis of reachable sets of the system (5)–(6) is based on the following transformation of the system (1)–(4) to the new one which will include only positive definite quadratic forms, this case is more convenient for the analysis and for further numerical modeling. So we consider the following modified control system

$$\begin{aligned} \dot{z} &= A^* z + f_\varepsilon^{(1)}(z) \cdot d^{(1)} + f_\varepsilon^{(2)}(z) \cdot d^{(2)} + w(t), \\ z_0 &\in \mathcal{Z}_0, \quad w \in \mathcal{W}, \quad t_0 \leq t \leq T, \end{aligned} \quad (7)$$

with

$$A^* = \begin{pmatrix} A & -C \\ -C & A \end{pmatrix}$$

and with functions $f_\varepsilon^{(1)}(z)$ and $f_\varepsilon^{(2)}(z)$ being the positive definite quadratic forms with matrices $B_\varepsilon^{(1)} = \text{diag}\{1, \varepsilon^2\}$ and $B_\varepsilon^{(2)} = \text{diag}\{\varepsilon^2, 1\}$, respectively.

We can find now the external ellipsoidal estimates of reachable set $Z(t)$ of the system (7) applying for this purpose results of [7]. The case of the presence of a state constraint on the dynamics of the dynamical system is considered separately; here, the possibility of applying the procedure for removing restrictions using the results of [2] is discussed.

We formulate also a numerical discrete-time algorithms of ellipsoidal estimating the reachable sets of the studied uncertain system. Examples and numerical simulation results related to procedures of set-valued approximations of trajectory tubes and reachable sets are also presented.

Conclusions

The paper deals with the problems of control and state estimation for a dynamical control system with unknown but bounded initial state. The solution to the differential control system is studied through the techniques of trajectory tubes of the theory of differential inclusions. The estimation approach uses the special nonlinear structure of the Lotka-Volterra system. Examples and numerical results related to state estimation procedures of reachable sets are presented.

Controlled motion of two interacting particles on a rough inclined plane

Ivan Bogoslavskii*, Nikolay Bolotnik* and Tatiana Figurina*

*Institute for Problems in Mechanics of the Russian Academy of Sciences, Moscow, Russia

Summary. Two interacting particles on a rough inclined plane are considered. Coulomb's friction acts between the particles and the underlying surface. The system is controlled by the force of interaction of the particles. It is assumed that the parameters of the system are such that one of the bodies can be moved upward along a line of maximum slope provided that the other body is resting. The controllability of the system between two arbitrary states of rest is investigated. The system is proved to be controllable if the particles do not lie on a common line of maximum slope at the initial instant. A control algorithm that alternates quasistatic and fast modes of motion is constructed.

Statement of the problem

Consider a system of two particles on an inclined plane Π (Fig. 1a). Let m and M denote the masses of the particles ($m < M$), k the coefficient of Coulomb's friction between the particles and the underlying plane, γ the inclination angle of the plane, g acceleration due to gravity, \mathbf{F} the interaction force applied by particle M to particle m . We assume that for $\mathbf{F} = 0$, both particles can stay at rest and that particle m can be moved from the state of rest by the force \mathbf{F} upward along the line of maximum slope, while particle M does not move:

$$kM \cos \gamma \geq (M + m) \sin \gamma + km \cos \gamma. \quad (1)$$

Let the system under consideration be at rest at the initial instant. The aim of our study is to find out whether the system can be driven from the initial state to any other state of rest on the plane. For the horizontal plane ($\gamma = 0$), this is impossible. We are interested in the controllability of the system in principle. For this reason, we do not impose any constraints on the magnitude of the control force, allow instantaneous change in the positions of the particles, and assume that the particles may move through one another. If the particles at the initial instant rest on the common line of maximum slope, they cannot quit this line, and this case will not be considered. We will show that the system can be driven between

Figure 1: a) Two-particle system on an inclined plane, b) Quasistatic trajectories of particle m

the initial and terminal states by combining two types of motions: quasistatic motions and fast motions. The quasistatic motion is a slow motion that can be regarded as a continuous sequence of equilibria, while for fast motion we admit an instantaneous change in the positions of the particles.

Quasistatic motions

Inequality (1) implies that in quasistatic motions, only particle m moves, while particle M is at rest. Denote by L_M the line of maximum slope passing through the point M . Introduce in plane Π the coordinate frame Mxy (Fig. 1a). The axis y lies on line L_M and is directed upward. The trajectories of the quasistatic motion of particle m are defined by the equation

$$\frac{dr}{d\alpha} = \pm \frac{r\sqrt{1 - a^2 \cos^2 \alpha}}{a \cos \alpha}, \quad a = \frac{\tan \gamma}{k}, \quad (2)$$

where r and α are the polar coordinates of particle m in plane Π related to the pole M and the polar axis Mx . When moving quasistatically, particle m cannot intersect line L_M ; therefore we assume $\alpha \in (-\pi/2, \pi/2)$. Sign minus on the right-hand side in Eq. (2) corresponds to the repulsive motion when the interaction force \mathbf{F} applied to particle m acts from M toward m , while sign plus corresponds to the attractive motion. Equation (2) has a closed-form solution in terms of elementary functions. Denote by $r_{\pm}(\alpha, \alpha_0, r_0)$ the solution of Eq.(2) subject to the initial conditions $r(\alpha_0) = r_0$. The function r_+ (r_-) monotonically increases (decreases) as α increases in the interval $(-\pi/2, \pi/2)$. The functions r_+ and r_- have the following properties:

$$\lim_{\alpha \rightarrow \pi/2} r_-(\alpha) = 0, \quad \lim_{\alpha \rightarrow -\pi/2} r_-(\alpha) = \infty, \quad \lim_{\alpha \rightarrow -\pi/2} r_-(\alpha) \cos \alpha = \infty. \quad (3)$$

$$\lim_{\alpha \rightarrow \pi/2} r_+(\alpha) = \infty, \quad \lim_{\alpha \rightarrow -\pi/2} r_+(\alpha) = 0, \quad \lim_{\alpha \rightarrow \pi/2} r_+(\alpha) \cos \alpha = \infty. \quad (4)$$

$$r_-(\alpha, \alpha_0, r_0) = r_+(-\alpha, -\alpha_0, r_0). \quad (5)$$

According to the properties of Eqs. (3)–(5), the trajectories of the quasistatic motion of particle m on plane Π have the shape shown in Fig. 1b. For each point (α_0, r_0) on the plane, one can indicate an area (attainable area) to each point of which particle m can be driven quasistatically. This area is bounded by the curves $r_{\pm}(\alpha, \alpha_0, r_0)$ (thick lines in Fig. 1b). One can drive particle m to any internal point (α_1, r_1) of the attainable area using one switching between the repulsive and attractive motions; the particle moves first along the curve $r_-(\alpha, \alpha_0, r_0)$ or $r_+(\alpha, \alpha_0, r_0)$ and then, respectively, along the curve $r_+(\alpha, \alpha_1, r_1)$ or $r_-(\alpha, \alpha_1, r_1)$. In particular, using one switching, one can get quasistatically to the point $(\alpha_0 - \delta\alpha, r_0)$, $\delta\alpha \ll 1$, from the point (α_0, r_0) . Then, similarly, using one switching, one can get to the point $(\alpha_0 - 2\delta\alpha, r_0)$ from the point $(\alpha_0 - \delta\alpha, r_0)$, and so on. By letting $\delta\alpha \rightarrow 0$, we obtain that the trajectory of particle m can be made arbitrarily close to the circular arc of radius r_0 ; the angle α monotonically decreases, approaching but not reaching a value of $-\pi/2$. Therefore, particle m can be driven from the point (α_0, r_0) quasistatically along a trajectory arbitrarily close to the circular arc $r = r_0$, $\alpha \in (-\pi/2, \alpha_0]$, with monotonically decreasing angle α . We will call such a motion the quasistatic motion along a circumference.

All the aforesaid remains valid for the quasistatic motion for $\alpha \in (\pi/2, 3\pi/2)$. In this case, the repulsive and attractive trajectories will be symmetric about the My -axis to the respective trajectories for $\alpha \in (-\pi/2, \pi/2)$; particle m can be driven along a circumference, with α monotonically approaching but not reaching a value of $3\pi/2$.

Fast motions. An algorithm for driving the system to the terminal state

By fast motions we understand the motions that drive the system between different states of rest in an infinitesimal time. The force of interaction between the particles for such motions is much larger than the external friction forces; therefore, the system's center of mass and the line that connects the particles are fixed. We allow the particles in the fast motion to pass through one another, changing as a result the direction of the vector \overrightarrow{Mm} to the opposite one. By means of the fast motion, we can move particle M to any position on the initial line Mm .

By alternating fast and quasistatic motions one can move particle m to any position on the plane, with particle M remaining arbitrarily close to its initial position. We will show this for the case where the initial and terminal positions of particle m belong to different half-planes with respect to line L_M . We assume for definiteness that $\alpha \in (\pi/2, 3\pi/2)$ for the initial positions and $\alpha \in (-\pi/2, \pi/2)$ for the terminal position. We will show first that particle m can be brought onto a semi-circumference of an arbitrarily small radius on the right half-plane, i.e., to any position (α^*, r^*) such that $r^* = \varepsilon$, $\varepsilon \ll 1$, and $\alpha^* \in (-\pi/2, \pi/2)$, while the change in the position of particle M is small. To this end we at the first stage move quasistatically particle m toward particle M until the distance r between the particles becomes $r = \varepsilon$. If at this instant the angle α does not satisfy the inequality $|\alpha - 3\pi/2| \leq |\pi/2 - \alpha^*|$, we move particle m along a circumference until this inequality holds. After this, we perform the fast motion as a result of which particles m and M change their positions on the line Mm to the positions that are symmetric about the center of mass. The change in the position of particle M at this stage is small (the distance moved by this particle is less than ε), while the distance between the particles does not change. At the final stage, particle m moves quasistatically clockwise (with the angle α monotonically decreasing) until the angle α becomes equal to the desired value α^* . Thus we proved the possibility for particle m to be driven to an arbitrary point of a circumference of small radius on the right half-plane. Taking into account the fact that the quasistatic repulsive and attractive trajectories that go out from all points (α^*, r^*) , $\alpha^* \in (-\pi/2, \pi/2)$, $r^* = \varepsilon$, sweep the entire right half-plane, we conclude that particle m can be driven quasistatically into any position on the right half-plane. Somewhat simplifying, we can regard the algorithm presented above as driving particle m onto particle M followed by the motion of particle m along an arbitrary trajectory of quasistatic repulsion that goes out from the origin.

In conclusion, we describe an algorithm that drives the system to the desired terminal state. We will confine ourselves to the case where the terminal positions of the particles do not lie on the common line of maximum slope. At the first stage, by alternating fast and quasistatic motions as was described above, we bring the system to a position in which the line that connects the particles passes through the terminal position of particle M . Then by means of fast motion we move particle M to its terminal position. Finally, by using the algorithm described above, we move particle m to the desired terminal state; at this stage, the change in the position of particle M is arbitrarily small.

Conclusions

It is proved that if at the initial instant the particles do not lie on the common line of maximum slope, the system can be driven into an arbitrarily small neighborhood of any terminal position on an inclined rough plane by combining quasistatic and fast motions. A system of two interacting particles is a simple model of limbless worm-like crawlers. This biomimetic principle of motion can be used for mobile microrobots. It is important that when on a horizontal plane, a two-particle locomotion system that is in a state of rest at the initial time instant can move only along a line that connects the initial positions of the particles, whereas on an inclined plane, the system can be driven to any terminal position.

Reorientation of a rigid body by means of an auxiliary mass

Felix Chernousko*

**Institute for Problems in Mechanics, Russian Academy of Sciences, Moscow, Russia*

Summary. Possible control of the space orientation for a rigid body by means of an auxiliary movable point mass is considered. The motion of the point mass is proposed that provides the prescribed change of the body orientation.

Introduction

Control of the space orientation of a rigid body can be implemented by means of an auxiliary internal mass that is equipped with an actuator and can move relative to the body. Two-dimensional motions of such systems in the absence of external forces are analyzed in [1, 2, 3] where time-optimal controls are obtained. Three-dimensional motions are considered in [4]. In the paper, a simple control is proposed which provides, in the absence of external forces, the prescribed change of the rigid body orientation by means of an internal movable mass.

Basic equation

We consider a mechanical system consisting of a rigid body P of mass M and a particle Q of mass m (Fig. 1). Denote by C the center of mass of body P and by O the center of mass of system $P+Q$. Suppose that external forces are negligible and system $P+Q$ is at rest at the initial time moment $t = 0$. Then its center of mass O is at rest for all t , whereas the momentum of system $P+Q$ and its angular momentum stay constant and equal to zero. The following equation is derived from these conservation laws [1, 3, 4]:

$$\mathbf{J} \cdot \boldsymbol{\omega} + \mu M \mathbf{r} \times (\boldsymbol{\omega} \times \mathbf{r} + \mathbf{v}) = 0, \quad \mu = m/(M + m), \quad (1)$$

where \mathbf{J} is the tensor of inertia of body P relative to its center of mass C , $\boldsymbol{\omega}$ is the angular velocity of body P , $\mathbf{r} = CQ$ is the position vector of point mass Q relative to C , and \mathbf{v} is the velocity of point Q relative to body P .

Reorientation

Let us introduce the Cartesian coordinate system $Cx_1x_2x_3$ connected with body P , its axes Cx_i being principal central axes of inertia of body P , $i = 1, 2, 3$. Suppose that body P should be transferred from its initial state of rest to the prescribed terminal state of rest by means of an auxiliary particle Q . We assume that the initial and terminal positions of particle Q coincide with the center of mass C of body P . Hence, the required motion is the change of the orientation of body P .

This motion can be implemented by means of three successive plane turns of body P about its three principal central axes of inertia Cx_i , $i = 1, 2, 3$. For the rotation about axis Cx_i , body P must turn by a given angle $\Delta\varphi_i$ while the movable mass Q must start and finish its motion at point C . Both body P and particle Q should be at rest at the beginning and the end of this motion. Therefore, to design the required three-dimensional re-orientation, it is sufficient to construct such

Figure 1: Mechanical system

plane motion of particle Q , with $\mathbf{r} = \mathbf{v} = 0$ at the beginning and the end of motion, that provides the required rotation of body P .

Plane motion

Without loss of generality, let us consider rotation of body P about axis Ox_3 . Point Q will move in plane Cx_1x_2 , its trajectory begins and ends at point C . Time-optimal trajectories of point Q found in [1, 3] for small μ , are circular arcs. Following this example, we will seek the trajectory of point Q as a circle with radius R passing through point C . Its center S can be chosen arbitrarily in plane Cx_1x_2 .

Denote by I the moment of inertia of body P about axis Cx_3 and by φ the angle of rotation of the body about this axis. Then the vectorial equation (1) is reduced to the following equation

$$\dot{\varphi} = -\frac{\mu MR^2(1 - \cos \psi)}{I + 2\mu MR^2(1 - \cos \psi)}\dot{\psi}, \quad (2)$$

where ψ is the angle between radii SC and SQ ; this angle defines the position of point Q along its circular trajectory. By integrating equation (2), we obtain

$$\varphi(t) = \frac{1}{a} \operatorname{Arctan}\left(a \tan \frac{\psi}{2}\right) - \frac{\psi}{2}, \quad (3)$$

where

$$a = (1 + 4\mu MR^2 I^{-1})^{1/2}. \quad (4)$$

According to equation (3), the angle φ of rotation of body P about axis Cx_3 depends only on angle ψ , i.e., on the position of particle Q on its circular trajectory. When point mass Q makes the full rotation along its trajectory ($\psi = 2\pi$), body P turns by angle

$$\Delta\varphi = \pi(a^{-1} - 1), \quad -\pi < \Delta\varphi < 0.$$

To turn body P by an arbitrary angle, mass Q can make several (n) revolutions along its circular trajectory. Hence, the total angle of rotation $\Delta\varphi$ of body P can be estimated as follows

$$|\Delta\varphi| = \pi n(a - 1)/a. \quad (5)$$

Using formulas (4) and (5), we obtain the expression for the radius R of the circular trajectory of point mass Q :

$$R = \frac{[I\alpha(1 - \alpha/2)]^{1/2}}{(2\mu M)^{1/2}(1 - \alpha)}, \quad \alpha = \frac{|\Delta\varphi|}{\pi n}. \quad (6)$$

To turn body P about axis Cx_3 by angle $\Delta\varphi$, particle Q should move in plane Cx_1x_2 along a circular trajectory of radius R given by (6). The center of the trajectory and the time history of motion $\psi(t)$ can be arbitrary.

This trajectory must pass through the center of mass C of body P , and the velocity of particle Q at point C must be zero. To decrease the domain of motion for particle Q , we can, according to equation (6), increase the number of revolutions n . The circular motions of particle Q relative to body P can be accomplished by means of rotating wheels.

Conclusions

Possible motions of an auxiliary point mass relative to a rigid body are described which provide an arbitrary prescribed reorientation of the body in space in the absence of external forces.

Summary. Phase resetting is used in experiments with the aim to classify and characterise different neurons by their responses to perturbations away from a periodic bursting pattern. The same approach can also be applied numerically to a mathematical model. Resetting is closely related to the concept of isochrons of a periodic orbit, which are the submanifolds in its basin of attraction of all points that converge to this periodic orbit with a specific phase. Until recently, such numerical phase resets were performed in an ad-hoc fashion, and the development of suitable computational techniques was only started in the last decade or so. We present an approach based on the continuation of solutions to a two-point boundary value problem that directly evaluates the phase associated with the isochron that the perturbed point is located on. We illustrate this method with the FitzHugh–Nagumo model and investigate how the resetting behaviour is affected by phase sensitivity in the system.

In certain physiological experiments, a perturbation is applied to an oscillator, and one is interested in how the dynamics relaxes back to its regular rhythm [3, 12]. The resulting phase-shift is known as a phase reset, and recorded in terms of a *phase response curve* (PRC) or *amplitude response curve* (ARC); these are obtained by varying the phase at which the reset is applied, or by varying the amplitude of the reset when applied at a fixed given phase, respectively. Phase resets give insight into the underlying dynamics of biological oscillator, such as circadian clocks, yeast cells, and the cell cycle [12].

Mathematically, the oscillator is an attracting periodic orbit. Points on the periodic orbit have a relative phase, and any point in the basin of attraction can similarly be assigned an asymptotic (or latent) phase, defined as the phase with which the point converges to the periodic orbit [11]. The set of all points with the same asymptotic phase forms a manifold, called an isochron, and the family of isochrons foliates the basin of attraction [5]. Theoretically, a PRC or ARC can be computed by determining the phases of the isochrons that are associated with the reset points. In practice, this idea has proved to be rather challenging. Traditionally, ad-hoc model simulation has been applied [2, 4, 11]. Recently, more accurate techniques have been developed for the computation of isochrons, which are amenable for isochrons of systems that exhibit strong or even extreme phase sensitivity in possibly large regions of phase space; see [8] and references therein. Consequently, there are now also much better algorithms for the computation of PRCs, ARCs, and other resetting curves [6, 9].

Our method [10] computes one-dimensional isochrons of planar systems by pseudo-arclength continuation of solutions to a suitable boundary value problem (BVP). It has the advantage that it can generate very accurate approximations of isochrons globally, over a very large part of phase space. We adapt this method here so that we can generate PRCs or ARCs also with a BVP approach; we use the package AUTO [1] throughout to obtain solution families of the respective BVPs. The BVP that defines a phase reset consists of four orbit segments that are related via boundary conditions. Each orbit segment is a solution to the vector field given in the form

$$\frac{d}{ds}\mathbf{u} = T\mathbf{f}(\mathbf{u}),$$

where $\mathbf{f} : \mathbb{R}^2 \rightarrow \mathbb{R}^2$ defines the original vector field and time is rescaled to time s measured in units T of total integration time of the respective orbit segment. Hence, T is treated as a parameter.

The first two orbit segments define the periodic orbit $\Gamma := \{\mathbf{u}(s) \in \mathbb{R}^2 \mid 0 \leq s \leq 1\}$, with period T_Γ , and its associated vector bundle $\mathbf{v} := \{\mathbf{v}(s) \in \mathbb{R}^2 \mid 0 \leq s \leq 1\}$ of the stable Floquet multiplier of Γ ; each vector $\mathbf{v}(s)$ is tangent to the isochron associated with the point $\gamma_\vartheta \in \Gamma$ such that $\gamma_\vartheta = \mathbf{u}(s)$. For both orbit segments, the parameter T is set to the period T_Γ of Γ . Instead of imposing a phase condition—which would be necessary if one wants to continue Γ in a parameter—we allow the head point $\mathbf{u}(0) = \mathbf{u}(1)$ on Γ to vary; in other words, $\mathbf{u}(0)$ is not necessarily equal to the point $\gamma_0 \in \Gamma$ with phase 0. We keep track of the phase that corresponds to a shifted head point $\mathbf{u}(0)$ by way of a third orbit segment $\mathbf{w} := \{\mathbf{w}(s) \in \mathbb{R}^2 \mid 0 \leq s \leq 1\}$ that starts at $\mathbf{w}(0) = \mathbf{u}(0)$ and ends at $\mathbf{w}(1) = \gamma_0$. For numerical reasons, the end condition for \mathbf{w} is relaxed so that $\mathbf{w}(1)$ is allowed to differ from γ_0 in the direction of its (linearised) isochron. The total integration time for \mathbf{w} is measured in fractions of T_Γ , that is, we set $T = \nu T_\Gamma$ for this orbit segment. The fourth and final orbit segment defines the orbit segment $\mathbf{p} := \{\mathbf{p}(s) \in \mathbb{R}^2 \mid 0 \leq s \leq 1\}$ of a reset point $\mathbf{p}(0)$ converging back to Γ . Its total integration time is an integer multiple of T_Γ and its end point is $\mathbf{p}(1) = \mathbf{u}(0) + \eta \mathbf{v}(0)$, for some small parameter $0 < \eta \ll 1$; here, $\mathbf{v}(0)$ has length 1.

The PRC is then found by continuation in ν as the variation in phase $\varphi = 1 - \nu$, while $\mathbf{p}(0)$ traces the path of a shifted periodic orbit; the ARC is defined similarly by setting $\mathbf{p}(0) = \gamma_\vartheta + A\mathbf{d}$ and varying the reset amplitude A , where \mathbf{d} is a reset direction.

Figure 1: Phase-resetting for the FitzHugh–Nagumo system (1) where a reset is applied in the direction $\mathbf{d} = (1, 0)^t$ from the point $\gamma_{0.6} \in \Gamma$ with varying amplitude $A \in [0, 0.75]$. Panel (a) shows Γ with its isochrons plotted on a colour gradient from cyan at phase 0 to dark blue at phase 1; the purple curve indicates the A -dependent reset. Panel (b) shows the resulting phase $\varphi = 1 - \nu$ versus A .

As an example, we consider the two-dimensional FitzHugh–Nagumo system, which is the iconic polynomial model for which Winfree found that it exhibits extreme phase sensitivity due to its slow-fast nature [12]. The model is given as

$$\begin{cases} \dot{x} &= c \left(y + x - \frac{1}{3} x^3 + z \right), \\ \dot{y} &= -\frac{1}{c} (x + a - b y), \end{cases} \quad (1)$$

where we fix $z = -0.4$, $a = 0.7$, and $b = 0.8$ as in [12], but set $c = 2.5$. For these parameter values, there exists an attracting periodic orbit Γ with period $T_\Gamma \approx 10.71$. We define the point with zero phase as the point $\gamma_0 \in \Gamma$ that has a maximum with respect to the x -coordinate; this point is $\gamma_0 \approx (1.94, 0.89)$.

Figure 1(a) shows Γ together with its isochrons; the isochron associated with γ_0 is coloured cyan and the other isochrons are similarly coloured on a colour gradient from cyan to dark blue. We apply a reset to the point $\gamma_{0.6}$ that lies on Γ at time $0.6 T_\Gamma$ further along from γ_0 . The reset is in the horizontal direction $\mathbf{d} = (1, 0)^t$, and we vary its amplitude A in the interval $[0, 75]$; see the purple line in Figure 1. Hence, $\gamma_{0.6}$ is reset to the point $\gamma_{0.6} + A \mathbf{d}$ and we compute the ARC as the corresponding A -dependent asymptotic phase $\varphi = 1 - \nu$ of the reset point $\gamma_{0.6} + A \mathbf{d}$.

Figure 1(b) shows the computed ARC as φ against A . Note that the A -parametrised line of reset points passes through a region with extreme phase sensitivity [7]. Consequently, the ARC becomes near vertical in this region, which lies approximately at $A \approx 0.42$. Our numerical continuation set-up has no trouble traversing such a phase-sensitive region and the ARC can be obtained reliably and efficiently even if it has a near-vertical derivative; note also the discontinuity at $A \approx 0.67$, where φ jumps from 1 to 0.

Resonant nonlinear triad interactions of acoustic-gravity waves

Usama Kadri

School of Mathematics, Cardiff University, Cardiff CF24 4AG, UK

Summary. Acoustic waves, such as underwater sounds generated by earth-plate movements, and gravity waves, such as surface ocean waves, are two types of waves that are thought to share very little in common. However, recently it has been shown theoretically that acoustic-gravity waves can interact and share energy. Such interaction could explain natural phenomena such as microseisms (faint earth tremor), but also has many implications from tsunami mitigation and energy harnessing, to creating new measurement techniques that can be applied in invasive medical operations. In this talk I will present a review on nonlinear interaction of acoustic-gravity waves, theory and applications.

Background

Acoustic (compression) waves and free-surface (gravity) waves are virtually decoupled for two main reasons. Firstly, the speed of sound in water far exceeds the maximum phase speed of gravity waves. Secondly, the mode shape with depth is oscillatory for acoustic modes, and exponentially decaying for gravity waves. Nevertheless, it has been argued theoretically that these two types of wave motion could exchange energy via resonant triad nonlinear interactions [1, 2, 3, 4, 5]. There are two cases of interest this review talk focuses on: (I) two gravity waves interacting with an acoustic mode of a comparable frequency (almost double) [1, 2, 3]; and (II) two acoustic modes interact with a gravity wave of a comparable lengthscale [4, 5]. In the first case, the theory suggests that for a perfectly tuned triad almost all energy initially stored in the gravity waves can transfer into the generated acoustic mode, whereas for wavepackets a maximum of 40% energy transfer can be obtained [2]. This has implications at the ocean scale where interacting surface gravity waves can generate microseism (faint earth tremor) deep at the ocean floor [6, 7]. Not less interestingly is the particular solution where two gravity waves of identical frequency generate a standing acoustic mode [8]. Such setting might explain a physical phenomenon known as time reversal [9, 10]. The same solution might explain the evolution of Faraday waves [8, 11] that find various applications in physics. In the second case, the interaction of two acoustic modes with one gravity wave has implications on underwater communication [4], wave energy harnessing, or more ambitiously tsunami mitigation [5].

Amplitude evolution equations

We consider the propagation of surface-gravity waves interacting with acoustic wave disturbances in water of constant depth over a rigid bottom. The equation governing the velocity potential in the fluid interior is obtained by combining continuity with the unsteady Bernoulli equation, i.e cubic nonlinear wave equation. The boundary conditions are the standard higher order kinematic and dynamic conditions, at the surface; and the no-penetration condition at the bottom. In the first case, resonance is possible among two surface -gravity waves and a single acoustic mode. The conditions for resonance comprise an interplay of the frequencies $\sigma_+ + \sigma_- = \omega$, and wavenumbers $k_+ + k_- = \kappa$, where σ_{\pm} and k_{\pm} represent the two gravity waves, which combined form the acoustic mode represented by ω and κ . To derive the evolution equations we employ multiple-scale analysis, which yields

$$\frac{\partial A}{\partial t} + c_1 \nabla A + c_2 \nabla^2 A \propto S_+ S_-, \quad \frac{\partial S_{\pm}}{\partial \tau} \propto A S_{\mp}^* + [\text{cubic terms}] \quad (1)$$

where A and S_{\pm} are the amplitudes of the acoustic and two gravity waves, t is the interaction timescale, ∇ is the gradient (∂_x, ∂_y) , and c_1 and c_2 are constants. The derived evolution equations allow quantifying the parameters (i.e. frequency, wavelength, and amplitude) needed to finely tune the interaction, which controls the energy exchange. Following a similar approach we derive the amplitude evolution equations for two acoustic modes interacting with a gravity wave. Now, the conditions for resonance become $\omega_+ + \omega_- = \sigma$, and wavenumbers $\kappa_+ + \kappa_- = k$ and the evolution equations are fundamentally different. The following are some examples that will be discussed.

Example 1: Faraday Waves

This case is analogous to a surface gravity disturbance (Gaussian) of frequency ω over a fluid layer that is subject to a continuous vertical oscillation, e.g. due to underwater tremor, at double the frequency. The interaction excites subharmonic standing field of Faraday-type waves of frequency 2ω , as shown in the figure 1 (from [11]).

Figure 1: Evolution of Faraday-type waves from a gravity disturbance interacting with a long-crested acoustic mode [11].

Example 2: Time-Reversal

A mathematical model for the evolution of a time-reversed gravity wave packet from a nonlinear resonant triad perspective is derived [8]. Here the sudden appearance of an acoustic mode is analogous to a sudden vertical oscillation of the liquid film, which resonates with the original surface-gravity wave packet causing the generation of an oppositely propagating (time-reversed) surface-gravity wave of an almost identical shape, see figure 2

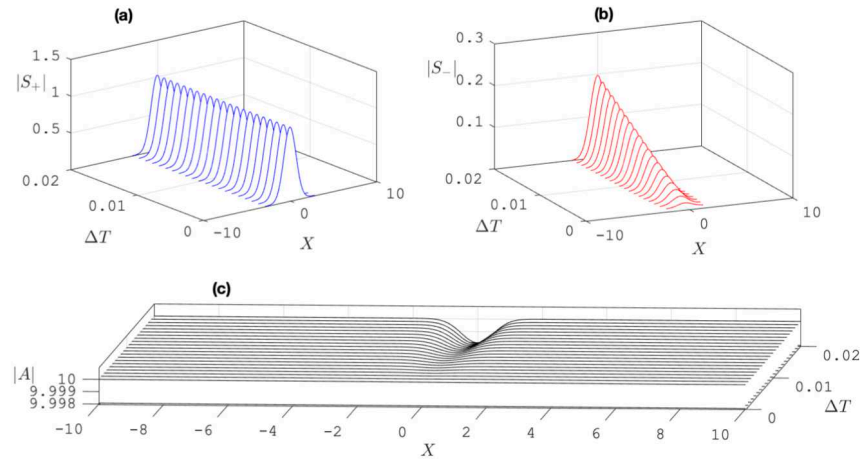

Figure 2: Amplitude evolution of time reversal triad: (a) original disturbance; (b) time reversed disturbance; (c) sudden acoustic mode.

Example 3: Tsunami Mitigation

A tsunami interaction nonlinearly with two acoustic modes. The tsunami envelope is redistributed behind over a larger space and its amplitude is reduced, see figure 3.

Figure 3: Amplitude evolution. A tsunami propagates from right to left (top), exchanges energy with two acoustic waves (middle and bottom), that propagate from left to right, [5].

Multi-scale and multi-pathways: How the ULF waves hoard electrons into precipitation

Dmitri Vainchtein^{*}, Xiaojia Zhang[†], and Anton Artemyev[†]
^{*}*Nyheim Plasma Institute, Drexel University, Philadelphia, USA*
[†]*University of California, Los Angeles, USA*

Summary. The nonlinear resonant electron scattering by whistler-mode chorus waves is one of the main drivers of the electron precipitation into the Earth's atmosphere. However, the electron precipitation shows signs of modulation by much slower ultra-low-frequency (ULF) waves, that cannot be in resonance with electrons. In this presentation we use the Hamiltonian frameworks for slow-fast systems to consider two-pronged impact of the ULF waves on the electrons' dynamics: First, ULF waves modulate the whistler waves; and second, ULF waves directly affect electron distribution functions. We implement THEMIS observations of ULF waves and modulated whistler waves to perform numerical simulations of electron dynamics. We show how the quasi-linear and nonlinear regimes of electron scattering by whistlers interchange within one ULF period and how this interplay of the two regimes affect the electron scattering (precipitation) rates.

Ultra-low-frequency (ULF) and whistler waves in the Earth magnetosphere

Ultra-low-frequency (ULF, 0.001–1 Hz) perturbations are generated at the magnetopause and propagate into the inner magnetosphere, and effectively modulate whistler waves. Close to the magnetopause, VLF wave bursts have the same periodicity as the ULF perturbations. Our results demonstrate that almost the entire outer magnetosphere (from the geostationary orbit to most elliptical orbits), including the outer radiation belts, is significantly influenced by ULF perturbations excited by magnetopause dynamic responses to the solar wind. Space observations show that ULF wave modulate not only whistler intensity, but also pitch-angle distributions of electrons. ULF waves propagate with velocities much smaller than electron thermal velocity. Therefore the interaction of ULF waves with electrons is non-resonant (in this proposal we do not consider the azimuthal resonances effective mostly for relativistic electrons). This interaction causes quasi-periodic changes of characteristic pitch-angle of distribution functions. We use conservation of the electron adiabatic invariants (the magnetic moment and the second adiabatic invariant) to describe the evolution of electron distributions. We will fit spacecraft measurements of electron distributions in the 1-100 keV energy range, and rewrite this fitted distribution in terms of adiabatic invariants. With ULF magnetic field included in calculation of invariants, we compute electron distribution for several time moments within one ULF wave period.

The nonlinear wave-particle interaction

Consider a relativistic electron interacting with a whistler wave propagating at an arbitrary angle θ relative to the background magnetic field. In the absence of the resonance overlapping, which is the most typical situation in the inner magnetosphere, the corresponding Hamiltonian is

$$H = m_e c^2 \gamma + \frac{e B_w}{k_{\parallel} \gamma} \sum_{n=0, \pm 1, \dots} h^{(n)} \sin(\phi + n\psi), \quad \gamma = \sqrt{1 + \frac{p_{\parallel}^2}{m_e^2 c^2} + \frac{2\mu\Omega_{ce}}{m_e c^2}} \quad (1)$$

In (1), n is a harmonic number, function $h^{(n)}(\mu, \theta, s, p_{\parallel})$ defines the effective wave amplitude for a particular harmonic [1], (s, p_{\parallel}) are field-aligned coordinate and momentum, (ψ, μ) are gyrophase and magnetic moment ($\mu = p_{\perp}^2 / 2m_e \Omega_{ce}$), $\Omega_{ce} = \Omega_{ce}(s)$ is an electron gyrofrequency, $\phi, k_{\parallel}(s)$, and $\omega(t)$ are a wave phase, field-aligned wave vector component, and wave frequency. Particle energy $E \approx H - m_e c^2 = m_e c^2(\gamma - 1)$, magnetic moment $\mu = \mu(\gamma, \alpha)$ is defined by γ and particle equatorial pitch-angle α . Wave amplitude B_w is much smaller than a typical particle energy ($e B_w / k \ll E$). Dynamics of particles governed by Eq.(1) includes nonlinear resonant scattering and trapping, cite Omura, Artemyev. Nonlinear scattering occurs at almost every resonant interaction and produces changes of the electron energy and pitch-angle, $\Delta^S E$ and $\Delta^S \alpha$, see Fig. 1(a,b). Such changes cause a drift in the energy/pitch-angle space, directed towards relatively small values of E and α . This drift cannot be described by the quasi-linear diffusion. Not every resonant particle is scattered, though, but some of them are trapped. Particle trapping (such as the one occurring at about $t = 90$ in Fig. 1(a,b)) results in significant changes of the energy and pitch-angle, $\Delta^P E, \Delta^P \alpha$. Such changes are much stronger than any individual change due to scattering, but the number of particles trapped at a single resonance crossing is much smaller than the number of scattered particles. The relative amount of resonant particles (with a given energy and pitch-angle) being trapped during a given resonant interaction is called *probability of trapping*.

Probabilistic approach: a single wave

Consider a 2D space (E, α) with a discretization (i, j) , i.e., the electron distribution function $f(E, \alpha)$ is defined as $f_{ij} = f(E_i, \alpha_j)$. We can introduce the quantity $s_{mn}^{kl}(W)$ as a probability of a particle to move from the state (E_k, α_l) to the state (E_m, α_n) due to a single scattering with a given wave. The letter W indicates all the relevant wave's characteristics, most importantly the amplitude, the frequency, and the angle of the wave propagation. For each concrete wave, one can

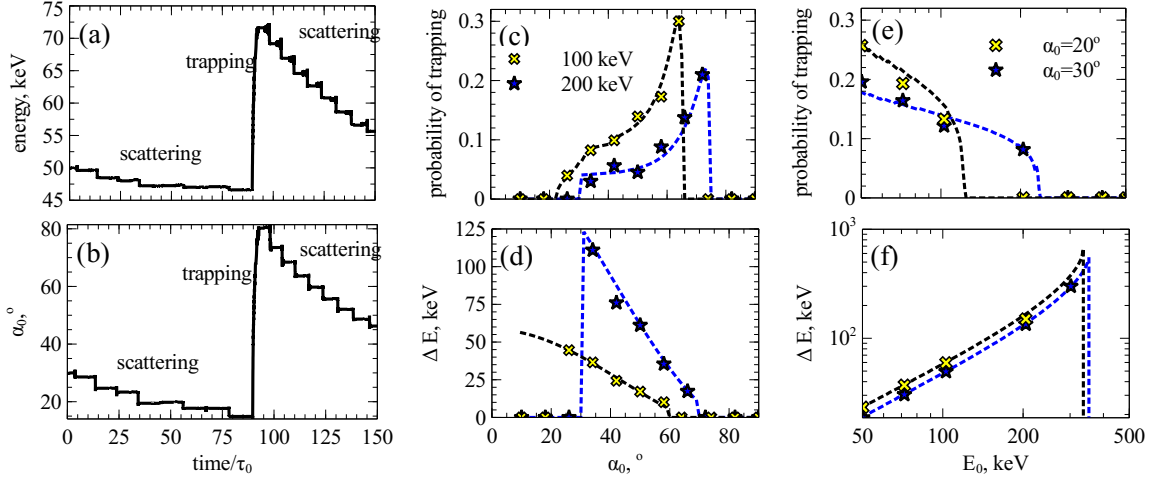

Figure 1: (a,b) A fragment of a 100 keV electron trajectory: electron energy (panel (a)) and pitch-angle (panel (b)). This fragment includes several scattering and one trapping. Time is normalized by a typical bounce period $\tau_0 = LR_E/c \sim 1/7s$ (R_E is the Earth radius). (c-f) Main characteristics of electron trapping by oblique (c,d) and parallel (e, f) waves. Analytic results (curves) are shown together with test particle simulations (symbols): energy change in trapping $\Delta^P E$ and the probability of trapping for various initial energy E_0 and pitch-angle α_0 .

view all $s_{mn}^{kl}(W)$ as the elements of a big 4D matrix, that defines the phase space transport due to scattering. Similarly, we can introduce the probability for trapping in the same way as we did for scattering: $p_{mn}^{kl}(W)$ is a probability of a particle to move from the state (E_k, α_l) to the state (E_m, α_n) due to a single trapping into resonance with a given wave. Almost all of the matrix elements are zero. Thus we arrive at

$$\frac{\partial f_{ij}}{\partial t} = -\frac{2}{\tau_{ij}} f_{ij} + \sum_{kl} R_{ij}^{kl}(W) f_{kl}; \quad R_{ij}^{kl}(W) = \frac{N_{kl}}{\tau_{kl}} (s_{ij}^{kl}(W) + p_{ij}^{kl}(W)) \quad (2)$$

where each $\tau_{ij} = \tau(E_i, \alpha_j)$ is the bounce period. Elements of $R_{ij}^{kl}(W)$ depend on wave characteristics. There is a noticeable difference between $s_{mn}^{kl}(W)$ and $p_{mn}^{kl}(W)$: while the non-zero elements of $s_{mn}^{kl}(W)$ correspond to nearby cells (around $k = m, l = n$), the elements of $p_{mn}^{kl}(W)$ are somewhat removed from there. Note that Eq. (2) is linear with respect to the distribution function f_{ij} , and nonlinear with respect to properties of the wave, W . The nonlinearity is included in the array $R_{ij}^{kl}(W)$.

Multiple waves

For an ensemble of waves, let $\rho(W)$ define the statistical weight of a certain set of parameters, $\rho(W)$ describes statistics of the wave amplitude B_w and frequency ω). The distribution $\rho(W)$ is normalized so that $\int \rho(W) dW = T_{int}/T_{tot}$ where T_{tot} is the total duration of spacecraft measurements and T_{int} is a cumulative duration of observations of intense waves. Normalized $\rho(W)$ gives a

$$\frac{\partial f_{ij}}{\partial t} = -\frac{n_{ij}}{\tau_{ij}} \frac{T_{int}}{T_{tot}} f_{ij} + \sum_{kl} \left(\int_W R_{ij}^{kl}(W) \rho(W) dW \right) f_{kl} = -\frac{n_{ij}}{\tau_{ij}} \frac{T_{int}}{T_{tot}} f_{ij} + \sum_{kl} \langle R_{ij}^{kl} \rangle f_{kl} \quad (3)$$

where $\langle R_{ij}^{kl} \rangle = \int_W R_{ij}^{kl}(W) \rho(W) dW$. For a given state (E_i, α_j) , $\langle R_{ij}^{kl} \rangle$ contains two groups of nonzero elements in the (E, α) space. The elements located near the “target” cell describe the efficiency of scattering, which, for the first cyclotron resonance, results in energy/pitch-angle decrease. The elements related to trapping are located relatively far from the “target” and they correspond to energy/pitch-angle increase.

Conclusions

The objective of the current research was to describe how the ULF waves impact the dynamics of electrons in the Earth magnetosphere: directly through the non-resonant interaction, and indirectly through modulating the whistler waves, that do have the non-linear resonance interaction with electrons. The research was supported in part by the NASA award 80NSSC19K0266.

Slow-fast dynamics in vibratory pile driving: field tests and numerical modelling

Athanasios Tsetas*, Apostolos Tsouvalas* and Andrei V. Metrikine *

*Faculty Of Civil Engineering and Geosciences, Delft University of Technology, The Netherlands

Summary. This paper presents a study of vibration-based pile driving methods on the basis of field data and numerical modelling. Based on field data from an extensive field test campaign and existing results found in the relevant literature, the vibratory pile installation is shown to constitute a slow-fast dynamical process. Moreover, a three-dimensional numerical model for the analysis of vibratory pile driving is presented, comprised by a thin cylindrical shell (pile), a linear elastic layered half-space (soil) and a frictional interface. Based on the latter numerical model, the relevant experimental findings are discussed and compared in order to shed light into the complex pile-soil behavior during vibratory driving and the emergence of slow-fast pile motion.

Extended abstract

Presently, over 80% of the offshore wind turbines (OWTs) in Europe are founded on monopiles [1]. These foundations are most commonly installed by impact hammer, albeit this method poses a source of noise pollution, harmful to marine life, and can compromise the structural integrity and fatigue life of a monopile [2]. To this end, environmentally friendly alternatives are investigated for offshore monopile installation, such as vibratory methods. The standard axial vibratory pile driving is used onshore for decades, with advantageous features such as high installation speed and low axial pile loading. However, in the offshore industry the use of the vibratory driving technique is limited, due to the lack of field data and knowledge gaps related to the complex pile-soil behaviour during installation and the post-installation effects. To further the potential of vibration-based methods a new technology – the Gentle Driving of Piles (GDP) – has been proposed by TU Delft [3]. The GDP method is based on simultaneous application of low-frequency/axial and high-frequency/torsional vibrations at the pile head and aims to improve installation performance and reduce underwater noise emissions. Medium-scale field tests have been performed at Maasvlakte II site, at the port of Rotterdam (see Fig. 1), in which different pile installation methods were investigated, with a focus on the classical vibratory and GDP methods.

Figure 1: (a) Test pile layout and (b) GDP test site.

In this paper, the vibratory and GDP installation methods are studied and the emergence of pile penetration into the soil medium as a slow-fast dynamical process is presented. In principle, the pile is forced by the combination of a periodic excitation at the pile top and the self-weight of the pile and the vibratory device. The resulting motion can be distinguished into a slow motion of the rigid body type and a fast motion characterized by the fundamental driving frequency and its super-harmonics. The main findings of the installation tests and the comparison of the two methods are discussed. Furthermore, a three-dimensional model for the analysis of pile installation for the considered methods is presented. Specifically, the pile is modelled as a thin cylindrical shell, according to the Love-Timoshenko theory [4], in order to properly capture the pile motion. The soil continuum is modelled as an elastic layered half-space, by means of the thin layer method (TLM), augmented with perfectly matched layers (PMLs) [5]. Finally, a frictional interface is used to couple the pile-soil system and permit pile slip. The numerical solution of the presented model is based on the alternating frequency-time harmonic balance method, in order to address the problem with a computationally fast approach.

In the topic of vibratory pile driving two classes of models are employed, i.e. the engineering-oriented one-dimensional models and the advanced research-oriented three-dimensional models. The former describe in a simplistic manner the non-linear pile-soil interaction during driving, neglecting effects such as the non-local and frequency dependent soil-reaction. The latter models -although more rigorous- rely on a multitude of parameters for the soil constitutive model, which cannot be customarily obtained by *in situ* measurements. Therefore, their use in engineering practice remains unfeasible, especially considering their excessive computational cost. The model presented in this work aims to bridge the gap between the two classes, by employing a more physically sound soil reaction with reduced semi-empirical soil parameters, while retaining the computational efficiency required for use in engineering practice. To that end, the predictions of the developed model are validated with the field data; the latter is of great essence for the GDP method, which cannot be analysed by other existing numerical models.

Figure 2: Installation test of a pile driven by the GDP method.

On the Escape of a Resonantly Excited Couple of Colliding Particles from a Potential Well under Bi-harmonic Excitation

Attila Genda^{*}, Alexander Fidlin^{*} and Oleg Gendelman^{**}

^{*}*Institute of Engineering Mechanics, Karlsruhe Institute of Technology, Karlsruhe, Germany*

^{**}*Mechanical Engineering, Technion – Israel Institute of Technology, Haifa, Israel*

Summary. Escape dynamics of a damped two-particle system with internal collisions in a truncated quadratic potential well under biharmonic excitation is investigated. It is assumed that the excitation frequencies are tuned to the $2l$ -fold values of the modal natural frequency of the relative motion and to the modal frequency of the center of mass on the bottom of the potential well. Although the escape is an essentially non-stationary process, the critical forcing amplitude strongly depends on the stationary amplitudes of the relative vibrations within the two particles. The characteristic escape curve for the critical force moves up with the increasing relative vibrations.

Introduction

Escape from a potential well is an important topic in non-linear dynamics. The problem arises in various fields of physics and engineering [1]-[5].

A broad spectrum of physical phenomena from the dynamics of molecules to celestial mechanics has been studied in the literature, discussing topics such as energy harvesting [6], the physics of Josephson junctions [7], transient resonance dynamics of oscillatory systems [8, 9] or such phenomena as capsizing of ships [3, 10]. A further example for an escape related topic is the dynamic pull-in in microelectromechanical systems (MEMS) [11]-[16].

First, in 1940, Kramer started to investigate the forced escape phenomenon regarding the thermal activation of chemical reactions [17, 18]. Despite of much research which has taken place in the last 80 years, important unsolved problems still exist regarding the escape process [19].

In the case of constant forcing, escape might occur as a consequence of the slow variation of the system parameters which leads to subsequent bifurcations of the steady-state regimes of the response [2, 11, 12]. Thompson investigates extensively the mechanisms leading to escape in a cubic model potential. His numerical results describe the phenomenon of escape along a broad scale of the excitation frequency of the harmonic forcing. It reveals the chaotic processes leading to escape near the critical forcing amplitude curve. Using Melnikov's method [32] a good approximation can be given for the numerical location of a part of the critical force curve.

Different modeling approaches can be found in the literature to give analytic criteria for the escape. In the paper of Virgin, [3] harmonically forced and damped particles are investigated in three different model potentials, where the steady state response of the particle's motion is used to obtain the partly empirically corrected analytic criterion. The author assumes a harmonic response with an additional bias to correct asymmetries of the potential.

Technically relevant potential wells in general exhibit a monotonically decreasing stiffness when moving away from the center of the potential well. This is necessary to flatten out the profile of the potential, otherwise its depth could not be finite.

In the paper [3] some model potential wells are also investigated numerically. The numerical results show a sharp minimum of the critical forcing amplitude depicted along the forcing frequency. This sharp minimum takes smaller values than the linearized eigenfrequency of the potential well. Papers [14, 15] investigating the problem of dynamic pull-in in MEMS devices also come to similar results regarding the shape of the critical forcing curve.

In the papers [20, 21] investigating the safe basins of attraction for various dynamical systems similar patterns for the sharp minimum were found. This let's the reader formulate a hypothesis about the above mentioned feature of the critical forcing curve as an inherent property of the escape phenomena. In the papers [22, 25] for different potentials this hypothesis was investigated using harmonic forcing.

The above two papers investigate the escape dynamics of the harmonically forced bodies assuming 1:1 resonance. The applied method is able to take into account the transient dynamics of the system, which can be described by the slow flow on the resonance manifold. Varying the initial conditions (IC) allows the identification of two different escape mechanisms. The simpler to describe maximum mechanism (MM) corresponds to the case when the oscillation amplitude reaches the escape threshold as a consequence of the excitation. In this case, exciting with the critical force results in an amplitude value that just reaches the escape threshold. The other mechanism is the so called saddle mechanism (SM). It is different from the previous mechanism, because the amplitude of the vibration stays quite small even if the forcing amplitude is almost critical. When the critical forcing amplitude is reached, the vibration amplitude starts to increase abruptly and escape takes place. At the lowest point of the critical force curve both mechanisms can be observed at the same time. The approach resembles the research done in [23, 24] describing transient phenomena in coupled oscillator systems with the use of limiting phase trajectories (LPT).

In paper [28] a system of a pair of strongly coupled particles in a truncated quadratic potential well with a bi-harmonic excitation, consisting of a high and a low frequency component, was investigated. The paper introduced a new method to model the effect of the high-frequency excitation using an effective force field which was derived by convolution of the original force field and the probability density function of the fast movement around the center of mass of the two particles.

Figure 1: The setting of the collision problem in a potential well with harmonic force excitation.

The multi-body problem was simplified that way to a single body problem for which standard techniques could be applied. The research also showed that the high-frequency excitation has a stabilizing effect on the escape behavior with the used model potential, for which, being the model of a linear oscillator, a single particle has a critical forcing amplitude tending to 0 at the resonance frequency. In the case of two bodies, however, the minimal value of the critical force curve is greater than 0 and it is shifted to a lower frequency than the linearized eigenfrequency of the potential.

In the present paper, the model presented in [28] is modified such that the particles, although they are still considered as point masses, are not able to penetrate each other, but an almost elastic collision, with the coefficient of restitution R takes place every time they get in touch with each other, i.e. the distance between them is $\Delta := r_1 + r_2$.

First, the mathematical model of the problem is introduced. Then, after bringing the equations into an appropriate form using a coordinate transformation, the first step of the model reduction based on the so called 'unfolding transformation' is described. With the use of this result, the further reduction of the model takes place in the next section, which is based on a probabilistic type of averaging, that leads to a single particle problem in a modified, effective potential. In the section 'Numerical results and discussion' the reduced model is compared to the original problem by direct numerical integration using parameter values spanned by a grid on the excitation frequency – force amplitude plane, highlighting the stabilizing effect of the high-frequency excitation. The findings of the paper are summarized in the 'Conclusions' section.

Description of the model

Let us consider the following problem setting depicted in Fig. 1.

The coupled pair of particles with masses m_1 and m_2 is excited harmonically in a one-dimensional quadratic potential well. The linear spring between the particles has the stiffness $k \gg 1$ and the linear damper is described by the damping coefficient c of $\mathcal{O}(1)$. The potential well is defined individually for both of the particles by $V_1(x) = m_1 V(x)$ and $V_2(x) = m_2 V(x)$, respectively, where m_1 and m_2 are of $\mathcal{O}(1)$. Poly-harmonic forces, given by $F_1(t)$ and $F_2(t)$, respectively, can act on both of the bodies. The particles cannot penetrate through each other and hence collide every time they are at a distance $\Delta := r_1 + r_2$ from each other. The collision is nearly elastic, which means the coefficient of restitution is close to one, i.e. $R \approx 1$.

The differential equations describing the motion of the system are given by

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \begin{bmatrix} \ddot{x}_1 \\ \ddot{x}_2 \end{bmatrix} + \begin{bmatrix} c & -c \\ -c & c \end{bmatrix} \begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} + \begin{bmatrix} k & -k \\ -k & k \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} m_1 V'(x_1) \\ m_2 V'(x_2) \end{bmatrix} = \begin{bmatrix} F_1(\tau) \\ F_2(\tau) \end{bmatrix} \quad \text{if } x_1 + \Delta < x_2, \quad (1)$$

$$x_{1+} = x_{1-}, \quad x_{2+} = x_{2-}, \quad \text{if } x_1 + \Delta = x_2, \quad (2)$$

$$\dot{x}_{1+} = \frac{Rm_2(\dot{x}_{2-} - \dot{x}_{1-}) + m_1\dot{x}_{1-} + m_2\dot{x}_{2-}}{m_1 + m_2}, \quad \dot{x}_{2+} = \frac{Rm_1(\dot{x}_{1-} - \dot{x}_{2-}) + m_1\dot{x}_{1-} + m_2\dot{x}_{2-}}{m_1 + m_2}, \quad (3)$$

where V is defined as

$$V(x) = \begin{cases} \frac{1}{2}x^2 - \frac{1}{2} & |x| \leq 1, \\ 0 & |x| > 1, \end{cases} \quad (4)$$

The excitation force can be chosen in general as

$$F_j(\tau) = \sum_{i=1}^p A_{ji} \sin(\Omega_{ji}\tau + \beta_{ji}), \quad \text{with } j \in 1, 2 \text{ and } p \in \mathbb{N}^+. \quad (5)$$

In order to be able to excite the center of the mass in the potential well and the relative vibrations within the particles simultaneously, the excitation in the current investigation is chosen to be

$$F_1(\tau) = F_{11} \sin(\Omega_{11}\tau + \beta_{11}) + F_{12} \sin(\Omega_{12}\tau + \beta_{12}), \quad (6)$$

$$F_2(\tau) = 0. \quad (7)$$

The coordinates x_1 and x_2 can be linearly transformed to the new coordinates

$$y_1 := \frac{m_1 x_1 + m_2 x_2}{m_1 + m_2}, \quad y_2 := x_2 - x_1, \quad (8)$$

thus, y_1 describes the movement of the particle's center of mass and y_2 gives the distance between the particles. By having collisions, y_2 can never be smaller than Δ . The inverse of the coordinate transformation is substituted back into Eq. (1), which leads to

$$\begin{aligned} \ddot{y}_1 + \mu V'(y_1 - (1 - \mu)y_2) + (1 - \mu)V'(y_1 + \mu y_2) \\ = \frac{1}{m_1 + m_2} (F_{11} \sin(\Omega_{11}\tau + \beta_{11}) + F_{12} \sin(\Omega_{12}\tau + \beta_{12})) \quad \text{if } y_2 > \Delta, \end{aligned} \quad (9)$$

$$y_{1+} = y_{1-}, \quad \dot{y}_{1+} = \dot{y}_{1-}, \quad \text{if } y_2 = \Delta, \quad (10)$$

$$\begin{aligned} \ddot{y}_2 + \frac{c}{m} \dot{y}_2 + \frac{k}{m} y_2 + \underbrace{V'(y_1 + \mu y_2) - V'(y_1 - (1 - \mu)y_2)}_{\text{small coupling term of } \mathcal{O}(1) \text{ since } \frac{k}{m} \gg V'(x)} \\ = -\frac{F_{11}}{m_1} \sin(\Omega_{11}\tau + \beta_{11}) - \frac{F_{12}}{m_1} \sin(\Omega_{12}\tau + \beta_{12}) \quad \text{if } y_2 > \Delta, \end{aligned} \quad (11)$$

$$y_{2+} = y_{2-}, \quad \dot{y}_{2+} = -R\dot{y}_{2-}, \quad \text{if } y_2 = \Delta, \quad (12)$$

with

$$\frac{1}{m} := \frac{1}{m_1} + \frac{1}{m_2}, \quad \mu := \frac{m_1}{m_1 + m_2}. \quad (13)$$

Eq. (11) is coupled to Eq. (9) only through a small term, which, if both terms of the sum are evaluated inside of the potential, is equal to y_2 and if both terms are evaluated outside of the potential, is equal to 0. Otherwise, the small coupling term is not independent of y_1 anymore, but still, even in this case the force of the potential is very small compared to the force of the spring. In addition, the case, when both particles are in the potential well, is the most dominant one, thus the small coupling term can be approximated by y_2 very well. By doing so, Eq. (11) becomes linear and can be solved easily.

$$\ddot{y}_2 + \frac{c}{m} \dot{y}_2 + \left(\frac{k}{m} + 1 \right) y_2 = -\frac{F_{11}}{m_1} \sin(\Omega_{11}\tau + \beta_{11}) - \frac{F_{12}}{m_1} \sin(\Omega_{12}\tau + \beta_{12}) \quad \text{if } y_2 > \Delta, \quad (14)$$

$$y_{2+} = y_{2-}, \quad \dot{y}_{2+} = R\dot{y}_{2-}, \quad \text{if } y_2 = \Delta, \quad (15)$$

Since the damping coefficient, $\frac{c}{m}$ in the investigated case is not small, the homogeneous solution will decay in relatively short time and the relevant part of the solution becomes the particular solution [29]-[30]. The frequency of the resonance peak in the motion of y_2 without collision would be

$$\Omega_{02} = \sqrt{\frac{k}{m} + 1 - \frac{c^2}{2m^2}}, \quad (16)$$

but the collisions have a significant effect on the high frequency vibration, which has to be discussed first in order to be able to determine the vibration amplitude and so the probability density function (PDF) of the high-frequency oscillations. In the current investigation we are interested in the escape behavior of the two-particle system with large inner vibrations under a low-frequency and small force amplitude excitation. To get large vibrations in the relative motion of the particles the appropriate excitation frequencies should be found.

The resonance frequency of the particle's center of mass in the potential well is not influenced by the collisions. When both particles are in the potential well, Eq. (9) simplifies to

$$\ddot{y}_1 + y_1 = \frac{1}{m_1 + m_2} (F_{11} \sin(\Omega_{11}\tau + \beta_{11}) + F_{12} \sin(\Omega_{12}\tau + \beta_{12})), \quad (17)$$

which means that the linearized eigenfrequency of y_1 is $\Omega_{01} = 1$.

In the next section the focus is set on the description of the vibration amplitude of the relative movement depending on the choice of the excitation frequency.

The first step of the model reduction: resonance of the colliding particles under high-frequency excitation

The analysis of the resonance frequencies of Eq. (14) is already performed by *Fidlin* in chapter 3.5 of [31]. In the present section of this paper the content of the book is repeated mostly, however, due to a printing error in the book, a somewhat different result is obtained in the end.

In order to be able to apply the results from the book, a preliminary step is needed. With a coordinate transformation it has to be ensured that the term y_2 in Eq. (14) has the coefficient 1.

Introducing the new, dimensionless time $t = \omega_0 \tau$, with $\omega_0 = \sqrt{\frac{k}{m} + 1}$ the time derivatives can be rewritten as follows

$$\dot{y}_2 = \frac{dy_2}{d\tau} = \omega_0 \frac{dy_2}{dt} = \omega_0 y_2', \quad (18)$$

$$\ddot{y}_2 = \frac{d^2 y_2}{d\tau^2} = \omega_0^2 \frac{d^2 y_2}{dt^2} = \omega_0^2 y_2'', \quad (19)$$

where the time derivative with respect to the dimensionless time is indicated by a prime ('). Rewriting Eq. (14) in the dimensionless time yields

$$y_2'' + \frac{c}{\omega_0 m} y_2' + y_2 = \underbrace{-\frac{F_{11}}{m_1 \omega_0^2} \sin\left(\frac{\Omega_{11}}{\omega_0} t + \beta_{11}\right)}_{\text{Negligible}} - \frac{F_{12}}{m_1 \omega_0^2} \sin\left(\frac{\Omega_{12}}{\omega_0} t + \beta_{12}\right). \quad (20)$$

Given that Ω_{11} is chosen to be in the nearby of $\Omega_{01} = 1$, the effect of the first term on y_2 is negligibly small. Defining the following parameters

$$\beta := \frac{c}{\omega_0 m}, \quad \varepsilon := \frac{F_{12}}{m_1 \omega_0^2}, \quad \omega := \frac{\Omega_{12}}{\omega_0}, \quad (21)$$

we can rewrite Eq. (20) can be rewritten as follows

$$y_2'' + \beta y_2' + y_2 = -\varepsilon \sin(\omega t + \beta_{12}) \quad \text{if } y_2 > \Delta, \quad (22)$$

$$y_{2+} = y_{2-}, \quad y_{2+}' = -R y_{2-}' \quad \text{if } y_2 = \Delta. \quad (23)$$

Using the so called 'unfolding transformation'

$$y_2 = |z| + \Delta, \quad (24)$$

Eq. (22) can be written as

$$z'' + \beta z' + z = (-\Delta - \varepsilon \sin(\omega t + \beta_{12})) \operatorname{sgn} z \quad \text{if } z \neq 0, \quad (25)$$

$$z_+' - z_-' = -(1 - R) z_-' \quad \text{if } z = 0. \quad (26)$$

Using the Van der Pol transformation with

$$z = A \sin \varphi, \quad z' = A \cos \varphi. \quad (27)$$

and a newly defined, uniformly rotating phase

$$\psi = \omega t + \beta_{12}, \quad (28)$$

Eq. (25) can be transformed to

$$\begin{aligned} A' &= -\beta A \cos^2 \varphi + (-\Delta - \varepsilon \sin \psi) \cos \varphi \operatorname{sgn} \sin \varphi & \text{if } \varphi \neq n\pi, \\ A_+ - A_- &= -(1 - R) A_- & \text{if } \varphi = n\pi, \end{aligned} \quad (29)$$

$$\varphi' = 1 + \beta \sin \varphi \cos \varphi + \frac{\Delta + \varepsilon \sin \psi}{A} |\sin \varphi|, \quad (30)$$

$$\psi' = \omega. \quad (31)$$

With the usual definition of the *resonant surface* and *resonant solutions* as also defined in [31], we focus on the parameter values of ω for which the averaged right hand side becomes discontinuous, as in the vicinity of those values, large amplitude responses may occur. 'Dangerous' terms are

$$\langle \sin \psi \cos \varphi \operatorname{sgn} \sin \varphi \rangle = \frac{1}{2\pi} \int_0^{2\pi} \sin(\omega t + \gamma) \cos t \operatorname{sgn} \sin t dt, \quad (32)$$

$$\langle \sin \psi |\sin \varphi| \rangle = \frac{1}{2\pi} \int_0^{2\pi} \sin(\omega t + \gamma) |\sin t| dt, \quad (33)$$

$$\gamma = \psi_0 - \varphi_0, \quad (34)$$

which expression can have values different from zero for values $\omega_l = 2l$, $l = 1, 2, 3 \dots$. Then, by introducing

$$\delta = \frac{\omega}{2l} - 1, \quad \theta = \varphi - \frac{\psi}{2l}, \quad (35)$$

Eq. (29) can be rewritten as

$$A' = -\beta A \cos^2 \varphi - \Delta \cos(\varphi) \operatorname{sgn}(\sin \varphi) - \varepsilon \sin(2l(\varphi - \theta)) \cos \varphi \operatorname{sgn}(\sin \varphi) \quad \text{if } \varphi \neq n\pi, \quad (36)$$

$$A_+ - A_- = -(1 - R)A_- \quad \text{if } \varphi = n\pi, \quad (37)$$

$$\theta' = -\delta + \beta \sin \varphi \cos \varphi + \frac{\Delta + \varepsilon \sin(2l(\varphi - \theta))}{A} |\sin \varphi|, \quad (38)$$

$$\varphi' = 1 + \beta \sin \varphi \cos \varphi + \frac{\Delta + \varepsilon \sin(2l(\varphi - \theta))}{A} |\sin \varphi|. \quad (39)$$

Taking small values for δ , the discontinuous averaging procedure can be performed. Using the notations of [31], the four integrals to be evaluated are

$$J_1 = \frac{1}{2\pi} \int_0^{2\pi} \sin(2l\varphi) |\sin \varphi| d\varphi = \frac{1}{\pi} \int_0^\pi \sin(2l\varphi) \sin \varphi d\varphi = 0, \quad (40)$$

$$J_2 = \frac{1}{2\pi} \int_0^{2\pi} \cos(2l\varphi) |\sin \varphi| d\varphi = -\frac{2}{\pi(4l^2 - 1)}, \quad (41)$$

$$J_3 = \frac{1}{2\pi} \int_0^{2\pi} \sin(2l\varphi) \cos \varphi \operatorname{sgn} \sin \varphi d\varphi = \frac{4l}{\pi(4l^2 - 1)}, \quad (42)$$

$$J_4 = \frac{1}{2\pi} \int_0^{2\pi} \cos(2l\varphi) \cos \varphi \operatorname{sgn} \sin \varphi d\varphi = 0. \quad (43)$$

Using the above results and averaging yields the following differential equations

$$A' = -\left(\frac{1}{2}\beta + \frac{1-R}{\pi}\right)A - \frac{4l\varepsilon}{\pi(4l^2 - 1)} \cos 2l\theta, \quad (44)$$

$$\theta' = -\delta + \frac{2\Delta}{\pi A} + \frac{2\varepsilon}{\pi(4l^2 - 1)} \frac{\sin(2l\theta)}{A}. \quad (45)$$

Eq. (44) differs from Eq. (3.95) in [31] by the additional factor 3 in the denominator, which is a printing error. Setting the left hand side to 0, the stationary solution, A_* and θ_* can be obtained.

$$\frac{\frac{1}{2}\beta + \frac{1-R}{\pi}}{2l} A_* = -\frac{2\varepsilon}{\pi(4l^2 - 1)} \cos 2l\theta_*, \quad (46)$$

$$\delta A_* - \frac{2\Delta}{\pi} = \frac{2\varepsilon}{\pi(4l^2 - 1)} \sin 2l\theta_*. \quad (47)$$

Eliminating θ_* and introducing

$$\beta_l = \frac{\frac{1}{2}\beta + \frac{1-R}{\pi}}{2l}, \quad \varepsilon_l = \frac{\varepsilon}{4l^2 - 1}, \quad (48)$$

one obtains

$$\beta_l^2 A_*^2 + \left(\delta A_* - \frac{2\Delta}{\pi}\right)^2 = \frac{4\varepsilon_l^2}{\pi^2}. \quad (49)$$

Its solution for A is then

$$A_{1,2} = \frac{2}{\pi} \frac{\delta \Delta \pm \sqrt{\varepsilon_l^2(\beta_l^2 + \delta^2) - \Delta^2 \beta_l^2}}{\beta_l^2 + \delta^2}. \quad (50)$$

Only the root with the plus sign is a stable solution (see proof in [31]) therefore the stationary amplitude is

$$A_* = \frac{2}{\pi} \frac{\delta \Delta + \sqrt{\varepsilon_l^2(\beta_l^2 + \delta^2) - \Delta^2 \beta_l^2}}{\beta_l^2 + \delta^2}. \quad (51)$$

For fixed Δ , β_l and ε_l but for varying δ the maximal value of A_* can be found by setting

$$\left. \frac{\partial A_*}{\partial \delta} \right|_{\delta_{\max}} \stackrel{!}{=} 0, \quad (52)$$

which leads to

$$\delta_{\max} = \frac{\Delta \beta_l}{\varepsilon_l}. \quad (53)$$

Inserted in Eq. (51) the biggest amplitude value estimated by the analytic approach is

$$A_{*,\max} = \frac{\varepsilon_l}{\beta_l}, \quad (54)$$

independent from Δ , i.e. for every feasible choice of Δ the maximal amplitude is the same for some δ_{\max} . Now we can write the solution

$$z(t) = A_* \sin\left(\frac{\omega t}{2l} + \varphi_0\right) \quad (55)$$

for some φ_0 , thus

$$y_2(t) = A_* \left| \sin\left(\frac{\omega t}{2l} + \varphi_0\right) \right| + \Delta. \quad (56)$$

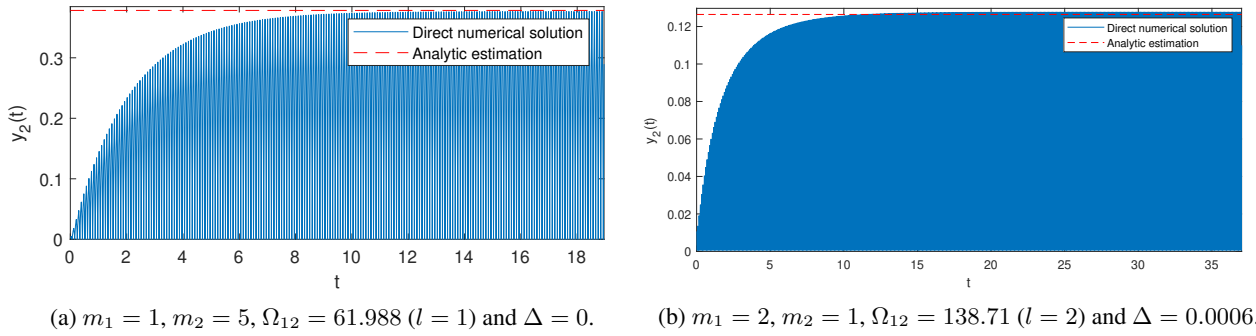

Figure 2: Comparison of the numerical solution for y_2 with the theoretically estimated stationary amplitude for $c = 0.5$, $k = 800$, $F_{12} = 15$. The theoretical model can predict the stationary amplitude very accurately.

The second step of the model reduction: calculating the effective slow potential using the probabilistic description of the high-frequency oscillations

Given the amplitude of y_2 , the PDF of the high-frequency oscillations around the common center of mass, y_1 can be determined as

$$\begin{bmatrix} z_1 \\ z_2 \end{bmatrix} = \begin{bmatrix} x_1 - y_1 \\ x_2 - y_1 \end{bmatrix} = \begin{bmatrix} y_1 - \frac{m_2}{m_1+m_2} y_2 - y_1 \\ y_1 + \frac{m_1}{m_1+m_2} y_2 - y_1 \end{bmatrix} = \begin{bmatrix} -\frac{m_2}{m_1+m_2} y_2 \\ \frac{m_1}{m_1+m_2} y_2 \end{bmatrix}. \quad (57)$$

As it can be expected, the movement is not symmetric around y_1 , unless the masses are equal. In general the PDFs of the individual particles, $\rho_i(x)$ are given by arcsine distributions cut in the middle as depicted in Fig 3. To write the probability density function of z_1 and z_2 , first, we define

$$A_{1*} = (1 - \mu)A_*, \quad A_{2*} = \mu A_*, \quad \Delta_1 = (1 - \mu)\Delta, \quad \Delta_2 = \mu\Delta, \quad (58)$$

thus

$$z_1 = -A_{1*} \left| \sin\left(\frac{\omega t}{2l} + \varphi_0\right) \right| - \Delta_1, \quad z_2 = A_{2*} \left| \sin\left(\frac{\omega t}{2l} + \varphi_0\right) \right| + \Delta_2. \quad (59)$$

In general the probability density function (PDF), $\rho(x)$ of a function, $f(t)$, which is strictly monotonically increasing and continuously differentiable on the interval (a, b) is given by

$$\rho(x) = \frac{1}{f'[f^{-1}(x)]} \cdot \frac{1}{b-a} \quad \text{for } f(a) < x < f(b). \quad (60)$$

If the function, $f(t)$ is strictly monotonically decreasing, its PDF is just the negative of the above expression. Thus in the special case of

$$f(t) = A_{i*} \sin(\Omega t + \beta) + \Delta_i \quad (61)$$

we have

$$\rho(x) = \frac{1}{\Omega \sqrt{A_{i*}^2 - (x - \Delta_i)^2}} \frac{1}{b - a}, \quad (62)$$

where a and b are such, that the function increases monotonically between them. Since $f(t)$ is periodic, it suffices to determine the PDF of one period, which in the case of z_1 and z_2 can be done by splitting the period into a monotonically increasing and monotonically decreasing part. As the two parts obviously has the same PDF in this case, it is enough to determine the PDF of the monotonically decreasing part for z_1 and the monotonically increasing part for z_2 , that we achieve by choosing

$$a = -\frac{2l\varphi_0}{\omega}, \quad b = \frac{2l\left(\frac{\pi}{2} - \varphi_0\right)}{\omega}, \quad \Omega = \frac{\omega}{2l}, \quad (63)$$

then we can write

$$\rho_1(x) = \begin{cases} \frac{2}{\pi \sqrt{A_{1*}^2 - (x + \Delta_1)^2}} & \text{for } -A_{1*} - \Delta_1 < x < -\Delta_1, \\ 0 & \text{otherwise,} \end{cases} \quad (64)$$

$$\rho_2(x) = \begin{cases} \frac{2}{\pi \sqrt{A_{2*}^2 - (x - \Delta_2)^2}} & \text{for } \Delta_2 < x < A_{2*} + \Delta_2. \\ 0 & \text{otherwise.} \end{cases} \quad (65)$$

The PDF of the particle system, $\rho(x)$ is obtained finally by the weighted sum of the individual probability density functions

$$\rho(x) = \mu \rho_1(x) + (1 - \mu) \rho_2(x). \quad (66)$$

A numeric example is given in Fig. 3.

Figure 3: One period of the high-frequency oscillation and the corresponding PDF with masses $m_1 = 1$ and $m_2 = 5$.

Effective potential by convolution

Eq. (9) can be rewritten now as follows

$$\ddot{y}_1 + \mu V'(y_1 + z_1) + (1 - \mu) V'(y_1 + z_2) = \frac{1}{m_1 + m_2} (F_{11} \sin(\Omega_{11}\tau + \beta_{11}) + F_{12} \sin(\Omega_{12}\tau + \beta_{12})). \quad (67)$$

The arguments of $V'(\cdot)$ oscillates with a high frequency around y_1 , instead of calculating the exact values for every moment, a kind of averaging is used to obtain an effective potential \tilde{V} . As during a period of the high frequency vibration z_i the change of y_1 is small, we can get the averaged force at y_1 by calculating the total force on the particle density cloud at y_1 having the PDF $\rho_1(x)$ and $\rho_2(x)$. The latter operation can be performed, as for any continuously distributed volume in a force field, by the following integral transformation

$$\tilde{V}'(y_1) = \int_{-\infty}^{\infty} V'(x) \rho(x - y_1) dx. \quad (68)$$

In our special case the integral can be evaluated analytically. First we define the positions

$$d_1 = -1 - \Delta_2 - A_{2*}, \quad d_2 = -1 - \Delta_2, \quad d_3 = -1 + \Delta_1, \quad d_4 = -1 + \Delta_1 + A_{1*}, \quad (69)$$

$$d_5 = 1 - \Delta_2 - A_{2*}, \quad d_6 = 1 - \Delta_2, \quad d_7 = 1 + \Delta_1, \quad d_8 = 1 + \Delta_1 + A_{1*}. \quad (70)$$

In the following, we will only consider the case, when $\Delta + A_* < 2$, so that we can guarantee that $d_1 \dots d_9$ are in ascending order. With the help of the above positions we can define the domains

$$D_1 = \{x \in \mathbb{R} | x \leq d_1\}, \quad (71)$$

$$D_i = \{x \in \mathbb{R} | d_{i-1} \leq x < d_i\} \quad \text{for } i = 2 \dots 8, \quad (72)$$

$$D_9 = \{x \in \mathbb{R} | d_8 \leq x\}. \quad (73)$$

Thus, the effective force field can be written as

$$\tilde{V}'(y_1) = \begin{cases} 0 & x \in D_1, \\ (1 - \mu) \left(y_1 + \Delta_2 + \frac{2}{\pi} \left(\sqrt{A_{2*}^2 - (1 + \Delta_2 + y_1)^2} - (y_1 + \Delta_2) \arcsin \left(-\frac{1 + \Delta_2 + y_1}{A_{2*}} \right) \right) \right) & x \in D_2, \\ (1 - \mu) \left(y_1 + \Delta_2 + \frac{2}{\pi} A_{2*} \right) & x \in D_3, \\ \mu \left(\frac{2}{\pi} \left(\sqrt{A_{1*}^2 - (\Delta_1 - 1 - y_1)^2} + (\Delta_1 - y_1) \arcsin \left(\frac{\Delta_1 - 1 - y_1}{A_{1*}} \right) - A_{1*} \right) \right) + (1 - \mu) \left(y_1 + \Delta_2 + \frac{2}{\pi} A_{2*} \right) & x \in D_4, \\ y_1 & x \in D_5, \\ \mu \left(y_1 - \Delta_1 - \frac{2}{\pi} A_{1*} \right) + (1 - \mu) \left(\frac{2}{\pi} \left(A_{2*} - \sqrt{A_{2*}^2 - (1 - \Delta_2 - y_1)^2} + (\Delta_2 + y_1) \arcsin \left(\frac{1 - \Delta_2 - y_1}{A_{2*}} \right) \right) \right) & x \in D_6, \\ \mu \left(y_1 - \Delta_1 - \frac{2}{\pi} A_{1*} \right) & x \in D_7, \\ \mu \left(-\frac{2}{\pi} \left(\sqrt{A_{1*}^2 - (1 + \Delta_1 - y_1)^2} + (\Delta_1 - y_1) \arcsin \left(\frac{1 + \Delta_1 - y_1}{A_{1*}} \right) \right) - \Delta_1 + y_1 \right) & x \in D_8, \\ 0 & x \in D_9. \end{cases} \quad (74)$$

Through integration the effective potential can be determined as well. As the potential can be shifted arbitrarily by a constant, we set the condition $\tilde{V}(-\infty) \stackrel{!}{=} 0$. However, the analytic expression for $\tilde{V}(y_1)$ is very complex, so we dispense with giving an exact formula here.

Please note, that Eq. (74) is valid for arbitrary values of Δ , however, in practical cases Δ is limited to $\mathcal{O}(\varepsilon)$, thus the intervals D_3 and D_7 do not have a significant role.

In Fig. 4 a graphical example is represented for a certain parameter choice (cf. the caption of Fig. 4).

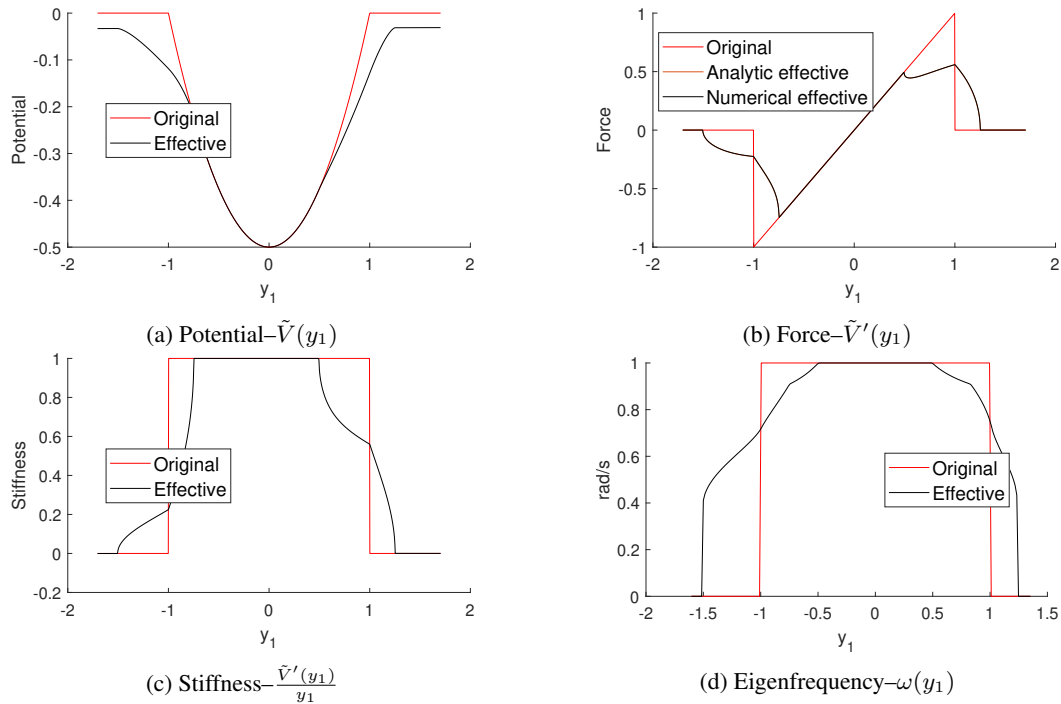

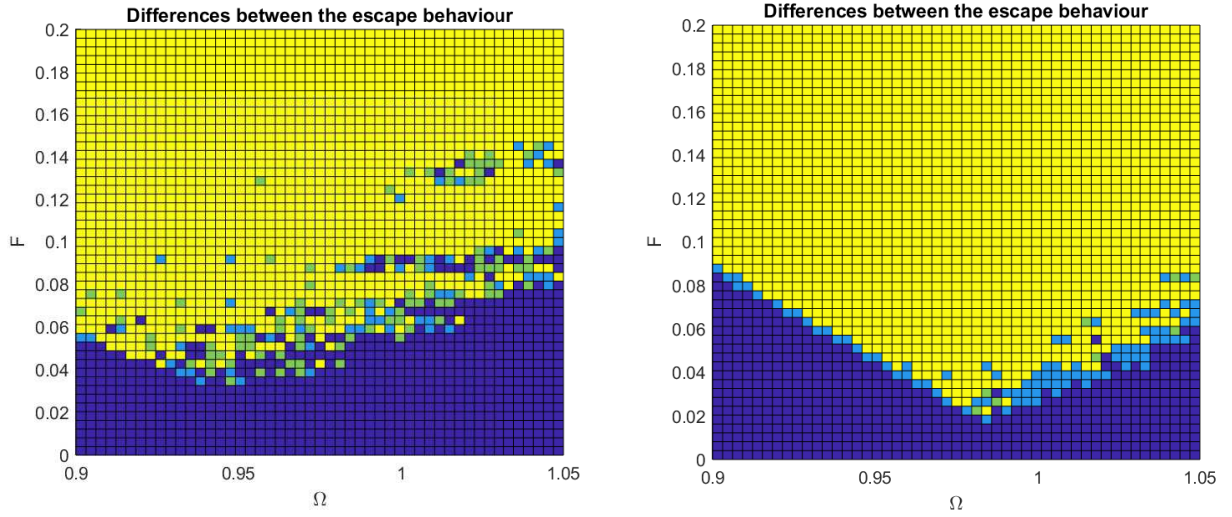

Figure 4: Non-linear force field and some other derived quantities generated by $m_1 = 2$, $m_2 = 1$, $c = 0.5$, $k = 800$, $F_{12} = 30$, $\Omega_{12} = 69.335$ ($l = 1$), $\Delta = 0.0006$.

A very important effect, due to the asymmetric integration kernel, is the asymmetry of the effective force field. Therefore all the other quantities derived from it, are asymmetric as well. Moreover, the potential energy on the right boundary of the potential is also different from the potential energy on the left hand side of the potential, which might lead to an asymmetric escape behavior. The probabilities of escaping to the right might differ from the probability of escaping to the left. The further the ratio $\frac{m_1}{m_2}$ is from 1, the greater is the asymmetry, which leads to vibrations with a symmetry center different from 0.

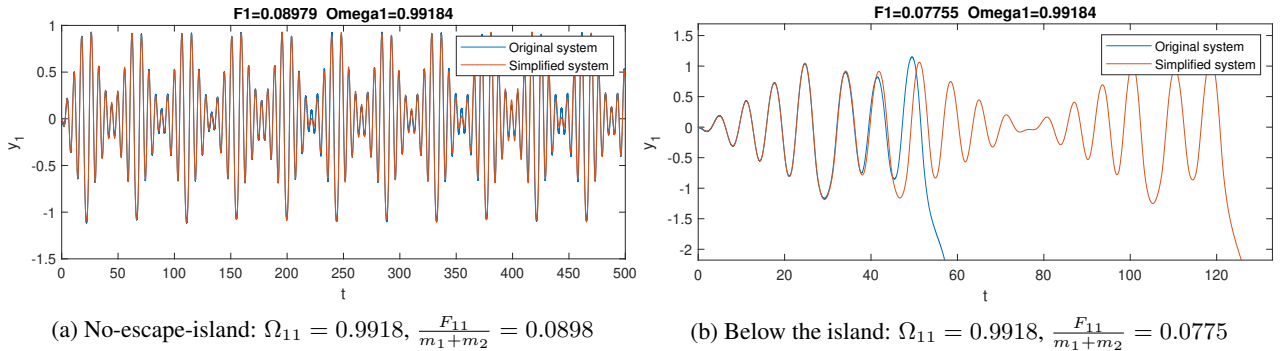

Numerical results and discussion

A good way to determine the goodness of the order reduction method applied above is to depict the escaping/non-escaping points on the low excitation frequency–low excitation force plane. In Fig. 5 such a comparison can be seen. It is important to note, that the sharp minimum (Ω_C, F_C), observed by many authors in the literature, can be determined more or less. However, in Fig. 5 on the right from the minimum, i.e. for $\Omega_{11} > \Omega_C$ there is not really a frequency dependent critical forcing value, above which escape happens for whatever forcing amplitude. Instead the transition from no-escape into escape happens through a fractal-like boundary and there exist even separated non-escaping 'islands' in the 'see' of escaping $\Omega_{11} - F_{11}$ parameter combinations. Such a time evolution is shown in Fig. 6. The remarkable feature of the model reduction is, that even these non-escaping islands of the parameter combinations remain preserved. When the non-linear part of the effective force gets smaller (cf. 5b), we can observe a less chaotic behavior around the critical force values. Moreover, it is also obvious that the minimally needed force amplitude moves up, as the non-linearity of the effective force field increases, due to the increasing amplitude of the relative motion. This simple fact explains also, why the escaping region in the $\Omega_{11} - F_{11}$ plane moves closer to the point (1, 0), when the relative motion is excited with a higher resonant frequency but unchanged force amplitude. Eq. (54) and Eq. (48) show the simple relationship between the excitation frequency and the amplitude of the caused resonant motion that shows a decreasing amplitude with increasing value for l .

(a) First resonant frequency is excited, $\Omega_{12} = 69.34$ ($l = 1$). (b) Second resonant frequency is excited, $\Omega_{12} = 138.67$ ($l = 2$).

Figure 5: Comparison of the reduced model to the original one with parameter values $m_1 = 2, m_2 = 1, c = 0.5, k = 800, F_{12} = 30$, and $\Delta = 0.0006$. Dark blue dots mean no escape for both models, bright blue is escape in the simplified model, but no escape in the original model, green is no escape in the simplified model, but escape in the original one. Yellow stands for escape in both models. $F := \frac{F_{11}}{m_1 + m_2}$.

(a) No-escape-island: $\Omega_{11} = 0.9918, \frac{F_{11}}{m_1 + m_2} = 0.0898$

(b) Below the island: $\Omega_{11} = 0.9918, \frac{F_{11}}{m_1 + m_2} = 0.0775$

Figure 6: $m_1 = 2, m_2 = 1, c = 0.5, k = 800, F_{12} = 30, \Omega_{12} = 69.335$ ($l = 1$) and $\Delta = 0.0006$.

Conclusions

In the present work escape of a strongly coupled, colliding pair of particles from a potential well under bi-harmonic excitation was investigated. Through a coordinate transformation from the physical coordinates of the particles into the coordinates of the common center of mass and into the distance of the particles the motion could be decomposed into a

slow and into a fast variable. After determining the oscillation amplitudes of the fast motion with the use of the so called 'unfolding transformation', a certain type of averaging, appropriate to use also with piece-wisely defined functions being based on the probability density function of the fast motion, was performed. The resulting formulas for the effective force-field are fully analytic, thus a huge reduction in the simulation time can be achieved (5 hours vs 4 minutes in the example shown). It turns out, that even such properties of the system remain well conserved, as for example the location of the non-escaping islands on the low excitation frequency–low forcing amplitude ($\Omega_{11} - F_{11}$) plane. Although in the current work escape was investigated in a truncated quadratic potential well, the application of the PDF based averaging method is straightforward for several different potentials as well.

Many questions may remain open in the Reader regarding the further analysis of the escape behavior of a colliding pair of coupled particles. What happens if the resonant frequencies of the relative motion are of the same magnitude as the eigenfrequency of the bottom of the potential well? How do the initial conditions of the particles influence the escape behavior? How to proceed in case of poly-harmonic excitation? What if the collision of the particles is a random process? What happens when there are more than two colliding particles?

The authors of this paper hope, that many of the readers will feel motivated to find answers to these and many other different questions arising when studying the thrilling topic of escape from a potential well.

Summary. The goal of this work is to develop a theoretical and numerical models of the coupled and uncoupled vibration of bi-material beams subjected the combined action of mechanical and thermal loads. The geometrically nonlinear version of the Timoshenko beam theory is used to describe the theoretical model of the problem. Starting from the geometrical, constitutive and equilibrium equations of each layer the governing equations of the bi-material beam are derived. The beam is subjected to heat flux and periodic mechanical loading. The influence of the elevated temperature or the heat propagation along the beam length and thickness on the response of the beam was studied.

Introduction

Among the most popular composite structures the bi-material structures and especially the bi-material beams are frequently used in different braches in industry. The growing interest to mechanical behavior of the bi-material beam can be connected with different MEMS (see, for example <https://istegim2019.sciencesconf.org/285421>). The thermoelastic behaviour of such beams is a subject of interest because of their applicability as well as because of the complex behaviour of the structures due to the different elastic and thermal properties of the layers.

Generally, the most of the studies of the dynamic response of the thermally loaded beam consider that the structure gets elevated temperature instantly, and the heat propagation is not included in the model.

The goal of the present work is to derive the equations of the geometrically non-linear vibration of a bi-material beam with non-symmetric layers according to the Timoshenko beam theory. Based on these equations it is aimed to study the coupled and uncoupled geometrically nonlinear vibrations of the beam as well as the vibration of the beam at constant elevated temperature. The influence of the coupled terms in the governing equations and the new terms counting the non-uniform layers are specially studied for different material properties and different thermal loadings. The speed of the propagation of the temperature along the different layers is also analyzed. The reduced model created on the base of Galerkin approach allows analysis of the beam response in the frequency and time domains and an estimation of the stability of the solution, as well. Three dimensional finite element model of the bi-material beam is created in order to verify the results.

Theoretical model

A beam with length l , width b and thickness h is considered. The beam consists of two layers made of different materials (Material 1 and Material 2) with thickness h_1 and h_2 ($h=h_1+h_2$). The geometrical scheme of the beam is shown in Fig. 1.

Fig. 1 The geometrical scheme of the beam model

The equations describing the coupled problem of the temperature propagation and the beam vibrations as a result of the action of a heat flow and of mechanical load with intensity $p(x, t)$ are:

$$\begin{aligned} \frac{c_p^{(i)}}{\lambda_T^{(i)}} \frac{\partial T}{\partial t} &= \frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial z^2} - \frac{\alpha_T^{(i)} E^{(i)} T_0}{\lambda_T^{(i)}} \frac{\partial \varepsilon^{(i)}}{\partial t}, \quad i = 1, 2 \\ \frac{\partial N}{\partial x} - c_1^{(i)} \frac{\partial u}{\partial t} - \rho^{(i)} b h^{(i)} \frac{\partial^2 u}{\partial t^2} &= 0, \quad -\frac{\partial M}{\partial x} + Q - c_2^{(i)} \frac{\partial \psi}{\partial t} - \rho^{(i)} I^{(i)} \frac{\partial^2 \psi}{\partial t^2} = 0, \\ \frac{\partial Q}{\partial x} + N \left(\frac{\partial^2 w}{\partial x^2} \right) &+ \frac{\partial N}{\partial x} \frac{\partial w}{\partial x} - c_1^{(i)} \frac{\partial w}{\partial x} - \rho F \frac{\partial^2 w}{\partial t^2} = -p(x, t) \end{aligned}$$

where $I^{(i)}$ is the inertia moment of i^{th} layer, $\rho^{(i)}$ is the density of the i^{th} material $T(x, z, t)$ is current temperature, T_0 is the initial constant temperature, $\lambda_T^{(i)}$ is the thermal conductivity of i^{th} material and $c_p^{(i)}$ is the heat capacity per unit volume,

$\alpha_T^{(i)}$ is the coefficient of the thermal expansion, $E^{(i)}$ is the Young's modulus of the i^{th} layer, $c_1^{(i)}$ and $c_2^{(i)}$ are damping coefficients, $w(x, t)$ is the transverse displacement, $\psi(x, t)$ is the rotation angle and

$$\varepsilon^{(i)} = -z \frac{\partial \psi}{\partial x} + \alpha_T^{(i)} (T - T_0) + \frac{\partial u}{\partial x} + \frac{1}{2} \left(\frac{\partial w}{\partial x} \right)^2$$

After integrations along each layer thickness the generalized stresses N , M and Q are expressed by the displacements and then the governing equations of the bi-material beam are derived.

In comparison with the classical Timoshenko beam equations, additional nonlinear terms appear in the equations describing the longitudinal displacements, transverse displacements and the angular rotations.

Numerical approach

The equation for the heat propagation is discretized with respect to the space variables (x and z) by the finite difference method. The partial differential equations for the beam vibration are transformed to a system of coupled nonlinear ordinary differential equations by the Galerkin approach using the expansion of the generalized displacement vector in a series of the product of the normal modes of the linear Timoshenko beam and time dependent coefficients. The algorithm for the solution of the problem is based on the successive solution of the equations for the mechanical vibrations of the beam and for the heat transfer. The algorithm is similar to the one described in [1].

Numerical examples

Two cases of the problem have been studied: (i) beam at elevated temperature and (ii) beam subjected to a heat impact. The influence of the elevated temperature applied together with periodic loading on the beam is studied in time and frequency domain.

In the case of the heat impact the propagation of the temperature along the beam layers and specially at the interface layer is studied. It is shown that in the case of short and intensive heat pulses the beam can buckle (Fig. 2). The influence of the nonlinear terms appeared due to the different properties of the materials is estimated.

In some cases, the coupled terms may influence the temperature propagation as can be seen in Fig. 3.

Fig. 2. Time history of the response of the beam subjected to thermal and harmonic loading with 1- no heating; 2-heat impact with duration $\bar{t}_0=30$ (dimensionless time) and $q_0=9000 \text{ W/m}^2$.

Fig. 3. Variation of the temperature at the beam center at 6th interface layer of the beam cross-section.

Conclusions

A theoretical model of the dynamic behaviour of Timoshenko beam is developed. The model includes a full coupling of the mechanical and thermal fields i.e. the thermal field influences the beam motion and the beam motion influence the heat propagation. The dynamic behavior of the beam is studied in the case of coupled, uncoupled vibration, as well as the case of elevated constant temperature. 3D finite element model of the problem and a reduced model are used and the results obtained by both models are compared.

Summary. The drillstring dynamics is a complicated nonlinear rotordynamics problem. The slender drillstring is immersed in a 3D well in the presence of mud, drillstring-well contacts, fluid-structure interactions, bending-torsion-axial vibrations. The induced vibration problems increase the energy loss and cause failures. In order to understand and predict better the vibrations phenomena a Finite Element model is proposed. The simulation results are compared to field data.

Keywords: Nonlinear rotordynamics, drillstring, fluid-structure interaction, rotor-stator contact, contact models

Drillstring description

In rotary drilling which addresses today more and more geothermal application, drillstring is a very slender rotor immersed in a well with a 3D trajectory, Fig. 1. The drillstring, driven by an electrical motor within a 0-180 rpm range, is an assembly of pipes 9 to 10 m long confined in tension in a 3D curvilinear well of several kilometers. Towards the drill bit, over 100 to 200 meters long, the drill collars have a larger outer diameter to ensure the Weight On Bit (WOB) on the rock and then constitute the Bottom Hole Assembly (BHA). Stabilizers act as bearings to maintain the drill collar concentric with the well and permit directional drilling. The drill collar is kept in compression with, at its upper end, the tension-compression neutral point. The mud, i.e. the drilling fluid, circulates downward inside the drill-pipes and upward in the pipe-well annular space. The role of the mud is to clean out rock debris and calories, to lubricate the numerous drillstring – bore hole contacts.

Fig. 1. Sketch of the drillstring immersed in the well

Fig. 2. Configuration of nonlinear response computation

Nonlinear phenomena

Solicited by mud pulses, mass unbalances, pipe-well interactions and friction, motor and resistant torques as well as the axial forces of the various drill-bit shapes, the drill string has a dynamic behavior governed by equations of motion involving in particular the fluid-structure coupling, the nonlinearities of contact, and the axial-bending-torsion couplings. The drillstring is therefore a complex dynamic system because it is non conservative, gyroscopic, with parametric excitations, and necessarily non-linear. Thus, it is expected in the different portions of the drill string, nonstationary behaviors, stick-slip motion, tool-bit bouncing, forward and backward, periodic, quasi-periodic, and chaotic whirls. This set of phenomena induces, in particular, energy loss, failures. Consequently, the Rate of Penetration (ROP) decreases while the Non-Productive Time (NPT) increases.

Coupled and nonlinear proposed model

Facing these technical issues requires to understand as well as possible the drillstring behavior with the implementation of a specific nonlinear rotordynamics model in order to predict in fine the forced dynamics response, the total amount of friction torques, and the drill pipe stresses. The proposed model is based on the Finite Element method using Timoshenko beam elements with 6 degrees of freedom per node. At the beginning of the computational process, the FE mesh of the drillstring is vertical and its positioning on the 3D-well neutral line is computed without any external load, combining the Newton-Raphson technique with a co-rotational formulation. The obtained path serves for starting the Newton-Raphson iterative method for calculating the drillstring quasi-static equilibrium position inside the well by considering: the drillstring pre-loading induced by the 3D-well, the gravity, the buoyancy, the nonlinear well end-stops, the inner and annular fluids, the static stress-stiffening due to the Weight-on-Bit (WOB), and the torque on-Bit (TOB). The drillstring-well contacts are modeled with contact stiffness and damping which are smoothed by using the arctan function. From this quasi-static equilibrium, assuming that the contacts remain permanent and linear, a classical modal analysis is carried out and a Campbell diagram is plotted by employing specific criteria that tracks the mode shapes and

classifies them. In the case of the nonlinear response, the contacts are free to become unilateral, see Fig. 2. Finally, the dynamic response of the complete FE model in the time domain is governed by the following set of nonlinear equations:

$$\begin{aligned}
 M\ddot{\delta} + C\dot{\delta} + K\delta &= F(t, \delta, \dot{\delta}) \\
 M &= M_a + M_{fe} + M_{fi} \\
 C &= \Omega(C_{ac}^T - C_{ac}) + C_{ad} + C_{fe}(\Omega) \quad C_{ad} = c_M M_a + c_K(K_a + K_{gpa} + K_{gpo}(\delta_s)) \\
 K &= K_{pa} + K_{gpo}(\delta_s) + C_{ac}^T \dot{\Omega} \quad K_{pa} = K_a + K_{gpa} + K_{fe} \\
 F &= F_s + F_u(t) + F_c(\delta, \dot{\delta}, \Omega, ROP) - F_{\theta_z} \dot{\Omega} + R_{ipa} \\
 M_a, M_{fi} & \text{Mass matrices of the drillstring and of the inner mud} \\
 M_{fe}, C_{fe}, K_{fe} & \text{Mass matrices of the annular mud} \\
 C_{ac}, C_{ad} & \text{Matrices of gyroscopic effect and of Rayleigh damping (coeff } c_M, c_K) \\
 F_{\theta_z} \dot{\Omega} & \text{Torque vector} \\
 F_c, F_u & \text{Contact load and mass unbalance force vectors} \\
 R_{ipa} & \text{Vector of the static pre-loading}
 \end{aligned}$$

The dynamic response is computed using a RK4 scheme with an adaptative time step. A reduced model based on the Craig and Bampton technique is also available. The simulations are carried out on a field unconventional well with downhole measurements. Figure 3 presents the full-spectral analysis of the orbits all along the drillstring abscissa while Fig. 4 compares predicted and measured lateral accelerations.

Fig. 3. Full spectrum analysis all along the drillstring.

Escape Dynamics of a Parametrically Excited Particle from an Infinite Range Potential

K. R. Jayaprakash^{*}, Oleg Gendelman^{**}

^{*}*Discipline of Mechanical Engineering, Indian Institute of Technology Gandhinagar, Gujarat, India*

^{**}*Faculty of Mechanical Engineering, Technion-Israel Institute of Technology, Haifa, Israel*

Summary. The current papers dwells on the classical problem of escape from a potential well. The considered potential well in this study is infinite range, with one global minimum and reaching maximum asymptotically at infinity. The particle is parametrically excited and we consider the threshold of escape of this particle from the bottom of the well. The analytical study is based on invoking the canonical action-angle variables and the averaged dynamics on a resonance manifold.

Introduction

The oscillatory behavior of a dynamical system is governed by the potential to which the system is subjected to. In order to study the dynamics of the system close to the center (local minimum in a conservative system), one could linearize the system and add the nonlinear terms as weak perturbations. However, such quasilinear dynamical systems seldom model the behavior away from the center. For example, the classical case of escape dynamics of a forced particle from a potential well can hardly be analytically studied using a weakly nonlinear model, since problem of escape is essentially a transient phenomenon. Such problem are plenty in the domain of applied physics and engineering and have been quite extensively studied [1]. From an engineering perspective, the dynamical behavior of capsizing of sea vessels is provided by Virgin [2], whereas the dynamic pull-in and the escape dynamics thereof in MEMS devices were reported by Younis et al. [3], studies by Virgin et al. [4] considers escape from a well under harmonic excitation, while Mann [5] considers an energy-based criterion for escape from the double well of a magnetic pendulum. Recent studies by Gendelman et al. [6, 7] invoke the canonical action-angle (AA) variables and averaging [8] to study the escape. Current study is based on the framework of AA variables.

As such, an analytical prediction of the particle escape from the potential well becomes quite relevant. We consider an undamped particle oscillating in an infinite-range potential. The minimum of the well is Lyapunov stable and the fixed point persists even with the application of parametric excitation. However, the excitation can render the fixed point unstable, but may not necessarily lead to escape. In contrast, for certain parameter range (excitation frequency and amplitude) one can observe escape (ref. Fig. 1) of the particle. The objective herein is to numerically and analytically study the parameter range of amplitude and frequency that leads to escape and the route thereof. The escape is characterized by breaching of the separatrix (connecting the two fixed points at $(\pm\infty, 0)$) as shown in Fig. 1.

Mathematical modeling and analysis

Consider the dynamics of a parametrically excited (amplitude ε and frequency Ω) particle in an infinite-range potential

$$\ddot{q} + \frac{\partial V(q, t)}{\partial q} = 0; V(q, t) = -\frac{\{1 + \varepsilon \sin(\Omega t)\}}{2 \cosh^2(q)} \quad (1)$$

We are interested in the transition values of (Ω, ε) that would render a particle situated close to the bottom (but not exactly at the bottom) of the well to escape. To this end, we introduce the AA (I, θ) variables and the canonical transformation resulting in $p = p(I, \theta)$, $q = q(I, \theta)$. The perturbed Hamiltonian in AA variables is

$$\mathcal{H}(I, \theta, t) = \mathcal{H}_0(I) - \varepsilon \sin(\Omega t) \{1 + C^2 \sin^2(\theta)\}^{-1/2} \quad (2)$$

Where $\mathcal{H}_0(I) = -(1 - I)^2/2$, $C = \sqrt{2I - I^2}/(1 - I)$ and $I = 0$ corresponds to the bottom of the well. Since $q(I, \theta)$ is 2π periodic, the perturbation term in Eq. 2 can be expanded in Fourier series. We consider 2:1 resonance and thereby introduce slow phase variable $\vartheta = 2\theta - \Omega t$. On averaging the slow-flow equation corresponding to the evolution of AA variables over the fast phase variables, we have the averaged $(I \mapsto J, \vartheta \mapsto \psi)$ slow-flow equations in the form,

$$\begin{aligned} \dot{J} &= -\varepsilon J \{1 + (J - 2)^{-1}\} \cos(\psi) \\ \dot{\psi} &= 2(1 - J) + \varepsilon \{1 - 2(J - 2)^{-2}\} \sin(\psi) - \Omega \end{aligned} \quad (3)$$

The fixed points of the slow-flow equations are readily calculable to be (i) $J = 0, \sin(\psi) = 2(\Omega - 2)/\varepsilon$, (ii) $J = 1, \sin(\psi) = -(\Omega/\varepsilon)$ (iii) $\psi = \pi/2, 3\pi/2, \{2(1 - J) - \Omega\}(J^2 - 4J + 4) \pm \varepsilon(J^2 - 4J + 2) = 0$ respectively. The fixed point at $\psi = \pi/2, J > 0$ is a center and $\psi = 3\pi/2, J > 0$ is a saddle for $\Omega < 2$. For a specific value of $\Omega < 2$, with an increase in the excitation amplitude, the saddle goes through a pitchfork bifurcation and there is emergence of two additional fixed points (i). Upon bifurcation, fixed point at $\psi = 3\pi/2, J < 0$ is a center, but not of much significance. The bifurcations would become apparent by investigating the integral of motion of the averaged system given by

$$\mathcal{M}(J, \psi) = -(1 - J)^2 + \varepsilon J(J - 1)(J - 2)^{-1} \sin(\psi) - J\Omega \quad (4)$$

The bifurcation point corresponds to the threshold of the excitation amplitude resulting in escape. The locus of these points is shown in Fig. 2 as red curves (LB_{avg}, RB_{avg}) emanating from $\Omega = 2$. Incidentally, these curves also correspond to the instability boundary of the Mathieu equation $\ddot{x} + x\{1 + \varepsilon \sin(\Omega t)\} = 0$, resulting from the linearization of Eq. 1 about $(0, 0)$. The escape threshold for the exact system (Eq. 1) is indicated as LB_{ex}, RB_{ex} . As observable, there is the close match of the LB_{avg} and LB_{ex} . However, the right boundary shows a very distinct transition wherein the averaged system predicts a much lower escape threshold in comparison to the actual dynamical system (Eq.

1). It is noted that along the boundary predicted by the averaged system, the center corresponding to the bottom of the potential well bifurcates to a saddle. This is evidenced by the Poincare maps of Fig. 3 ($\Omega = 1.8$). In fact, along LB_{ex} , the creation of this saddle leads to the particle escape. In contrast, in the regions other than LB_{ex} , the creation of the saddle (along LB_{avg} , RB_{avg}) leads to chaotic motion albeit bounded. On further increase in the excitation amplitude, the tori are broken and the particle escapes. This behavior is observable in the Poincare maps of Fig. 4 ($\Omega = 1.9$). The minimum force amplitude required for the escape corresponds to a frequency $\Omega < 2$ ($\Omega \cong 1.85$) and is owing to the fact that Eq. 1 exhibits softening nonlinearity.

Figure 1: Particle escape from the bottom ($q(0) = 10^{-6}$, $\dot{q}(0) = 0$) of the potential well for $\varepsilon=0.4$, $\Omega=1.8$. (Broken red curves correspond to the separatrix)

Figure 2: Escape threshold. Blue shaded region (num. simulation of Eq. 1) corresponds to particle escape (for $t \leq 6000$). The red lines emanating from $\Omega = 2$ correspond to the point of bifurcation corresponding to Eq. 3 and those emanating from $\Omega = 1$ correspond to the Mathieu equation described above

Figure 3: Poincare maps corresponding to $\Omega = 1.8$ (left panel) $\varepsilon = 0.3$ (right panel) $\varepsilon = 0.39$

Figure 4: Poincare maps corresponding to $\Omega = 1.9$ (a) $\varepsilon = 0.2$, (b) $\varepsilon = 0.3$, (c) $\varepsilon = 0.4$ (a-c refers to the points indicated in Fig. 2)

Conclusions

The current study considers the escape dynamics of a parametrically excited particle (located close to the bottom of the well) from an infinite-range potential. We invoke the AA variables and study the dynamics of the system on the resonance manifold and predict the threshold for escape as a function of frequency. For certain (Ω, ε) , the bifurcation of the bottom of the well to a saddle leads to the escape, whereas for other parametric range, the escape is through a chaotic route as evidenced by the Poincare maps and the slow-flow model fails to predict the escape in this case.

Explanation of the Locomotion of a Rigid Body along a Vibrating Nonlinear Beam

Florian Müller*, Alexander F. Vakakis[‡] and Malte Krack*

^{*}University of Stuttgart, Germany

[‡]University of Illinois at Urbana-Champaign, USA

Summary. Several independent research groups have investigated the self-adaptive behavior of a clamped-clamped beam with attached slider. Under harmonic base excitation the slider passively moves to a certain position on the beam, going along with a significant increase of amplitude. We are the first to fully explain this complex process theoretically by means of a model reproducing the behavior. Moreover, we show that the slider's movement takes places on a slower time scale compared to the beam's vibration. Exploiting this temporal separability, we explain the different mechanisms yielding transport towards or away from beam's center.

Introduction

A harmonically forced clamped-clamped beam with a slider free to move axially on the beam has been experimentally investigated by different groups [1, 2, 5]. After initially small vibrations, the slider moved to a certain position, where vibration amplitude increased significantly. After this process, the amplitude and the final slider position, which is in many cases away from the antinode at beam's center, were maintained in steady state. In case the slider is initially placed close enough to the beam's center, it moves towards clamping first and turns back towards center at some point. The turning point is accompanied with a jump to higher vibration level and the movement back goes along with a further increase of amplitude [1]. In [1, 2], beside experimental results, models were presented, assuming that the slider is constrained to the beam in the vertical direction. Simulation results exhibit a slider movement towards the beam's center going along with an increase of amplitude. However, a movement towards clamping, a jump of amplitude and a steady state slider position away from center couldn't be reproduced. In [3, 4], we present a model accounting for a gap between slider and beam, which gives rise to unilateral and frictional contact interactions and consider also the beam's stiffening geometric nonlinearity. This model has the capability to reproduce all features of the self-adaptive process. In [5] we present an experimental validation of this model, yielding excellent agreement of measurements and simulation. In the present contribution we demonstrate that the beam's vibration and the slider's movement take place on well separated time scales and exploit this separability to study the different mechanisms producing locomotion of the slider systematically.

Separable timescales of vibration and slider movement

The considered specification of the self-adaptive beam-slider system corresponds to the beryllium-copper beam described in [1]. A schematic of the model is depicted in Fig. 1a. The beam is modeled according to Euler-Bernoulli theory, where the deformation is approximated by the lowest frequency bending mode and the stiffening geometric nonlinearity due to the fixed ends is considered. To model unilateral and dry frictional contact interactions between beam and slider, the Signorini and Coulomb laws combined with Newton's impact law are used. The resulting set-valued force laws are solved numerically applying Moreau's time stepping scheme. The contact model and simulation procedure are adopted from [3]. A simulation of a successful self-adaptive process is depicted in Fig. 1b in terms of the vibration's amplitude as a function of the resulting slider position (dashed black). While vibration amplitude is initially small, the slider moves towards clamping. At $\tilde{s}/L \approx 0.24$, the slider turns and the amplitude jumps to a higher level. After this, the slider moves back towards center, while the amplitude increases further. During the whole process, the global horizontal movement of the slider is slow compared to the beam's vibration [4]. To prove the independence of these time scales, we study the steady state response depending on the relative slider position. In order not to affect the slider's dynamics by an additional constraint, we let the slider's horizontal displacement s free, but consider the given relative slider position \tilde{s} always when evaluating the contact kinematics during the simulation. This essentially yields a model where the beam is moved with the slider horizontally [5]. For each relative slider position we numerically integrate until steady state, increase the relative slider position by a small $\Delta\tilde{s}$ and again integrate until steady state, starting from the final state of the previous point. The results for increasing and decreasing \tilde{s} exhibit a high and a low amplitude branch, see Fig. 1b (green and orange lines). This behavior can be explained by the beam's stiffening nonlinearity [4]. Clearly, the response of the system with free slider follows the low amplitude branch first, jumps, and follows the high amplitude branch then. The steady state model enables us to evaluate also the slider's absolute horizontal displacement s . In Fig. 1c we illustrate the steady state absolute slider velocity by means of slider's displacement per beam length and evaluation periods. In the range of \tilde{s} which is relevant for the self-adaptive process, the steady state slider velocity corresponding to the low (high) amplitude branch points towards clamping (beam's center). This is in qualitative and good quantitative agreement with the self-adaptive process. Also on the fast time scale of vibration, the steady state model coincides very well with the system with free slider (time histories not shown for brevity). Altogether, this proves the separability of the different time scales [6].

Vibration induced locomotion towards center or clamping

We now want to explain, why the slider is transported towards clamping (beam's center) during the low (high) amplitude phase. To this end, we study the periodically dominated vibrations obtained by the steady state model exemplary

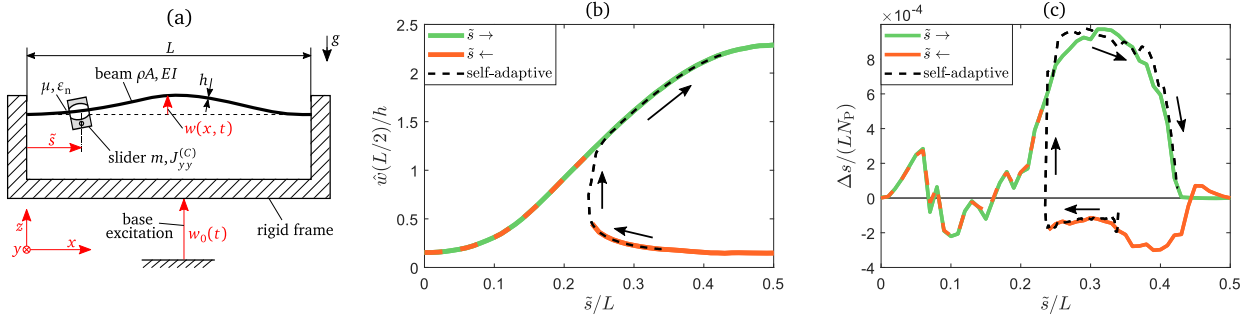

Figure 1: (a) Two dimensional model of self-adaptive system. (b) Vibrational amplitude versus relative slider position. (c) Averaged normalized slider velocity versus relative slider position. [6]

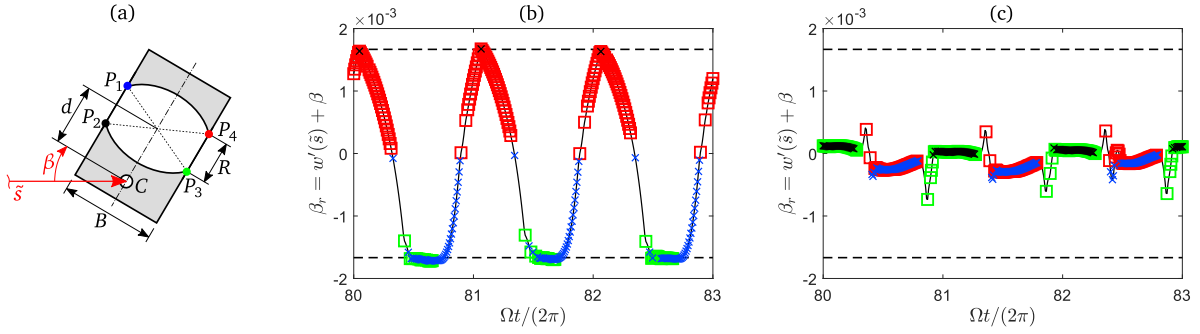

Figure 2: (a) Slider detail. (b) Relative slider rotation (steady state model, $\tilde{s} = 0.3$, low vibration level). (c) Relative slider rotation (steady state model, $\tilde{s} = 0.3$, high vibration level). Markers indicate active contacts, where the colors match with P_1 through P_4 in (a). [6]

at $\tilde{s}/L \approx 0.3$. We start with the simple explanation for the high amplitude phase. Here, the beam's elastic deformation is close to a monoharmonic oscillation which is approximately in phase with the excitation and big compared to the clearance between slider and beam. During almost one half of an excitation cycle, both upper contact points are in contact. During the other half of the cycle, both lower points are in contact, see Fig. 2c. Therefore the system behaves like a beam with vertically constrained but horizontally movable body. For this simplified system, the inertia force acting on the slider has a horizontal component stemming from the beam's slope, which can be approximated $m\ddot{s} = -m[\ddot{w}(s) + \ddot{w}_0]w'(s)$. This force points always to center. In case of a very small [3, 4] or no [2] gap, the slider moves to center also for low amplitude level. Instead of that, successful adaptation is obtained in case the clearance is chosen in the order of magnitude of the vibration level corresponding to the low amplitude branch, which allows for a complex limit cycle, see Fig. 2b. This limit cycle contains states of maximum and minimum possible relative rotation between slider and beam. The crucial transportation of the slider's center of mass C towards clamping is obtained during rolling on the upper contacts P_1 and P_4 from minimum to maximum possible rotation [6].

Conclusions

The beam's vibration and slider's movement take place on well separated time scales, which can be shown by using a steady state model with prescribed relative slider position. Studying the periodically dominated steady state responses corresponding to the different phases of the self-adaptive process explains the slider's locomotion. Further work could focus on optimization of the system and application as energy harvester or vibration absorber.

Summary. Under harmonic excitation, soil exhibits softening behaviour that can be captured through the so-called hyperbolic soil model. The response of systems with such a material model can elegantly be obtained using the classical Harmonic Balance Method (HBM). Soil also exhibits nonlinear hysteretic damping under harmonic excitation, feature which is not incorporated in the hyperbolic soil model. The response of a system that includes also the nonlinear hysteretic damping cannot be obtained using the classical HBM. This work demonstrates the application of an advanced HBM (more specifically, alternating frequency-time HBM) for finite and infinite systems that exhibit softening behaviour and nonlinear hysteretic damping. The purpose of this model is to, in the future, investigate the influence of the nonlinear hysteretic damping on the response of such systems, as opposed to linear viscous or hysteretic damping that is usually adopted. To conclude, we show that the advanced HBM is an effective tool for revealing fundamental characteristics of continuous systems with softening behaviour and nonlinear hysteretic damping whose stationary responses consist of either standing or propagating waves.

Introduction

The Harmonic Balance Method (HBM) is often applied to compute the stationary response of nonlinear *discrete* systems to harmonic loading. It is known to be very efficient as it does not require the simulation of the transient response before reaching the stationary regime, and it can efficiently yield frequency-response curves.

The HBM has been applied to nonlinear *continuous* systems too, but in many cases the nonlinearity is discrete and thus localized at one or multiple points; both finite [1] and infinite [2,3] models have been considered. Furthermore, Chronopoulos [4] presents the general framework for the application of the HBM to an infinite composite structure having distributed but still localized nonlinearity; however, the considered numerical example still only deals with a discrete nonlinear spring connecting two linear parts of the structure. To fill this gap, one of the authors' previous works [5] presents the application of the HBM to continuous systems with distributed nonlinearity, where both finite and semi-infinite systems are considered.

In the previous work [5], the material damping is assumed to be linear. However, soil (among other materials) exhibits nonlinear and hysteretic damping under cyclic loading. For systems with such a material model, the stress-strain relation consists of loading and unloading branches that are different from each other. As the transition points (in the stress-strain relation) from loading to unloading are response dependent and, therefore, not known a priori, the classical HBM, being a purely frequency-based method, cannot be applied. Instead, a so-called alternating frequency-time HBM can be used. Furthermore, the material behaviour described by the so-called Masing model, well-known in soil mechanics, is used to introduce the strain dependence of the shear modulus as well as the nonlinear hysteretic damping, which obviously leads to nonlinearity of non-polynomial type.

To demonstrate the application of this advanced HBM, three canonical problems are investigated (like those in [5]). More specifically, one finite-size system and two semi-infinite systems are considered, and all of them are subject to harmonic excitation at a boundary. The three systems and their stationary responses can be described as follows (see also Figure 1):

- a 1-D nonlinear layer with a free surface and rigid base: standing shear waves
- a 1-D nonlinear half-space with a rigid base: vertically propagating shear waves
- a 2-D axially symmetric nonlinear medium of infinite extent with a circular cavity: radially propagating compressional waves

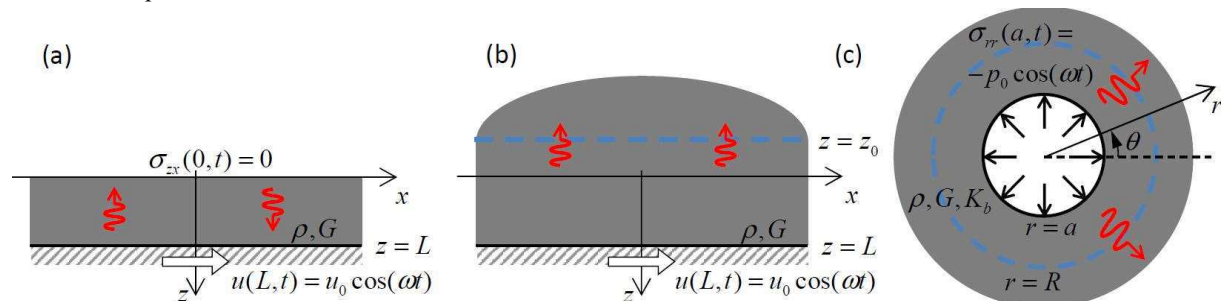

Figure 1: The three different systems (a, b, c) considered in this study. The blue line indicates the fictitious surface beyond which the behavior is linear.

Solution method

The methodology of the alternating frequency-time HBM is as follows. Firstly, an initial guess of the system's response is made based on which the transition points from loading to unloading can be determined. Then, these transition points are assumed to be fixed (not anymore response dependent) and the resulting nonlinear system can then be solved using the classical HBM. This leads to a different response than the initial guess and different transition points from loading to unloading. This process is then repeated until the response has converged. The iterations are performed using a slightly more sophisticated form of the Newton-Raphson method (so-called Levenberg-Marquardt method), which is used to circumvent a potentially singular Jacobian matrix.

As for the spatial discretization, a basic lumping method is used to derive a lattice that mimics the behaviour of the continuous systems (a, b, and c). Additionally, to accommodate the semi-infinite extent of systems b and c, it is possible to identify a fictitious surface beyond which the behaviour is essentially linear (due to the amplitude decay of the waves propagating away from the source). The region beyond that surface is therefore replaced by an exact frequency-dependent non-reflective boundary condition that is applied at the fictitious surface, so that only a finite domain needs to be discretized in the application of the advanced HBM.

Results and conclusion

In Figure 1, we present the response of the system with an expanding cavity (c). The softening behaviour can be observed by the larger amplitude of vibration compared to the linear system. The third harmonic can also be clearly observed, although its amplitude is significantly smaller than the one of the fundamental harmonic; this characteristic has also been observed in [5]. Additionally, it can be seen that the induced nonlinearity is significant from the more than 60% reduction in shear modulus at the cavity surface. Finally, the stress-strain relation follows the Masing model, and it shows that the advanced HBM is capable of handling systems with non-smooth transition in properties.

Figure 2: The response of system (c); the amplitude of the first and third harmonics (top and middle panels), the normalized shear modulus (bottom panel), and the stress-strain relation evaluated at the cavity surface (right panel).

To conclude, the advanced HBM is an effective tool for revealing fundamental characteristics of nonlinear continuous systems of finite and semi-infinite dimension that have nonlinear hysteretic damping and whose stationary responses consist of, respectively, standing and propagating waves. The considered systems have applications in earthquake and geotechnical engineering, among others, but the presented methodology is generic.

Harmonic balance-based crack size estimation in an ultrasonic fatigue specimen

Shawn L. Kiser*, Mikhail Guskov*, Marc Rebillat*, and Nicolas Ranc*

*PIMM, Arts et Métiers Institute of Technology, CNRS, Cnam, HESAM University, 151 boulevard de l'Hopital, 75013 Paris, France

Summary. Closing-opening cracks during ultrasonic fatigue tests are suspected to generate nonlinearities in the vibration signal. Due to the periodicity of the ultrasonic transducer and choice of non-smooth stiffness nonlinearity, the Harmonic Balance method is utilized to simulate the resulting 1DOF dynamic model. The energy that transferred from the fundamental harmonic to higher harmonics is represented as a harmonic amplitude ratio parameter and is utilized to inverse model a nonlinear crack parameter for an experimental signal. A feature of this dynamic model allows for the addition of nonlinear effects that evolve with the fatigue specimen's life.

Introduction

During ultrasonic fatigue tests, the evolving spectrum of a vibration signal is suspected to contain essential information about the nature of fatigue damage, such as crack initiation time and actual size. Traditionally, the properties studied from this information are the second harmonic, the eigenmodes, or the extremely small variations of resonance frequency. These vibration properties are affected by micro-plasticity and by the formation of cracks which can therefore be used to detect micro-structural changes [1, 2].

The approach proposed here consists of modeling the dynamical response of the standing wave of the system. A key feature of a cyclically closing-opening crack is an instantaneous, nonlinear, and very local change of stiffness of the system. This nonlinearity leads to a nonlinear dynamic response of the system and, as a consequence, manifestation of higher-harmonic generation in the vibration response. A closing-opening crack's restoration force is typically modeled by an asymmetric piecewise linear or bilinear stiffness [3]. Thus the goal of this study is to inverse model a nonlinear crack parameter γ using the Harmonic Balance method (HBM) [4] to obtain a nonlinear dynamic response of the system. Ideally, this can allow for real-time crack initiation and possibly size evolution monitoring.

Harmonic Balance dynamic modeling

During ultrasonic fatigue testing, seen in fig. 1(a), repeatedly transmitted ultrasonic waves at a resonant or anti-resonant frequency form a longitudinal standing wave in the fatigue specimen [1]. The undamaged fatigue specimen can be schematized as an equivalent 2 degree-of-freedom (DOF) lumped mass-spring oscillator. The oscillator's total mass $2m$ and stiffness k are tuned to resonate at the specimen's first longitudinal mode. The phase difference between the excitation and vibration is minimized by a phase-locked loop (PLL) within the converter. A longitudinal standing wave is produced with peaks at specimen's extremities, i.e., the oscillator's masses. This phenomenon has two consequences: First, the power required from the converter can be minimized. Second, the specimen's motion allows for a half specimen representation, or 1DOF system, that is dynamically modeled with respect to the specimen's elongation, i.e., a mass-spring excited by base motion at an anti-resonance frequency $\omega_{\text{anti}} = \sqrt{2}\omega_{\text{res}}$ with $\omega_{\text{res}} = \omega_0\sqrt{1 - \zeta^2}$ [5], where $\omega_0 = \sqrt{k/m}$.

Figure 1: (a) Schematic of ultrasonic fatigue test experimental setup, (b) fatigue specimen model with absolute displacement of mass X and Galilean reference displacement for mass x and base y , and (c) concept of crack nonlinearity parameter $\gamma \sim S_d/S_0$ with plot of the bilinear stiffness restoration force f_{NL} .

The 1DOF system has the equation of motion:

$$m\ddot{X} = F, \quad \text{with} \quad F = -c\dot{x} - f_{NL} = -c\dot{x} - k(1 - \gamma H)x, \quad (1)$$

where m , X , F , represents the upper mass, the absolute displacement of the system, and the force transmitted to the upper mass through the central part of the specimen respectively. The fatigue specimen is forced at the base, with displacement y , seen in fig. 1(b). The force F is obtained by splitting X into the relative displacement of the fatigue specimen free-end x and base (lower mass) motion y . When the exerted force on the mass is due to base excitation, eq. (1) becomes:

$$m\ddot{x} + c\dot{x} + k(1 - \gamma H)x = -m\ddot{y}, \quad (2)$$

with γ suspected to be correlated to the crack area ratio (see fig. 1(c)) and H represents the Heaviside function evaluated for values of x . It is assumed that the base moves harmonically with the amplitude of the base's motion U , and the frequency of the base's motion, ω_b , such that $y(t) = U \cos(\omega_b t)$. Eq. (2) is solved via HBM, yielding a finite Fourier decomposition for x , with j harmonics:

$$x \approx \text{Re} \left(\sum A_j e^{ij\omega_{\text{anti}} t} \right). \quad (3)$$

Since the standing wave is distorted as it passes through the crack nonlinearity, energy is transferred from the fundamental harmonic to the higher harmonics. Thus, a harmonic amplitude ratio α is defined at the anti-resonant frequency ω_{anti} as:

$$\alpha_n = \frac{A_n(\omega_{\text{anti}})}{A_1(\omega_{\text{anti}})}, \quad \text{for } n > 1, \quad (4)$$

where peak amplitudes A_1 and A_n correspond to the fundamental and n^{th} higher harmonics, respectively. This anti-resonant frequency is assumed to be the frequency of the base's motion.

Experimental details and results

A short-time Fourier transform (STFT) algorithm [6] is utilized to extract the first five harmonics and the anti-resonant frequency from the down-sampled velocity vibration signal, seen in fig. 2(a). Consequently, $\alpha'_2, \dots, \alpha'_5$ is calculated using the relation in eq. (4) with $(\cdot)'$ representing an experimentally determined parameter. The dynamic model, seen in eq. (2), is computed via HBM for $1e-4 < \gamma < 2e-1$ and the corresponding $\alpha_2, \dots, \alpha_5$ are extracted. The dynamic model's γ , α relationship are curve fitted with first-order power equations. Experimental $\alpha'_2, \dots, \alpha'_5$ are found with their respective curve fits, seen in fig. 2(b). Under modeling assumptions, γ' at the zeroth cycle is undamaged. Thus, fig. 2(c) shows the evolution of damage parameters $\gamma'_2, \dots, \gamma'_5$. The second and third harmonics are seen to follow similar paths until $8e5$ cycles in which they diverge exponentially. At cycles nearing fatigue, the third, fourth, and fifth harmonics rapidly grow, with the fifth harmonic the quickest. Despite γ' not equal throughout the evolution, the order of magnitude is consistent between the different harmonics. The authors estimate that there is a magnitude factor of approximately $1e2$ that would lead to a measurement of crack size evolution if $\gamma S_0 = S_d$.

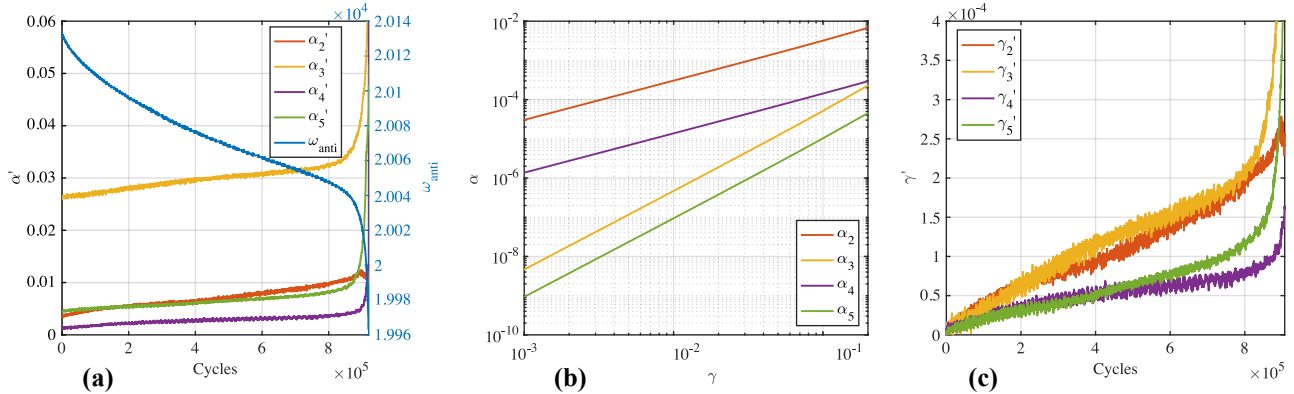

Figure 2: (a) Experimental α' (left axis) and experimental ω_{anti} (right axis) versus cycles, (b) HBM simulated γ versus α first-order power equations fits, and (c) experimental γ' versus cycles

Conclusions

The nonlinear crack parameter γ was calibrated with a bilinear stiffness dynamic model. α is computed with HBM for multiple harmonics and compared with experimental γ' s versus cycles. Bilinear stiffness can qualitatively describe nonlinear behaviors for the second and third harmonics for cycles before approximately $8e5$, but other nonlinearities are influencing higher harmonics and at cycles nearing failure. The form of eq. (3) allows for additional non-linearities to dynamically model the fatigue behavior of higher harmonics in conjunction with bilinear stiffness.

Influence of friction damping on frequency lock-in in cyclic structure

Miroslav Byrtus* and Štěpán Dyk *

*Department of Mechanics, University of West Bohemia, Pilsen, Czech Republic

Summary. The paper deals with modelling and investigation of lock-in phenomena in bladed cyclic structure which is further influenced by friction damping couplings. The investigation is focused on how the friction can affect the unstable behaviour during frequency lock-in regimes.

Introduction

The fluid-structure interaction (FSI) phenomenon arises when an elastic structure interacts with the embracing fluid flow. A particular case of FSI in which an alternate shedding of vortices forms the vibration of the structure is Vortex-Induced Vibration (VIV). The natural vortex shedding frequency is dependent on the velocity of the flow. The vortex shedding exerts a periodic unsteady force on the body. As the vortex shedding frequency approaches the natural frequency of the body, the two frequencies lock-in for a small range of the velocity flow [2]. Experimental characterization of lock-in is performed in [1].

The FSI plays significant role in modern aerofoils and turbine blades which are designed for higher efficiencies and higher power under higher operational temperatures and flow rates. Higher operational safety and economical demands force the designers to be more precise during phase of design with respect to operational condition laying out of the area with loss of stability [3, 4, 5]. The fluid-induced forces create an aero-elastic couplings between the aerofoils and the fluid flow. Moreover, in the case of periodical structures (gas or steam turbine blades in bladed disks) the aero-elastic coupling influences not only the single blade but the adjacent blades as well. There are many experimental works investigating experimentally the conditions of instability origin, e.g. [7, 8]. The paper deals with the modelling and dynamical analysis of a periodic blade system influenced by VIV and friction-damping in inter-blade couplings.

Cyclic structure of blade profiles influenced by VIV

Further, it is assumed the cyclic structure formed by a bladed disk has N_B blades which are created by identical airfoil profiles. Each blade is modelled by the approach presented in the previous section, i.e. it comprises two degrees of freedom (bending and torsion) and moreover these two motion are mutually coupled by so called bending-torsion coupling, see [6]. Usually, in steam turbine applications, the bladed disks are equipped with different kinds of shrouding, which causes that the system of blades mounted on a rotating disk become more stiff, especially with respect to axial flow direction.

The time-varying vortex force due to the alternating shedding of vortices in the wake causing the VIV is modeled by the van der Pol equation. The van der Pol model has two significant properties: i) self-sustained stable limit cycle oscillation and ii) the lock-in with the frequency of external forcing [2].

In Fig. 1, the blade cascade of a bladed disk is depicted in a plane view. The axis of rotational symmetry designates the axis of rotor symmetry which is the bladed disk attached to. Further, it is assumed that the flow direction is parallel with the blade chords. The shrouding is supposed to be mounted at tips of the blades and it is modelled by means of two lumped springs representing bending k_{shb} and torsional k_{sht} stiffness of each shrouding section between two adjacent blades.

Figure 1: Bladed cascade section with contact-friction shrouding coupling modelling.

The derivation of the linearized mathematical model of a bladed disk with the influence VIV is based on the methodology presented in [2]. Here, it is extended for a cyclic structure and completed by the influence of interblade damping-friction forces which are incorporated in shrouding coupling. It can be advantageously written in matrix form

$$\mathbf{M}_{BD}\ddot{\mathbf{q}}_{BD} + \mathbf{C}_{BD}\dot{\mathbf{q}}_{BD} + \mathbf{K}_{BD}\mathbf{q}_{BD} = \mathbf{f}_{BD}^E + \mathbf{f}_{BD}^{FC}, \quad (1)$$

where \mathbf{M}_{BD} , \mathbf{C}_{BD} and \mathbf{K}_{BD} are rectangular of order $3N_B$ mass, damping and stiffness matrices of a complex bladed disk model. Right hand side of (1) contains force vectors of friction coupling \mathbf{f}_{BD}^{FC} . Vector of generalized coordinates is of following form $\mathbf{q}_{BD} = [\dots, x_i, \varphi_i, q_i, \dots]^T \in \mathbb{R}^{3N_B}$, where index $i = 1, \dots, N_B$ designates the particular blade. The coordinate q_i is governed by van der Pol equation which is used for the wake dynamics.

Lock-in in the cyclic structure

The figures below show multiple frequency lock-in regarding different mode shapes of the structure (left). Real parts of the eigen values witness of the stability. It is clear that when the frequency lock-in happens, the system exhibit can unstable vibration.

Figure 2: Frequency lock-in areas and stability charts for cyclic structure created of identical air-foil profile connected by shrouding.

Conclusions

The paper presents phenomenological model of vortex-induced vibration in a cyclic structure which is formed by blade profiles. The attention is paid on the investigation of lock-in phenomenon using linearized model, which will further completed by nonlinear friction terms based on LuGre friction model. There is obvious in the presented results, that the system losses its stability during the lock-in phases. The future aim is to propose suitable damping mechanism which is based on friction dampers and complete the analyses with experimental data.

Summary. In recent years, applications for drones have multiplied, from surveillance, exploration, rescue and transport applications. UAVs are more and more autonomous, therefore real-time trajectory planning is necessary and can be achieved with potential fields. A quick study is proposed to better scale attractive and repulsive forces which has always been problematic when dealing with artificial potential fields. The purpose of this article is to develop a new dynamical fractional potential attractive and repulsive field usable in a dynamical 3D environment by taking into account the obstacle dynamics (position and speed) and their dangerousness. This makes it possible to avoid the obstacle in a more robust way, both from a safety point of view and from a trajectory optimization point of view. The potential fields are based on the relative position and speed of the drone in relation to the target for the attractive potential field or to the obstacle for the repulsive one.

Introduction

Path planning is used to find a suitable path between two points (mostly provided by the GPS) while avoiding obstacles in the environment. These obstacles can be dynamical or static. The notion of danger is therefore necessary to avoid a type of obstacle in the most harmonious way. Research on potential field methods has been extensively studied [1, 2, 3, 4, 5]. However, most methods are generally adapted for a static environment or do not take into account the type of obstacle (see e.g. [6, 7]). [8] have improved work on artificial potential fields by taking into account the obstacle dynamics. In this sense, [9] and [10] have interpreted the attractive field as a control loop ensuring stability degree robustness of the trajectory towards mass variations of the ego-vehicle and disturbances by taking into account the position and speed of the target as defined by [8] (see Fig. 1). Also, a novel interpretation of robust control is proposed in [5] for autonomous vehicle. The objective of this article is to present a new potential attractive and repulsive field adapted to a dynamical 3D environment that ensures the robustness of the trajectory. Potential fields are well adapted for drone applications because its holonomic model can be identified by a point mass. The potential field method allows this mass to be taken into account for both attractive and repulsive. The concept of danger will also be taken into account, the obstacles will be considered as known and the method makes it possible to avoid the obstacle with a softer trajectory according to the obstacle type, in other words, its dangerousness (pedestrian, buildings, bicycle, car etc.). In Ge & Cui, no distinction is proposed to differentiate the dangerousness of obstacles (it is safer to go nearer a wall than a human). Therefore, Weyl repulsive potential definition has introduced a fractional degree to distinguish obstacles with their dangerousness. By gaining on differentiating obstacle danger, the dynamical behaviors of obstacle has been lost. Therefore, the paper proposes a new definition of attractive and repulsive field that takes into account both dangerousness and dynamics of the obstacles. Moreover, it is often difficult to scale the attractive and repulsive potential forces. A methodology is proposed to efficiently scale them.

A fractional attractive force is presented in section 2. Section 3 presents a new dynamical fractional repulsive force. To finally conclude in section 4.

Fractional Attractive Force

In [10], the [8] method has been reinterpreted as a control loop, see Figure 1. This virtual attractive force is defined by:

$$F_{att} = \alpha_p (p_{tar} - p_{ego}) + \alpha_v (v_{tar} - v_{ego}) \quad (1)$$

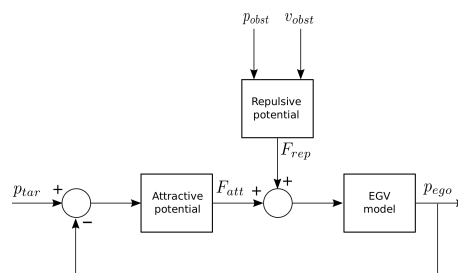

Figure 1: Dynamical interpretation of Ge and Cui attractive and repulsive forces

where \mathbf{p}_{tar} and \mathbf{p}_{ego} respectively are the real-time positions of the target and the ego-vehicle (EGV). \mathbf{v}_{tar} and \mathbf{v}_{ego} respectively are the real-time speeds of the target and the ego-vehicle. α_p and α_v are positive constants that define a lead-phase controller.

Introducing the error $e(t) = \mathbf{p}_{tar} - \mathbf{p}_{ego}$, and considering the fractional derivating of the velocity, it then comes:

$$F_{att} = \alpha_p e(t) + \alpha_v \frac{d^n e(t)}{dt^n}, \quad (2)$$

where \mathbf{a}_{tar} and \mathbf{a}_{ego} respectively are the real-time acceleration of the target and the ego-vehicle and m_{ego} is the mass of the ego-vehicle.

Under zero initial conditions, the Laplace transform of relation (2) gives:

$$F_{att}(s) = (\alpha_p + \alpha_v s^n) E(s), \quad (3)$$

where $E(s)$ is the transform Laplace of $e(t)$.

Fractional Repulsive Force

Ge & Cui potential field definition depends both on the distance ρ between the EGV and the obstacle, and their relative velocities \mathbf{v}_{RO} . Weyl potential field solely depends on the distance while distinguishing obstacle dangerousness with order n . Therefore, it is proposed to differentiate the obstacle dangerousness by keeping the order n in the Weyl repulsive field definition, and by adding distance and relative speed to add reactivity to the obstacle. The new fractional repulsive potential becomes:

$$U_{rep}(\mathbf{p}, \mathbf{v}) = \frac{(\rho_s(\mathbf{p}, \mathbf{p}_{obs}) - \rho_m(\mathbf{v}_{RO}))^{n-2} - \rho_{max}^{n-2}}{\rho_{min}^{n-2} - \rho_{max}^{n-2}}, \quad (4)$$

from where one draws the following repulsive forces:

$$F_{repv} = \eta \frac{(n-2)(\rho_s(\mathbf{p}, \mathbf{p}_{obs}) - \rho_m(\mathbf{v}_{RO}))^{n-3} \mathbf{v}_{RO}}{\rho_s(\mathbf{p}, \mathbf{p}_{obs}) a_{max} (\rho_{min}^{n-2} - \rho_{max}^{n-2})} \mathbf{v}_{RO} \perp \mathbf{n}_{RO} \perp \quad (5)$$

and

$$F_{repp} = \eta \frac{(n-2)(\rho_s(\mathbf{p}, \mathbf{p}_{obs}) - \rho_m(\mathbf{v}_{RO}))^{n-3} \left(1 + \frac{\mathbf{v}_{RO}}{a_{max}}\right)}{(\rho_{min}^{n-2} - \rho_{max}^{n-2})} \mathbf{n}_{RO}. \quad (6)$$

Now, the repulsive potential field function takes into account an order n to manage obstacle avoidance according to its dangerousness and the obstacle speed to operate in a dynamical environment.

Conclusion

In trajectory planning, artificial potential fields provide good results for trajectory planning in dynamical environments. It remains essential for real-time application and allows a good reactivity of the EGV. The Ge & Cui force allows taking into account the velocity of obstacles but it is not robust to a change in mass. The Weyl potential force associates a degree of danger with an obstacle. A new dynamical fractional attractive and repulsive field is presented allying both advantages and guarantees robustness due to mass variations. This method takes into account the obstacle dynamical aspects such as positions and speeds, and associates dangerousness to a fractional order. The fractional regulator in an attractive form, which allows robustness in terms of EGV mass variations.

Time-domain Wave Propagation in Rigid Porous Media using Equivalent Fluid Model with a Quadratic Nonlinearity

Ilyes Moufid*, Denis Matignon†, Rémi Roncen*, and Estelle Piot*

*ONERA / DMPE - Université de Toulouse, F-31055 Toulouse, France

†ISAE-SUPAERO - Université de Toulouse, F-31055 Toulouse, France

Summary. The acoustic properties of rigid porous media can be described by the equivalent fluid model (EFM) in the frequency domain, involving complex-valued functions. These physical quantities can be irrational, which leads to fractional derivatives in the time domain. Besides, this model is built with a constant flow resistivity, which is known to grow linearly with the flow velocity in the Forchheimer regime. Hence, a correction on the EFM is made according to the Darcy-Forchheimer law, leading to a more general model with an additional nonlinear term. Here, an approach is presented to formulate the EFM equations with the Forchheimer's correction in the time domain, where the fractional derivatives described by causal convolution are approximated by additional differential equations. It results in a nonlinear system on which an energy-based analysis is performed to ensure its stability under suitable conditions.

Nonlinear equivalent fluid model equations

When the material can be assumed rigid, acoustic wave propagation in porous media can be well represented by:

$$\begin{cases} \rho_0 \alpha_\infty \partial_t \mathbf{u} + \nabla p + M \mathbf{u} + N (g \star \partial_t \mathbf{u}) = -F_\xi |\mathbf{u}| \mathbf{u} , \\ \chi_0 \partial_t p + \nabla \cdot \mathbf{u} + (\gamma - 1) N' (h \star \partial_t p) = 0 , \end{cases} \quad (1a)$$

$$\quad (1b)$$

where ρ_0 is the ambient fluid density, α_∞ the high frequency limit of the material dynamic tortuosity, χ_0 the ambient fluid adiabatic compressibility, and γ the heat capacity ratio; \mathbf{u} and p are the particle velocity and pressure, respectively. Factor M is defined through Darcy's law. The two terms involving the kernel functions g and h and the convolution operator \star account for viscous and thermal losses in the porous medium. Definitions of M , N , N' , g and h are based on the dynamic tortuosity α and the dynamic compressibility β , for which complex-valued analytical models exist, such as the JCAPL model [1], presented below with the same parameters:

$$\hat{\alpha}(s) = \alpha_\infty \left[1 + \frac{M}{s} + N \frac{\sqrt{1 + \frac{s}{L}} - 1}{s} \right], \quad (2) \quad \hat{\beta}(s) = \gamma - (\gamma - 1) \left[1 + \frac{M'}{s} + N' \frac{\sqrt{1 + \frac{s}{L'}} - 1}{s} \right]^{-1}, \quad (3)$$

where \hat{f} denotes the Laplace transform of f , s is the Laplace variable and all the coefficients are defined from physical quantities, detailed in [1]. Lastly, an additional nonlinear term to the initial EFM is taken into account in the right-hand side of (1a), representing the inertial effects induced by high amplitude waves travelling in the material. It comes from the nonlinear Fochheimer equation [2] where the multiplying factor F_ξ depends on the Forchheimer nonlinearity parameter ξ , computed in experimental studies [3, 4] by considering a linear relation between the total flow resistivity σ and the velocity amplitude:

$$\sigma = \sigma_0 (1 + \xi \phi |\mathbf{u}|) , \quad (4)$$

where ϕ is the porosity and σ_0 is the static flow resistivity. This relation is known as Forchheimer's correction.

Nonlinear equivalent fluid model with additional differential equations

In order to build an efficient numerical scheme for (1), a reformulation of the equations is performed using the additional differential equations (ADE) method [5]. The irrational functions \hat{g} and \hat{h} are first approximated by rational functions \hat{G} and \hat{H} , written as multipole models and parameterized by a set of real or complex conjugate weights and poles:

$$\hat{G}(s) = \sum_{k=1}^K \frac{r_k}{s - s_k} , \quad (5) \quad \hat{H}(s) = \sum_{k=1}^{K'} \frac{r'_k}{s - s'_k} . \quad (6)$$

All the parameters r_k , r'_k , s_k and s'_k are here assumed to be real and can be computed using different available methods [6, 7, 8]. Then, using (5) and (6) in system (1) written in the Laplace domain, leads to the following system:

$$\begin{cases} \rho_0 \alpha_\infty s \hat{\mathbf{u}} + \nabla \hat{p} + M \hat{\mathbf{u}} + N \sum_{k=1}^K \left(r_k + \frac{r_k s_k}{s - s_k} \right) \hat{\mathbf{u}} = -F_\xi |\hat{\mathbf{u}}| \hat{\mathbf{u}} , \\ \chi_0 s \hat{p} + \nabla \cdot \hat{\mathbf{u}} + (\gamma - 1) N' \sum_{k=1}^{K'} \left(r'_k + \frac{r'_k s'_k}{s - s'_k} \right) \hat{p} = 0 . \end{cases} \quad (7)$$

In order to express the discrete equivalent in the time domain, the inverse Laplace transform is applied, leading to a new set of equations with causal convolutions which are computed by introducing additional variables as follows:

$$\varphi_k(t) = (e_{s_k} \star \mathbf{u})(t) , \quad (8)$$

$$\psi_k(t) = (e_{s'_k} \star p)(t) , \quad (9)$$

where $e_x : t \rightarrow e^{xt} \mathbf{H}(t)$ and \mathbf{H} is the Heaviside function.

Each of these additional variables is solution to a first-order ordinary differential equation and can be computed with a standard time-integration scheme. Finally, the global system of equations in the time domain reads:

$$\begin{cases} \rho_0 \alpha_\infty \partial_t \mathbf{u} + \nabla p + \left(M + N \sum_{k=1}^K r_k \right) \mathbf{u} + N \sum_{k=1}^K r_k s_k \boldsymbol{\varphi}_k = -F_\xi |\mathbf{u}| \mathbf{u}, \\ \chi_0 \partial_t p + \nabla \cdot \mathbf{u} + (\gamma - 1) \left(N' \sum_{k=1}^{K'} r'_k \right) p + (\gamma - 1) N' \sum_{k=1}^{K'} r'_k s'_k \psi_k = 0, \\ \partial_t \boldsymbol{\varphi}_k = s_k \boldsymbol{\varphi}_k + \mathbf{u} \quad (\forall k \in [1, K]), \\ \partial_t \psi_k = s'_k \psi_k + p \quad (\forall k \in [1, K']). \end{cases} \quad (10)$$

Note that in (10), there are no spatial derivatives in the ADE. Hence, when the system is discretized with a numerical scheme based on fluxes, these fluxes depend on the velocity and pressure variables, but not on the additional variables. Consequently, the problem to solve at each mesh interface does not grow with the number of additional variables.

Stability analysis

Hereafter, a stability analysis of system (10) is performed thanks to the energy functional defined below:

$$\mathcal{E}(t) := \frac{1}{2} \left(\rho_0 \alpha_\infty \int_{\Omega} \|\mathbf{u}\|^2 dx - N \sum_{k=1}^K r_k s_k \int_{\Omega} \|\boldsymbol{\varphi}_k\|^2 dx \right) + \frac{1}{2} \left(\chi_0 \int_{\Omega} p^2 dx - (\gamma - 1) N' \sum_{k=1}^{K'} r'_k s'_k \int_{\Omega} \psi_k^2 dx \right), \quad (11)$$

the derivative of which is

$$\begin{aligned} \frac{d\mathcal{E}}{dt}(t) = & -M \int_{\Omega} \|\mathbf{u}\|^2 dx - F_\xi \int_{\Omega} |\mathbf{u}| \|\mathbf{u}\|^2 dx - N \sum_{k=1}^K r_k \int_{\Omega} \|\partial_t \boldsymbol{\varphi}_k\|^2 dx \\ & - (\gamma - 1) N' \sum_{k=1}^{K'} r'_k \int_{\Omega} (\partial_t \psi_k)^2 dx - \int_{\partial\Omega} (p \mathbf{u}) \cdot \mathbf{n} d\sigma. \end{aligned} \quad (12)$$

From (11) and (12), combined with the fact that ρ_0 , α_∞ , χ_0 and $(\gamma - 1)$ are necessarily positive for porous media, as well as the parameters M , N , N' , F_ξ , we impose the following sufficient conditions to ensure stability:

$$(\mathbf{C}_1) \quad \text{the weights } (r_k, r'_k)_k \text{ are positive,} \quad (\mathbf{C}_2) \quad \text{the poles } (s_k, s'_k)_k \text{ are negative.}$$

When both these conditions are met, \mathcal{E} is a positive-definite functional, which is decreasing in time without external contributions at the boundary $\partial\Omega$ of the domain Ω .

Conclusion

This work formulates the nonlinear EFM equations for porous media in the time domain, with the diffusive part of the complex-valued functions α and β described by a set of weights and poles. In addition, a proof of stability is given under conditions on the sign of these, conditions satisfied by the JCPL model for a realistic range of physical parameters. A numerical study will be carried out in order to check the theoretical results and to investigate the effects of nonlinearity.

†College of Engineering, Swansea University, United Kingdom

Summary. Herein the dynamic response of a system of fractional viscoelastic beams embedded in fractional viscoelastic medium and excited by motion of their supports is analysed, and the influence of properties of the connecting medium, modelled as a set of connecting layers, on the system behaviour is investigated. First, the approximate solution to the problem is obtained through the use of the Galerkin discretisation, impulse response method, Fourier transform and Residue theory, and then it is applied to analyse, both qualitatively and quantitatively, the influence of fractional-order derivative model parameters on the dynamic properties of beam arrays.

Introduction

There are many possible mechanical and engineering applications of systems of cantilever beams connected into an array and excited by motion of their supports, particularly for vibration attenuation and energy harvesting purposes [1]. One type of such systems, where cantilever beams are embedded in fractional viscoelastic medium, which is modelled by a set of light viscoelastic layers, and placed inside a moving container, is the subject of this study, and it is schematically depicted in Fig. 1. Dynamics of beam arrays with elastic and viscoelastic properties has already been investigated, e.g. [2]. There has also been some research regarding the fractional-order derivative viscoelastic systems (e.g. [3]), but these solutions are applicable only for rational derivative orders. Freundlich [4] recently presented the exact solution for the dynamic response of a single cantilever with a tip mass under transverse motion of the support, while the beam material was modelled with damping of an arbitrary order of fractional derivative. In our recent study, we have obtained an approximate solution to the problem of vibration of a system of fractional viscoelastic cantilevers, connected by a fractional viscoelastic layers and excited by transverse motion of the support, where the fractional derivatives of arbitrary order were used. In the herein presented paper, this solution procedure is briefly described, and then it is applied to analyse the previously mentioned array of connected cantilevers confined in a transversally moving container, schematically presented in Fig. 1, in order to determine the influence of the connecting layers' material properties on the dynamic response of the system.

Mathematical model and the approximate solution to the considered problem

A system of N_b fractional viscoelastic Euler-Bernoulli cantilever beams embedded in fractional viscoelastic medium and confined inside a transversally moving container, as presented in Fig. 1, is analysed. Each beam is of length L and carries $N_{m(k)}$ concentrated masses $m_{(k)p}$ attached at $x_{m(k)} \in (0, L)$, $p = 1, 2, \dots, N_{m(k)}$, $k = 1, 2, \dots, N_b$. Beams can have mutually different mass density ρ_k , cross sectional area A_k , moment of inertia I_k and relaxed elasticity modulus E_k , but they have the same fractional derivative order α and retardation time τ_1 . The medium is modelled as a set of connecting layers, with prolonged compliance coefficient κ , fractional derivative order β and retardation time τ_2 being the same throughout the system. Here we will use only the left Riemann-Liouville fractional derivative of order γ as defined in [5], here denoted by $D^\gamma(\bullet) \equiv (\bullet)^{(\gamma)}$, $\gamma \in (0, 1)$. The container moves transversally, following an arbitrary function $w_s(t)$.

Figure 1: Schematic representation of the considered mechanical system

For the k -th beam of the system ($k = 1, 2, \dots, N_b$), the equation of motion for transverse beam displacements $w_{(k)}(x, t)$ and the corresponding boundary conditions (BCs), noting that $w_{(0)} = w_{(N_b+1)} \equiv w_s$, can be formulated as

$$E_k I_k (1 + \tau_1^\alpha D^\alpha) w_{(k)}'''' + \left(\rho_k A_k + \sum_{p=1}^{N_{m(k)}} m_{(k)p} \delta(x - a_{(k)p}) \right) \ddot{w}_{(k)} - \kappa (1 + \tau_2^\beta D^\beta) (w_{(k+1)} + w_{(k-1)}) + 2\kappa (1 + \tau_2^\beta D^\beta) w_{(k)} = 0; \quad \text{BCs: } w_{(k)}(0, t) = w_s(t), \quad w'_{(k)}(0, t) = w''_{(k)}(L, t) = w'''_{(k)}(L, t) = 0 \quad (1)$$

The solution procedure and the influence of the connecting layer properties

In order to homogenise the BCs, the absolute displacements are decomposed into the rigid body motion part and the displacements relative to the supported beam end - $w_{(k)}(x, t) = w_s(t) + v_{(k)}(x, t)$. Then, the relative displacements are approximated by the Galerkin weighted residual method as $v_{(k)}(x, t) \approx \sum_{i=1}^n \phi_{(k)i}(x) q_{(k)i}(t)$, $k = 1, 2, \dots, N_b$, with the bare beam mode shapes used as the trial functions and the weighting functions. This leads to a system $n \times N_b$ coupled fractional-order differential equations which can be expressed in matrix form as

$$\mathbf{K}\mathbf{q} + \mathbf{C}_\alpha \mathbf{q}^{(\alpha)} + \mathbf{C}_\beta \mathbf{q}^{(\beta)} + \mathbf{M}\ddot{\mathbf{q}} = \mathbf{Q} \quad (2)$$

where \mathbf{K} , \mathbf{C}_α , \mathbf{C}_β and \mathbf{M} are the stiffness matrix, beam material damping matrix, connecting layer damping matrix and mass matrix of the whole system, respectively, and \mathbf{q} and \mathbf{Q} are the vector of the yet undetermined time functions and the vector of the inertial forces in the whole system. The unknown time functions $\mathbf{q}^T = \{\mathbf{q}_1, \mathbf{q}_1, \dots, \mathbf{q}_{N_b}\} = \{q_{(1)1}, q_{(1)2}, \dots, q_{(1)n}, q_{(2)1}, \dots, q_{(N_b)n}\}$ will be determined by first finding the system impulse response \mathbf{g} , where \mathbf{g} is the vector of $n \times N_b$ corresponding Green functions $G_i(t)$, $i = 1, 2, \dots, n \times N_b$.

The impulse response is determined by taking the Fourier transform of the system and then using the equivalent elastic system to obtain the decoupled system of equations, assuming relatively small damping. This leads to (almost) diagonalised system matrices, i.e. a system of $n \times N_b$ decoupled polynomial algebraic equations with fractional exponents:

$$s_r^2 + C_{\alpha rr}^d s_r^\alpha + C_{\beta rr}^d s_r^\beta + \omega_r^2 = 0, \quad r = 1, 2, \dots, n \times N_b \quad (3)$$

where $s = i\omega$, with $\omega_r^2 = K_{rr}^d/M_{rr}^d$ being the r -th undamped system frequency, and $C_{\alpha rr}^d$, $C_{\beta rr}^d$, K_{rr}^d , M_{rr}^d are the r -th diagonal elements of the corresponding diagonalised matrices. After finding the roots of each of these equations, the inverse Fourier transform is applied with the use of the Residue theory, and the Green functions are again coupled to obtain the impulse response of the original system. Once the impulse response is determined, the sought time functions are obtained by taking the convolution with the inertial forces of the system $q_i(t) = \int_0^t G_i(t-\tau) Q_i(\tau) d\tau$, $i = 1, 2, \dots, n \times N_b$, thus providing the complete (approximate) solution to the considered problem. The influence of the connecting layer material properties was investigated on a system of $N_b = 3$ cantilever beams with $N_{m(1)} = 2$, $N_{m(2)} = 1$, $N_{m(3)} = 3$ equidistantly attached masses of half of each beam's weight. Geometrical and material properties of each beam were adopted the same as in [4], with $\tau_1 = 0.001s$, $\alpha = 0.8$. The container was set to follow the motion function $w_s(t) = w_0 \sin \omega_s t^2$, with $w_0 = 1mm$, $\omega_s = 10s^{-1}$. The parameters τ_2 , β and κ were varied, and their influence on the relative displacements of the free end of the first beam in the array are presented in Fig. 2.

Figure 2: Influence of the connecting layer properties on the dynamic response of the system

Conclusions

It can be seen that the connecting layer greatly affects system behaviour. An increase in retardation time τ_2 and order of fractional derivative β of the connecting layer leads to a more rapid vibration attenuation, as shown in Fig. 2a) and b), respectively, while an increase in the layer's relaxed compliance coefficient leads not only to an increase in damping, but in the fundamental system frequency as well, which causes the resonant state shift observed in Fig. 2c).

Summary. In this paper we study torsional oscillations of a complex rod made of material with viscoelastic properties. Free and forced modes of fractional-type torsional oscillations of a discrete system of a complex rod are described by a system of differential fractional order equations for a special case. The kinetic energy, deformation work, and generalized energy dissipation function of a fractional type system are identified for a special case. It has been shown that in the general case of such fractional type systems, with torsional oscillations, there are no independent modes, and that the system behaves as a nonlinear system.

Model of torsional oscillations of a complex rod

Figure 1 represents a model of a complex rod which is considered as a fractional-type discrete complex system. It consists of a discrete complex structure composed of light rigid rods of negligible mass, length ℓ_k , $k = 1, 2, 3, 4$ that bear material points m_k , $k = 1, 2, 3, 4$, at their free ends, and are rigidly connected to the main rod at an angle β_k , $k = 1, 2, 3, 4$ at the other end. The rods are in pairs symmetrically arranged and rigidly joined in the sections of the main rod 1, 2, 3 and 4 at distances $\frac{\ell}{4}$, $\frac{\ell}{2}$, $\frac{3\ell}{4}$ and ℓ , measured from the left fixed end of the main rod, and where ℓ is the length of the main rod. In the cross-section, at distance $\frac{\ell}{4}$ from left end of the main rod, a one-frequency momentum $M_{z,1} = M_{z,01} \sin(\Omega_1 t + \varphi_1)$, with amplitude $M_{z,01}$, frequencies Ω_1 and φ_1 phase is applied.

Figure 1. Model of a complex rod. This complex system which is considered as discrete system which torsional non-linear oscillations can be described using fractional derivatives.

For a case of an ideally elastic material, a segment rigidity of a torsion rod is equivalent to the rigidity of a torsion spring c_t and is determined by a constitutive relation of the torsion momentum-torsion angle, M_t and \mathcal{G} . The rigidity

of a torsion spring c_t is defined as $c_t = \frac{GI_0}{\ell}$ where G is the modulus of sliding of the rod's material, and I_0 is the polar moment of the cross-sectional area of the main rod [1.2]. **Assumptions of the model:** all masses are equal and all angles are equal and the indentations are of equal lengths. The system is homogeneous. Materials of which beam and rods are made have viscoelastic properties and the constitutive relation of the moment M_t of torsion of the angle \mathcal{G} , of torsion of the beam segment can be written in the form:

$$M_t = -(c_t \mathcal{G} + c_{t\alpha} D_t^\alpha [\mathcal{G}]) \quad (1)$$

where $c_{t\alpha}$ is the stiffness of the fractional type of dissipative properties of the torsion deformation of the beam segment considered as a torsion spring, and $D_t^\alpha [\bullet]$ is a differential operator of the fractional order in the following form (see References [3-6]):

$$D_t^\alpha [\mathcal{G}(t)] = \frac{d^\alpha \mathcal{G}(t)}{dt^\alpha} = \mathcal{G}^{(\alpha)}(t) = \frac{1}{\Gamma(1-\alpha)} \frac{d}{dt} \int_0^t \frac{\mathcal{G}(\tau)}{(t-\tau)^\alpha} d\tau, \quad \alpha \in (0,1), t \in (0,b) \quad (2)$$

where α is a rational number between 0 and 1, determined experimentally and $\Gamma(1-\alpha)$ is the Gamma function.

The kinetic energy, deformation work, and generalized energy dissipation function of the fractional type system

Free and forced modes of fractional-type torsional oscillations of a discrete system of a complex rod are described by a system of differential fractional order equations for a special case. The system of the fractional order differential equations can be written in matrix form:

$$\mathbf{A}\{\ddot{\mathbf{q}}_k\} + \mathbf{C}\{\dot{\mathbf{q}}_k\} + \mathbf{C}_\alpha\{\mathbf{D}_t^\alpha[\mathbf{q}_k]\} = 0 \quad (3)$$

where \mathbf{A} is the matrix of coefficients of inertia, \mathbf{C} is the matrix of coefficients of elasticity and \mathbf{C}_α is a matrix of coefficients of the system of fractional properties. If the relation $C_{t,\alpha,k} = \kappa_\alpha C_{t,k}$, $k = 1, 2, 3, 4$ is valid, then $\mathbf{C}_\alpha = \kappa_\alpha \mathbf{C}$ and, in that case, the system belongs to a special class of fractional type systems in which main modes of fractional type are independent. In this case, we can apply a procedure for transformation of the generalized coordinates into the main coordinates like for the corresponding linear system.

Expressions for kinetic energy \mathbf{E}_k , deformation work \mathbf{A}_{def} of the torsional deformed system, and the generalized function Φ_w [5,6] of fractional-type dissipation of the system energy are

$$\mathbf{E}_k = \frac{1}{2} \sum_{k=1}^{k=4} \mathbf{J}_{z,k} \dot{\mathbf{q}}_k^2 = \sum_{k=1}^{k=4} m_k (\ell_k \sin \beta_k)^2 \dot{\mathbf{q}}_k^2, \quad (4)$$

$$\mathbf{A}_{def} = \mathbf{E}_p = c_{t,1} \mathbf{q}_1^2 + \frac{1}{2} c_{t,2} (\mathbf{q}_2 - \mathbf{q}_1)^2 + \frac{1}{2} c_{t,3} (\mathbf{q}_3 - \mathbf{q}_2)^2 + \frac{1}{2} c_{t,4} (\mathbf{q}_4 - \mathbf{q}_3)^2 \quad (5)$$

$$\Phi_w = \frac{1}{2} c_{t,\alpha,1} (\mathbf{D}_t^\alpha[\mathbf{q}_1])^2 + \frac{1}{2} c_{t,\alpha,2} (\mathbf{D}_t^\alpha[\mathbf{q}_2 - \mathbf{q}_1])^2 + \frac{1}{2} c_{t,\alpha,3} (\mathbf{D}_t^\alpha[\mathbf{q}_3 - \mathbf{q}_2])^2 + \frac{1}{2} c_{t,\alpha,4} (\mathbf{D}_t^\alpha[\mathbf{q}_4 - \mathbf{q}_3])^2 \quad (6)$$

To obtain a system of fractional order differential equations that describe the torsional oscillations of the observed discrete complex structure, Lagrange differential equations of the second order were used.

Independent fractional order differential equations for describing free main fractional type modes are in the following form:

$$\ddot{\xi}_s + \omega_s^2 \xi_s + \kappa_\alpha \omega_s^2 \mathbf{D}_t^\alpha[\xi_s] = 0, \quad s = 1, 2, 3, 4 \quad (7)$$

and for describing forced main fractional type modes:

$$\ddot{\xi}_s + \omega_s^2 \xi_s + \kappa_\alpha \omega_s^2 \mathbf{D}_t^\alpha[\xi_s] = h_s \sin(\Omega_1 t + \varphi_1), \quad s = 1, 2, 3, 4 \quad (8)$$

where ξ_s are main coordinates, ω_s are eigen frequencies of a fractional order system, κ_α is the constant of proportionality. When $C_{t,\alpha,k} \neq \kappa_\alpha C_{t,k}$ and $\mathbf{C}_\alpha \neq \kappa_\alpha \mathbf{C}$, the fractional-type modes are coupled and the system behaves in a non-linear way, and there is an interaction between fractional-type modes.

Conclusions

Torsional oscillations of a complex rod with viscoelastic properties are analyzed. The main idea applied in the paper is that the segment rigidity of the described torsion rod is equivalent to the rigidity of a torsion spring. The kinetic energy, deformation work, and generalized energy dissipation function of the fractional type system are identified. Free and forced main fractional type modes are defined. It has been shown that in the general case of such fractional type systems with torsional oscillations, there are no independent modes, and that the system behaves as a nonlinear system. When system belongs to an after-mentioned special class of fractional type systems, main modes of fractional type are independent.

Summary. Dissipation is part of every physical system. This paper looks at a possible classification of such effects based on the dynamic response characteristics. It highlights some interesting non-trivial characteristics that particularly enter when a system otherwise unstable is stabilized by dissipative effects. These response properties can have various useful applications, and they can contribute to determining the dominant dissipation sources in mechatronic systems.

Introduction

Mechanical system models generally include forces that arise from fundamental physical phenomena [2]. Dissipative effects represent one of such basic classes of forces. The dissipative mechanisms at the micro-scale usually lead to some resultant effective representations at the macro-scale, which are commonly used in dynamic system models. These generally appear in two fundamental forms: one is when the damping/dissipative force model is directly proportional with the velocity, i.e., viscous and structural damping models, and the second group is when the dissipative force model depends on the sign of the velocity but not necessarily the magnitude, i.e., friction models [3].

Dynamic model

The mathematical models for these can be written considering one degree-of-freedom canonical models as

$$m\ddot{q} + b\dot{q} + kq + c \operatorname{sgn}(\dot{q}) = f, \quad (1)$$

where q represents the generalized coordinate parametrizing the single degree-of-freedom as a function of time, m is the related to the generalized mass/inertia, k is the stiffness, and b is the viscous/structural damping coefficient. The magnitude of the friction force is denoted by c , and f represents the other forces acting on the system.

If mechanical systems without dissipation are considered then one possible classification can be based on their stability. The behaviour of a mechanical system model with purely inertia and stiffness terms is always stable by the Lyapunov sense. These inertia and stiffness terms represent the physical system elements and generally derive from the Lagrangian of the system. However, this usually represent only one part of the physical system.

The other forces that can enter in f determine in general whether the overall system is stable or not. Instability can result from various effects that can be introduced by these forces. Several of the major effects include some form of time delay. One important group of applications is virtual environments where f include discrete-time computer generated representation of virtual interaction forces.

Based on Eq. (1), the two limit cases are considered where either only viscous/structural damping, $b\dot{q}(t)$ term, or friction-based dissipation, $c \operatorname{sgn}(\dot{q}(t))$ term, exists. As an illustration, these are shown for the case where f vanishes and when f represents a virtual stiffness with formula $f(t) = -k_p q(t_j)$, where k_p is the virtual stiffness coefficient, and $q(t_j)$ represents the sampled position in every j th sampling instant, i.e., $t_j = jt_s$ with $j \in \mathbb{Z}$, and t_s denotes the sampling time. With the reduced number of free parameters, Eq. (1) is rewritten

$$\ddot{q}(t) + 2\zeta\omega_n\dot{q}(t) + \omega_n^2 q(t) + \sigma\omega_n^2 \operatorname{sgn}(\dot{q}(t)) = -\frac{k_p}{m} q(t_j), \quad t \in [t_j, t_j + t_s), \quad (2)$$

where the natural angular frequency $\omega_n = \sqrt{k/m}$, the damping ratio $\zeta = b/(2m\omega_n)$, and $\sigma = c/k$. In order to obtain a more compact model, the dimensionless time $T = \omega_n t$ is also introduced. Thus, the dimensionless sampling instant is $T_j = j\omega_n t_s = j\tau$. Based on these, the equation of motion can be given as

$$q''(T) + 2\zeta q'(T) + q(T) + \sigma \operatorname{sgn}(q'(T)) = -p q(T_j), \quad T \in [T_j, T_j + \tau), \quad (3)$$

where $p = k_p/k$, and prime denotes the differentiation with respect to the dimensionless time.

Dissipation analysis

The first case of f results in a stable system, while the second case produces a system that can be unstable without dissipation, and adding dissipative effects can stabilize the system. In the case of only viscous/structural damping the response properties are well-known; it generally shows exponential decay type characteristics. In the case of unforced and in the case of applied virtual stiffness, the vibration characteristics are presented in Fig. 1a and Fig. 1b, respectively.

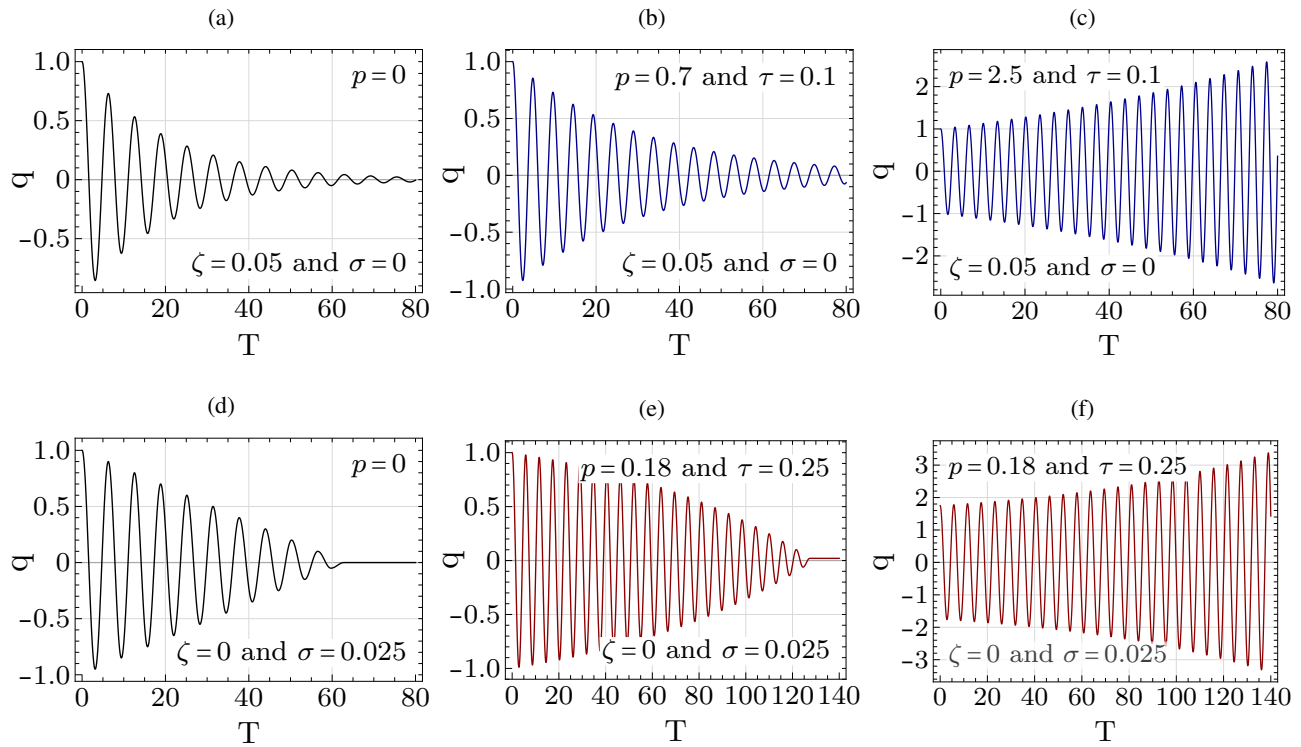

Figure 1: Fundamental vibration shapes due to the effect of different kind of dissipation phenomena

It can be also observed that the effect of sampling results in an effective negative viscous damping; thus with increasing virtual stiffness coefficient the effect of dissipation decreases, and there may be loss of stability, as it is shown in Fig. 1c. However, for the second case where only friction-based dissipative effects exist, the response characteristics are much less trivial.

There is a difference between the behaviours of a stable system and a dissipation-stabilized system. In the case when f vanishes, linear decaying amplitude exists, while in case of the additional virtual stiffness, the so-called concave amplitude decay [1] can be observed. These behaviours are shown in Fig. 1d and Fig. 1e, respectively. Due to the presence of friction-based dissipation, the system become sensitive to the initial conditions resulted in an unstable limit cycle. The resulted in unstable motion is presented in Fig. 1f.

It is noted that the behaviours of such concave decaying characteristics in various systems when generating discrete-time virtual interaction forces were experimentally observed [1]. Such observations can generally indicate that Coulomb friction may act as dominant dissipative and stabilizing effect for these cases.

Conclusions

In this paper, the vibration decay characteristics of mechanical systems were investigated by considering either viscous/structural damping or dry friction as the primary source of dissipation. The fundamental vibration shapes were presented for the unforced case, and for that case when the acting force represents virtual stiffness. It was highlighted that the influence of different physical dissipation resulted in some non-trivial vibration decaying characteristics that particularly enter when a system otherwise unstable is stabilized by dissipative effects.

Summary. Rotating machines are often subject to fluctuating torques, leading to vibrations of the rotor and finally to premature fatigue and noise pollution. These vibrations can be reduced using tuned vibration absorbers (TVA). These passive devices are made of several masses oscillating along a given trajectory relative to the rotor. Previous studies showed that the dynamics of these devices is subject to instabilities. In this paper, the dynamic stability of a new class of TVA is investigated. The particularity of this new class is that the TVA now admits a significant rotation motion relative to the rotor, in addition to the traditional translation motion. Efficiency of such devices is optimal for a perfect synchronous motion of oscillating masses. However, due to non linearities, masses unisson can be broken for the benefit of energy localization on a given absorber, leading to a loss of mitigation performances. To assess the stability of such devices, a dynamical model based on an analytic perturbation method is established. The aim of this model is to predict analytically localisation and jumps of the response. The validity of the model is confirmed through a comparison with a numerical resolution of the system's dynamics.

Presentation of the system

Figure 1: Scheme of the system studied for $N = 3$ absorbers

The system considered in this study consist of a rotor (or support plate) of inertia J_s rotating about its center O with a mean velocity Ω with respect to the galilean frame. Its angular position is written θ . On this rotor are articulated N identical absorbers of mass m and inertia I . These absorbers are located along their trajectory through the curvilinear abscissa S_i . The distance from point O to the mass center of the i^{th} absorber is written $R_i(S_i)$, $i = 1, \dots, N$. The shape of the trajectory is controlled through this function. In addition to the translation motion along the trajectory, the rotation of the absorbers about their mass center with respect to the rotor frame is considered in this study, and denoted by $\alpha_i(S_i)$. A mechanical device enables to prescribe it as a function of S_i . We choose R_i (respectively α_i) to be a symmetric (respectively antisymmetric) function as it is the case in practice due to design issues. Finally, this system is subject to an external torque $T(\theta)$. In this framework, the equations of the system take the form:

$$M(q)\ddot{q} + f_{in}(q, \dot{q}) + C\dot{q} + f_{int}(q) = F \cos(n_e \theta), \quad (1)$$

where $q = [\theta, \dots, S_i, \dots]^T$ is the vector of unknowns (T denotes the transpose). $M(q)$ is the mass matrix and depends on q . C is the damping matrix. $f_{in}(q, \dot{q})$ is the inertial forces vector, including Coriolis terms, and depends on q and \dot{q} . $f_{int}(q)$ is the internal forces vector and depends on q . The external forces vector is $F = [T_1, \dots, 0, \dots]^T$ where T_1 is the amplitude of the fundamental harmonic of the external torque. Finally, n_e is the excitation order and it can be regarded as a proportionality coefficient between the excitation frequency and the mean rotation speed.

Performing a linear study of this system, one can find that the $N + 1$ eigenfrequencies can be written $\omega_0 < \omega_1 < \omega_2$ where ω_1 is of multiplicity $N - 1$ and is also the natural frequency of the absorbers uncoupled from the rotor. The corresponding eigenmodes read $\phi_0 = [1, 0, \dots, 0]^T$, $\phi_2 = [-a, 1, \dots, 1]^T$, $a > 0$. ϕ_0 is a rigid body mode for which the absorbers are not excited and ϕ_2 is a mode for which absorbers are in-phase and in phase opposition with respect to the rotor. The mode shapes corresponding to the $N - 1$ degenerated modes of eigenfrequency ω_1 all have a zero first component so that this mode is not excited by the external torque. For instance, for $N = 2$, $\phi_1 = [0, 1, -1]^T$: the absorbers are out of phase.

Non-linear study

In practice, the absorbers create an antiresonance of the rotor at frequency ω_1 , which is thus the chosen operating point of the system [1]. In the following, a non-linear study of the steady-state response of the system is carried out in the vicinity of this operating point and we are interested in the response of the absorbers. An analytical model representing the dynamical behaviour of the system is developed. Following [2], the first step to build the model is to perform a change of the independent variable from t to θ and a scaling of the parameters. Then, to continue the study, we choose in this work to use the multiple scale method [3]. This approach leads to the obtention of a system of the form

$$\begin{cases} D_1 A_i = f_1(A_i, A_j, \varphi_i, \varphi_j) \\ D_1 \varphi_i = f_2(A_i, A_j, \varphi_i, \varphi_j) \end{cases} \quad (2)$$

where D_1 represents the derivative with respect to the slow time, and A_i and φ_i are the amplitude and phase of the first harmonic of the scaled i^{th} absorber's response. On the one hand, using the fact that the stable response of the absorbers is governed by the in-phase mode, one can solve (2) to get the unisson response of the absorbers. On the other hand, the stability of (2) can be assessed through the computation of the determinant of its jacobian [4]. This leads to the obtention of two bifurcation curves. The intersection of these curves with the absorbers' response indicates a stability change towards either a non-synchronous response of the absorbers (i.e. the absorbers stop moving in unisson) or an unstable periodic response (this leads to jumps phenomena).

Results and introduction of the design space

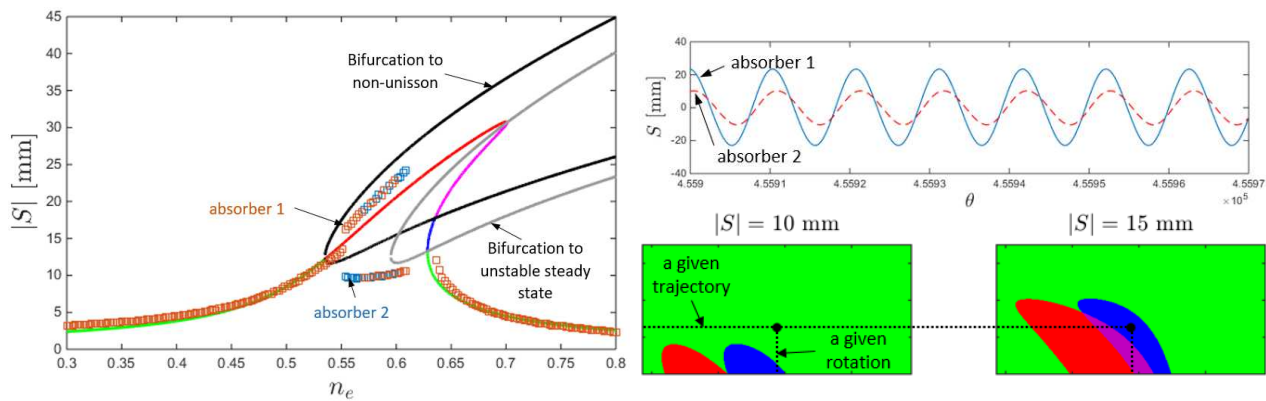

Figure 2: Left hand side: Analytic and numerical comparison of the absorbers' order response. Squares are numerical results. Top right hand side: Time signal of a non-unisson motion of the absorbers. Bottom right hand side: maps of designs representing their associated stability. The black dot corresponds to a given design (i.e. a given trajectory and a given rotation function). A color code indicates the stability of the response. Green: stable; red: unisson unstable; blue: steady state unstable; purple: unisson and steady state unstable

We choose here to apply the above study on a system of $N = 2$ absorbers. Fig.2 presents the response of the absorbers as a function of the excitation order, which has the meaning of a driving frequency. In this case, ω_1 corresponds to $n_e = 0.5$ and the resonance to ω_2 . The numerical results are obtained through time integrations of the equations of motion using a Runge-Kutta algorithm. Like what was observed in the case of absorbers with a pure translation motion [5], results show that the system loses its stability through a pitchfork bifurcation in favor of a non-synchronous response. The model allows to accurately predict the bifurcation point, which is theoretically located at the intersection of the black curve (limit of unisson instability region) and the unisson response. The time signal shown in Fig.2 clearly shows the difference in amplitude and in phase of the response of the non-synchronous response of the absorbers.

For a given excitation order and absorbers' amplitude, one can use the analytical model to assess the stability of several designs of TVA simultaneously. Designs can be defined by their associated trajectory and rotation functions, so that the result takes the form of 2D maps as it is shown on Fig.2. The black dot represented on these maps is fixed, as it is a given design. We can see that depending on the absorbers' amplitude of motion, this design goes through different stability states. These maps can be very efficient to determine whether a given design is prone to desynchronisation and/or jumps.

Conclusions

This study presents analytical and numerical results about non-linear localisation and jumps in a TVA. This work generalises previous studies to TVA with absorbers admitting a rotation about their mass center. The analytical and numerical results agree very well, showing that the model developed is able to give a good representation of the physical system. The design space has been introduced, allowing a quick assessment of the efficiency of TVA designs.

Analytical Criterion of Multimodal Snap-through Flutter of Thin-walled Panels

Valery Pilipchuk

Wayne State University, Detroit, USA

Summary. Condition, under which thin-walled shallow panels can develop cyclical snap through dynamics due to airflow loads, is derived in the explicit analytical form. The methodology is based on the asymptotic of a perfectly flexible structure whose continuous manifold of equilibrium positions in the multidimensional space of configurations serves as a family of generating solutions. It is shown that supercritical airflows can cause global trajectories near such manifolds associated with a two-way snap through between the original and inverted positions of the panel.

Introduction

The term ‘flutter’ may cover quite different situations involving different mathematical tools of analyses [1]. The focus of the present study is flow induced dynamics with essentially nonlinear snap-through effects. Complexity of such type of problems is due to a multimodal strongly nonlinear structural behavior accompanied by a strong spatial coupling between the modes. The adapted elastic model of a shallow cylindrical panel ignores the longitudinal inertia term while taking into account the influence of membrane forces on the bending deformation as the only cause of geometrical nonlinearity [2, 3]. Assuming the presence of some initial imperfection and thus existence of multiple equilibrium positions, we define a snap-through flutter as the global panel dynamics with a cyclical self-sustained snap-through effect caused by the non-conservative aerodynamic load. Note that preserving the symmetric configuration during the snap-through motion would typically require a significant compression of the panel surface. As a result, any path through the least potential barrier must involve certain modal transitions avoiding significant tension-compression deformations that requires multimodal considerations. On one hand, this essentially complicates the analysis by increasing the problem dimension. However, on the other hand, increasing the dimension reveals a simple enough analytical estimate for the generating trajectory due to the asymptotic of a perfectly flexible panel. This represents a core of the approach, which assumes a global linearization near the manifold of a perfectly flexible panel [5, 6].

Technical details

Let us consider the elastic panel in a gas flow as schematically shown in Fig.1. The problem is reduced to the two-dimensional provided that the panel is subjected to a cylindrical bending. The panel thickness h is small compared to the amplitude of initial imperfection α , which itself is small compared to the span of the panel l . The outer surface of the panel interacts with the gas flow whose unperturbed velocity U is directed along the x -axis as shown in Fig.1.

Figure 1: Aeroelastic model of a shallow panel in gas flow under the ‘external’ p_e and ‘internal’ p_i pressure loads.

The Lagrangian function of the panel is obtained based on the assumptions [2] as

$$L = \frac{1}{2} \rho h \int_0^l \left(\frac{\partial w}{\partial t} \right)^2 dx - V[w], \quad V[w] = \frac{Ehl}{2(1-\nu^2)} e[w]^2 + \frac{Eh^3}{24(1-\nu^2)} \int_0^l \left(-\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w_0}{\partial x^2} \right)^2 dx \quad (1)$$

$$e[w] = \frac{1}{2l} \int_0^l \left[\left(\frac{\partial w}{\partial x} \right)^2 - \left(\frac{\partial w_0}{\partial x} \right)^2 \right] dx \quad (2)$$

where $e[w]$ is the longitudinal strain, $V[w]$ is the potential energy of elastic deformations, and $w_0 = w_0(x)$ is the shape of initial imperfection. Also, the variation of work done by the static pressure drop and nonconservative aerodynamic loads is given by

$$\delta A = \int_0^l f_z \delta w dx, \quad f_z(t, x) = \Delta p - 2\gamma ph \frac{\partial w}{\partial t} - \rho_\infty c U \frac{\partial w}{\partial x}, \quad \Delta p = p_i - p_e \quad (3)$$

where the aerodynamic load corresponds to a linearized equation of the so-called piston theory; see an overview in [4]. The manifold of zero-strain configurations is defined as

$$M_f = \{w : e[w] = 0\} \quad (4)$$

Then the linearization of the differential equation of motion near the manifold (4) is conducted with a continual version of transformation [5, 6] in the form

$$w = \tilde{w} + \varepsilon n \zeta, \quad n = \nabla_w e[\tilde{w}] / \|\nabla_w e[\tilde{w}]\|, \quad \varepsilon^2 = (h/\alpha)^2 / 12 \ll 1 \quad (5)$$

where, $\nabla_{\tilde{w}}$ is the so-called variational derivative, which is taken at the arbitrary “point” $\tilde{w} \in M_f$, and the symbol $\|\dots\|$ denotes the Euclidian distance in the functional space of the panel configurations, therefore $n(5)$ is a unit vector, which is always perpendicular to the manifold.

Two-mode illustration

Transformation (5) admits a clear visualization (Fig.2) after the following two-mode approximation of the panel' shape

$$w(t, x) = \alpha \left(q_1(t) \sin \frac{\pi x}{l} + q_2(t) \sin \frac{2\pi x}{l} \right), \quad w_0(x) = \alpha \sin \frac{\pi x}{l} \quad (6)$$

Note that expansion (6) provides an exact discretization of the corresponding free panel. However, it becomes just an approximation due to the presence of first derivative $\partial w / \partial x$ in the loading function.

Figure 2: a) Two-mode snap-through trajectory around the potential hill of tension-compression deformations in the neighborhood of zero-strain manifold (4) M_f , and b) the local normal coordinate ζ near an arbitrary point $y(\theta)$ of the manifold M_f .

Fig. 2a shows a typical shape of the potential energy $V = V(q_1, q_2)$ with a sample trajectory of a free panel, which is averagely resembles the shape of elliptic zero-strain curve shown in Fig2b, including its generalized coordinate θ describing the tangential motion, and the coordinate ζ describing the fast normal component associated with tension-compression.

Result

Fig.2b justifies the averaging procedure with respect to the fast normal motion component compared to the slow tangential motion. This finally gives an asymptotic one-degree-of-freedom effectively conservative system for the tangential motion

$$\frac{d}{dt} \left[\frac{1+3\sin^2 \theta}{4} \left(\frac{d\theta}{dt} \right)^2 + \varepsilon^2 V_{eff}(\theta, Q) \right] = O(\varepsilon^4), \quad V_{eff}(\theta, Q) = \frac{4}{3} Q \theta + (10 + 6 \cos \theta) \sin^2 \left(\frac{\theta}{2} \right) \quad (7)$$

Analyzing equation $\partial V_{eff} / \partial \theta = 0$ gives the critical number Q above which this equation has no real roots:

$$Q_* = \frac{2cl^3 \rho_\infty U_*}{\pi^4 D} = \frac{1}{8} \sqrt{\frac{1}{2} (827 + 73\sqrt{73})} \quad (8)$$

If $Q > Q_*$ then system (7) has no equilibrium points and as a result will continue to rotate around the ellipse.

Conclusion

It is shown that a strong enough airflow can result in global dynamic trajectories near such manifolds associated with two-way snap through between the original and inverted positions of the panel. The effective tangential to the manifold forces created by the airflow, dissipation, static pressure drop, and structural elasticity adequately determine conditions for qualitatively different dynamic regimes. In particular, it is shown that a strong enough airflow can result in global dynamic trajectories near such manifolds associated with a two-way snap through between the original and inverted positions of the panel. It must be noted that the developed approach is applicable to other problems with different types of loading as well as analyses of free vibrations accompanied by large amplitudes with or without snap through events.

Summary. This study focuses on the nonlinear response of dynamical systems due to harmonic force excitation using numerical continuation methods. Nonlinear Normal Modes (NNMs) is a powerful tool for studying behavior of nonlinear vibrational systems. Pseudo arc length continuation method is a very powerful method which is capable to handle strongly nonlinear systems by calculate the NNMs. Several methods are available to compute NNMs. Recently reviewed articles mention the computational cost of the pseudo arc length continuation method that limits its application. Based on assumption presented in other references and eliminate a mathematical construction, in this research used an updating formula to reduce the computational cost of pseudo arc length continuation algorithm. This modified method is called Efficient Path-Following Method (EPFM). In order, forced response of a single degree of freedom duffing system is computed using EPFM method. It seen that this method has decreased computational time considerably up to 70%. The results are in very good conformance to those obtained in other references which shows the accuracy the method. To study the ability of EPFM to handle continues systems, a nonlinear Euler-Bernoulli beam is considered and stable and unstable branches of the solution are computed. It observed that as the nonlinearity of the system gets stronger the updating formula becomes more effective.

Introduction

The structural engineers have utilized modern engineering knowledge to modelling the complex dynamic behavior of structure. For example, rotorcraft, turbomachines, airplanes, bridges, marine platforms, and robotic complex arm have become lighter, this way provide the possibility of operating at higher rates and velocities. Obviously, these On the other hand it could be led to non-linear response of structural systems. The structural response is affected by the nonlinearity. It may also cause complex resonance phenomena. Which makes it impossible to predict system behavior. *Rauscher* and *Mikhlin* develop a definition for modal analysis in nonlinear systems and naming it as "Nonlinear Normal Mode (NNM)". Shaw and Pierre modified the concept of NNM for the class of weakly nonlinear systems. Today, One of the well-known tool to provide a solution of nonlinear dynamical systems is NNMs.[1, 2] Namely, The movement of a system during internal resonance described using NNMs. also nonlinear vibration absorbers designing [2], also providing reduce order model of a nonlinear dynamic system to show system frequency changes and system deformation during free or forced vibration in nonlinear structures [3]. Also it applications include micromechanical oscillators and energy harvesting. Along with analytical methods such as harmonics, multiple scales and other methods for calculating the periodic responses of nonlinear dynamical systems, there are many numerical methods that are preferred because of their less complexity and less mathematical operators. There are many numerical algorithms for computing periodic solution families in nonlinear systems [4, 5].

One of the powerful methods in computation of periodic solution are neumerical continuation methods. *Kerschen* by combination of Shooting method and Pseudo Arc length with continuation presented a High-performance algorithm to calculate the nonlinear normal modes which are defined as periodic solutions of the nonlinear system [3, 6]. Michael W. Sracic in 2010 try to extend the Peeters algorithm to a system with cubic nonlinearity under the harmonic forced excitation [7]. Renson in 2016 has published an reviewed article [8] and studied the various methods for computation of nonlinear normal modes [numerical computation of NNM]. They mention that the "continuation method is a very powerful method for computation of periodic solutions however the computational cost has limited its application to large scale systems". This paper presents the numerical continuation method modification to speed up the periodic solutions computations. The assumptions and basis of the modified algorithm based on [6, 7], changes made include integrating an updating formula in the algorithm and elimination of phase equation to decrease the computational time of the algorithm. To speed up the process of calculating the periodic solutions we eliminate the phase equation that presented by peeters, and using updating formula presented in [9]. The presented algorithm is called Efficient Path Following Method (EPFM)(Figure 1.f). Numerical experiments show that EPFM is approximately 60-70 percent faster. The theoretical foundations and the algorithm are presented first. Then, a one D.o.F.system and a nonlinear Euler-Bernoulli beam would be studied.

Theory and Algorithm

Governing equation of motion of a N-D.o.F system under harmonic force takes the following form in state space:

$$\dot{\mathbf{z}} = \mathbf{g}(\mathbf{z}(\mathbf{z}_0, t, T), t, T) = \begin{pmatrix} \dot{\mathbf{x}} \\ -\mathbf{M}^{-1}(\mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} + \mathbf{f}_{nl} - \mathbf{F}_e) \end{pmatrix} \quad (1)$$

Where \mathbf{M} , \mathbf{K} , and \mathbf{C} are the mass matrix, stiffness matrix and the damping coefficient matrix, respectively, \mathbf{f}_{nl} is the vector

Figure 1: Results figures

of stored nonlinear force and \mathbf{F}_e is the external harmonic force. $\mathbf{z} = [\mathbf{x} \dot{\mathbf{x}}]_{2N \times 1}^T$, t is independent variable of time and T is the period of oscillation s. The response of the system to the initial conditions of $\dot{\mathbf{z}}(t=0) = \mathbf{z}_0 = [\mathbf{x}_0 \dot{\mathbf{x}}_0]^T$ is represented as $\mathbf{z}(t) = \mathbf{z}(\mathbf{z}_0, t, T)$ to indicate the dependence of the system's response to the initial conditions, $\mathbf{z}(\mathbf{z}_0, t=0) = \mathbf{z}_0$. To compute periodic solution integrated Eq.(1) over time interval $[0, T]$. We need to look for the following conditions.

$$\mathbf{H}(\mathbf{z}_0, t, T) \equiv \mathbf{z}_T(\mathbf{z}_0, t, T) - \mathbf{z}_0 \approx 0 \quad (2)$$

Using Newton-Raphson algorithm process try to find periodic condition by expansion of the Eq.(2) as follows:

$$\left. \frac{\partial \mathbf{H}}{\partial \mathbf{z}_0} \right|_{(T, \mathbf{z}_0)} \Delta \mathbf{z}_0 + \left. \frac{\partial \mathbf{H}}{\partial T} \right|_{(T, \mathbf{z}_0)} \Delta T = -\mathbf{H}(\mathbf{z}_0, t=T, T) \quad (3)$$

To calculate the periodic response, the equation (3) must be established. The partial derivatives of the equation (3) is calculated based on the procedure given in [7].

The only difference is the calculation of the first derivative which is calculated in the first iteration. Monodromy matrix ($\frac{\partial \mathbf{H}}{\partial \mathbf{z}_0}$) calculated by sensitivity analysis, then in the next iterations, updating formula given in [9] is used to calculate it. the updating formula defined as follows:

$$\left. \frac{\partial \mathbf{H}}{\partial \mathbf{z}_0} \right|^{k+1} = \left. \frac{\partial \mathbf{H}}{\partial \mathbf{z}_0} \right|^k + \mathbf{H}^{k+1} \frac{(\Delta \mathbf{z}_0^k)^T}{|\Delta \mathbf{z}_0|} \quad (4)$$

Results

Considering a system with one degree of freedom governed by Duffing equation presented in [7]. The results show that for force amplitude equal 0.1, EPFM was %52 faster than [7] and for amplitude equal 1.0, EPFM faster about %70, that result show in Figure 1.a. Also a nonlinear Euler-Bernoulli (Figure 1.b) analysed, Figure 1.c depict the periodic solutions compute by EPFM method and Figure 1.d show two dimensional manifold of 1st NNM. EPFM also captured superharmonic and subharmonic peaks as well Figure 1.e. in this case EPFM is faster about %60 too.

Conclusions

An effective method is introduced in this study to compute periodic response of nonlinear systems under harmonic excitation. The method is called Efficient Path Following Method (EPFM). The algorithm is a combination of single shooting method and pseudo arc length continuation. The difference between EPFM and other algorithms is that, it uses an updating formula to compute jacobian matrix in correction step. that EPFM also reduces one of the equations in shooting method to speed up computation of periodic responses.

By analyzing the results and computational time, it is concluded that the EPFM is a very effective method for computation of periodic response of nonlinear systems and as the D.o.Fs of the system increase and the nonlinearity of the system gets stronger, this method gets more effective.

Summary. The present work addresses passive suppression of vibrations induced by internal axial flow in a cantilevered flexible pipe discharging fluid. The suppressor utilized is a rotative non-linear vibration absorber (NVA) composed of a mass connected to the extremity of a rigid bar hinged to the main structure by means of a dashpot. Numerical results from the mathematical model show that the NVA is able to bound the pipe structural response even in the supercritical flow regime.

Introduction

Today, the problem of a cantilevered pipe conveying fluid is considered as a classical problem in the study of the dynamics and stability of structures because of its simplicity and potential for displaying a wide range of complex dynamics. This problem belongs to a broader class of open dynamical systems with axial momentum transportation, and several studies, such as [1] and [2], have been made on the extension of Euler-Lagrange's equations and Hamilton's principle for such systems. Pipes conveying fluid, in their myriad of applications, such as heat exchangers and risers are susceptible to flow-induced instabilities and vibrations which in turn can lead to fatigue failure, excessive noise and leaks.

Non-linear vibration absorbers (NVAs) have been studied in the last decades as alternatives to linear suppressors, such as the tuned mass damper (TMD), for passive suppression of oscillations. Even though the literature on the use of NVAs for suppressing axial-flow-induced vibrations is recent, studies have shown that they are capable of adapting and effectively operating even if the load is broadbanded due to an energy transferring concept called Targeted Energy Transfer (TET), as documented in [3] and [4].

This paper focuses on the use of a particular class of suppressors, called rotative NVA, with the objective of suppressing axial-flow-induced vibrations of cantilevered pipes discharging fluid. Such a suppressor is composed of a point mass connected to the extremity of a rigid bar which, in turn, is hinged to the pipe via a dashpot. In [3], the authors discuss passive suppression of internal-flow-induced oscillations of a pinned-pinned pipe using a different type of NVA. To the best of the authors' knowledge, the use of a rotative NVA for suppressing axial-flow-induced vibrations of pipes conveying fluid has not been previously addressed and is the main novelty of the present work.

Mathematical model

Consider a flexible pipe discharging fluid as shown in Fig. 1a. The pipe has the length L , the diameter D , the bending stiffness EI and the mass per unit length m . The fluid has the mass per unit length M and flows at a constant velocity U . At a point \bar{x} along the pipe length, the NVA is placed and constrained to rotate in the (y, z) -plane. The device has the mass m_n , the radius r and the damping constant c . The pipe transverse displacement is represented by $w(x, t)$ while the angular displacement of the NVA is $\theta(t)$. It is assumed that the pipe is inextensible and that the flow is incompressible and has a uniform profile in the pipe (i.e. the plug flow model). By using the extended Hamilton's principle found in [5], the dimensional equations of motion can be found and are made dimensionless using the following quantities:

$$\begin{aligned} \tau &= \left(\frac{EI}{m+M} \right)^{1/2} \frac{t}{L^2}, \quad \xi = \frac{x}{L} = \frac{s}{L}, \quad \eta = \frac{z}{L} = \frac{w}{L}, \quad \gamma = \frac{(m+M)gL^3}{EI}, \quad \hat{\delta}(\xi - \bar{\xi}) = L\delta(x - \bar{x}), \\ \hat{c} &= \frac{cL^2}{m_n \left(\frac{EI}{m+M} \right)^{1/2} r^2}, \quad u = \left(\frac{M}{EI} \right)^{1/2} UL, \quad \hat{m}_n = \frac{m_n}{(m+M)L}, \quad \beta = \frac{M}{(m+M)}, \quad \hat{L} = \frac{L}{D}, \quad \hat{r} = \frac{r}{D}, \end{aligned} \quad (1)$$

where s is the curvilinear coordinate along the pipe length, and δ is the Dirac Delta function. The resulting dimensionless partial differential equation is then discretized using Galerkin's method, with the adoption of the first five mode shapes of a cantilevered Euler-Bernoulli beam, i.e., $\eta(\xi, \tau) \cong \sum_{n=1}^5 A_n(\tau) \psi_n(\xi)$, where ψ_n are the mode shapes and A_n are the corresponding generalized coordinates. Using the notation $(\cdot)' = \partial/\partial\xi$ and $(\cdot)^\cdot = \partial/\partial\tau$, the final system of six coupled second-order ordinary differential equations is obtained in the form of equations (2) and (3), for $k = 1, \dots, 5$.

Results

Consider three different systems: system 1 is the unaltered (or plain) pipe, system 2 is composed of the pipe and a lumped mass rigidly attached to the pipe at different spanwise locations and, finally, system 3 is the one with the NVA. System 2 allows for investigations into the effect of the placement of the stationary lumped mass on the critical flow velocity – “static” effect – via Lyapunov's Indirect Method. On the other hand, system 3 allows for investigations into the capability of the device to mitigate vibrations of the main structure due to its motion with respect to the pipe, which locally dissipates energy in the associated dashpot (TET mechanism). Here, passive suppression is achieved by a “dynamical” effect.

$$\begin{aligned}
 & \left(\sum_{n=1}^5 \int_0^1 \psi_k \psi_n d\xi + \hat{m}_n \sum_{n=1}^5 \int_0^1 \delta(\xi - \bar{\xi}) \psi_k \psi_n d\xi \right) \ddot{A}_n + \left(2\beta^{\frac{1}{2}} u \sum_{n=1}^5 \int_0^1 \psi_k \psi'_n d\xi \right) \dot{A}_n + \\
 & + \left(\sum_{n=1}^5 \int_0^1 \psi_k \psi_n''' d\xi + u^2 \sum_{n=1}^5 \int_0^1 \psi_k \psi_n'' d\xi - \gamma \sum_{n=1}^5 \int_0^1 (1 - \xi) \psi_k \psi_n'' d\xi + \gamma \sum_{n=1}^5 \int_0^1 \psi_k \psi'_n d\xi \right) A_n - \\
 & - \frac{\hat{r}}{\hat{L}} \hat{m}_n (\ddot{\theta} \sin \theta + \dot{\theta}^2 \cos \theta) \int_0^1 \delta(\xi - \bar{\xi}) \psi_k d\xi = 0, \quad (2) \\
 & \ddot{\theta} - \frac{\hat{L}}{\hat{r}} \sin \theta \sum_{n=1}^5 \ddot{A}_n \psi_n(\bar{\xi}) + \hat{c} \dot{\theta} = 0. \quad (3)
 \end{aligned}$$

Throughout this extended abstract, we assume $\beta = 0.20$ and $\gamma = 10$. An example of the analysis on the “static” effect of the device is given in Fig. 1b, which shows the variation of u_{cl}/u_c (u_c and u_{cl} being the critical flow velocities for systems 1 and 2, respectively) as a function of the lumped mass value and its location. As seen, counter-intuitively, the lumped mass has a destabilizing effect with the exception of the region approximately defined by $\bar{\xi} \in [0.35, 0.65]$ and $\hat{m}_n \in [0.025, 0.2]$, in which the critical flow velocity ratio u_{cl}/u_c increases as \hat{m}_n is increased. For system 3, the “dynamical” effect is then evaluated through a numerical integration of the equations of motion at $u = u_{cl}$, which leads to unbounded responses of system 2. Considering $A_1(0) = 0.1$ and $\theta(0) = 0.1$ as the non-trivial initial conditions, Fig. 3c presents the time-history of the displacement at the free end of the pipe, i.e. $\eta(\xi = 1, \tau)$, the associated amplitude spectrum and the angular response of the NVA, $\theta(\tau)$, for the case in which the suppressor is placed at $\bar{\xi} = 0.5$ and is characterized by $\hat{m}_n = 0.01$, $\hat{c} = 0.2$ and $\hat{r} = 0.6$. Both time series are shown within $\tau \in [2000, 4000]$ range. Note that the response is bounded, even though for a supercritical internal flow velocity for system 2.

Figure 1: a) Schematic drawing of the system, b) (u_{cl}/u_c) as a function of $(\hat{m}_n; \bar{\xi})$ - System 2, c) Example of response - System 3.

From Fig. 3c, a strongly modulated response composed of two intermittent regimes can be observed. The first regime is characterized by a growth in the pipe response, while the device oscillates around the positions that are aligned with the pipe motion, i.e. where $\cos \theta = \pm 1$. Then, when the energy reaches a certain threshold, the NVA rotates with practically the same frequency as the oscillation frequency, that is $\hat{f} = 2.37$. Hence, we may conclude that the observed passive suppression is associated with a 1 : 1 resonance.

Conclusions

A rotative NVA was utilized to successfully mitigate vibrations of a cantilevered flexible pipe discharging fluid. Both the “static” and “dynamical” effects were examined. While the former showed to have an important role in the stability of the system (i.e., the critical internal flow velocity), the latter was responsible for bounding the dynamical response due to energy dissipation. More numerical results along with a more comprehensive analysis of the static and dynamic effects will be presented in the full-length paper.

Passive Nonlinear Energy Sink for Pathological Tremor Reduction

Sarah Gebai, Alireza Ture Savadkoochi and Claude Henri Lamarque
LTDS UMR CNRS 5513, École Nationale des Travaux publics de l'État

Summary. Medications used to reduce the pathological tremor causes severe side effects which affects the life quality of the patients. A mechanical solution using nonlinear passive controllers is suggested to reduce the tremor. A light weight non-smooth nonlinear energy sink (NES) attached to the forearm of a modeled upper limb system was able to reduce the angular motions, of different parts of the upper limbs, after a short period of time.

Introduction

Tremor is an involuntary oscillatory movement of a body part triggered by alternating simultaneous antagonistic muscles contractions. It is associated with neurological disorders which lead to pathological tremor, like the Parkinson and essential tremors. Neurologically disordered patients suffer from a frustrating involuntary tremor which prevents the patients from achieving their daily life tasks and can cause social isolation. There is still no cure for the pathological tremor, and the effect of the used medication and surgical treatments are temporary. In addition, the treatments can cause severe side effects specially in case of non-responsiveness or medication failure.

Research interest was recently shifted to find a mechanical solution for reducing the vibration tremor energy at the upper limbs of the patient. The mechanical absorber is suggested to counter-act the tremor and to compensate the failure of the muscles in performing accurate motor movements. A passive controller, using a non-smooth nonlinear energy sink (NES) [1], is suggested in this paper to reduce the involuntary tremor of a modeled upper limb system.

Modeled system

The upper limbs of the human is modeled dynamically to reflect the tremulous motion. The response of the system is used to design the physical parameters of the nonlinear vibration absorber placed at the forearm segment. The performance of the suggested controller is examined by comparing the response of the system before and after the addition of the NES.

Upper limbs

The upper limb is modeled as a two degrees-of-freedom (DOF) system oscillating in the vertical plane as shown in shown in Figure 1. The upper limbs can be modeled as two rigid links, the upper-arm as one segment, and the forearm and hand together as a separated segment [2]. The links are represented as massless rods of length (l) with a concentrated mass (m) placed at the position of the centroid (r), where the indices 1 and 2 refer to the upper arm and forearm, respectively. The modeled system allows the flexion-extension planar motion at the shoulder and elbow joints, where θ_1 and θ_2 are the angular displacement responses at these joints, respectively.

The musculoskeletal modeling of the upper limb is reached by the addition of the shoulder, elbow and Biceps brachii muscles to the skeletal system. The passive elements of the muscles are the stiffness (k) and damper (c), such that the indices 1, 2 and 3 corresponds to the shoulder, elbow and Biceps brachii. The upper limb system is excited the active torques generated by the muscles. The signals of the muscles can be measured by the Electromyography (EMG), which can be used to detect the operational frequency of the muscle, and the amplitude of the signal at this frequency. The inertial measurement unit (IMU) can be used to determine the acceleration and angular velocity ranges, which needs to be reached by the responses of the modeled upper limb system.

Figure 1: Dynamical modeling of the upper limb in the vertical plane with a NES

Nonlinear absorber

The well modeled upper limb system leads to an accurate design of the NES parameters. The NES has a light weight mass (m_N), placed at the forearm segment at a distance (d_N) away from the elbow joint. The displacement response of the NES (u) is acting in the vertical place, in a direction perpendicular to the forearm segment. The NES oscillating in this direction, is designed to absorb the flexion-extension angular displacement of the upper limbs during its oscillation in the vertical plane. A non-smooth piece-wise linear function is chosen for the NES since it can create, a better controllability effects, when attached to a system affected by the gravitational field, than the cubic restoring function [3]. The piece-wise linear function is characterized by the stiffness of the NES (k_N) and the clearance ($2d$). The damping of the NES is c_N .

Complexification of the system

The nonlinear equation representing the motion of the global system (upper limbs with NES) is derived using Euler-Lagrange formula. The equations are linearized using Taylor series multivariable linearization method in terms of θ_1 and θ_2 , while preserving the nonlinearity of the NES (u).

The complex variables of Manevitch [4], are applied to the partially linearized equations of motion transformed to the modal coordinates. The multiple scale method [5] is used to treat the system at different timescales, low timescale $\tau_0 = t$ and fast timescale $\tau_j = \epsilon^j t$, such that t is the time, $\epsilon = \frac{m_N}{m_N}$ and $j = \{1, 2\}$. The averaged equation is obtained by applying a truncated Fourier series (constant terms and first harmonics) [6] to the equations transformed to the modal coordinates.

Results and discussion

The response of the system is analyzed in different time scales. The slow invariant manifold (SIM) and characteristic points of the system are obtained from the analytical study. The numerical response of the system shows to follow the SIM obtained analytically. The parameters of the NES are designed such that resonance occurs at the fundamental frequency of the main system. Figure 2 shows the angular displacement response at the shoulder and elbow joints before and after the addition of the NES, for different m_N . The controllability response of the NES is faster when its mass is higher. The NES of 20.7 g reduces the response of the system after 180 s. The mass of the NES can still be increased to obtain a faster performance.

Figure 2: Angular displacement signals at the shoulder and elbow joints simulated numerically with and without NES for different m_N

Conclusions

The NES with piece-wise linear function is effective in reducing the involuntary tremor gravitational energy transmitted to the upper limbs due to the muscles contraction. The NES can be designed in the form of a non-invasive device to help people with pathological tremor.

Resonance Capture Cascade in Nonlinear Piezoelectric Shunt

Kevin Dekemele*, Patrick Van Torre** and Mia Loccufer*

Summary. Nonlinear energy sinks (NESs) serve to transfer and absorb vibration energy of a mechanical system. They are locally attached to the system and consist of a light mass, a damper and a nonlinear stiffness. Compared to linear dynamic vibration absorbers (DVA), NESs mitigate vibrations over a wider frequency band. If the mechanical system is subjected to a shock load, a NES is able to dissipate the energy of each mode separately and sequentially, from high to low frequency. This unique feature is called resonance capture cascade (RCC). When piezoelectric (PE) patches are bonded with the vibrating mechanical system, it can serve as an electrical DVA, provided a suitable shunt circuit is attached over the PE electrodes. In literature, several nonlinear shunts have been proposed and implemented. While the increased robustness has been discussed, there has been no attempt thus far to design an electrical NES specifically for resonance capture cascade. In this abstract the RCC capabilities of a mechanical NES as well as an electrical NES is shown.

Introduction

Machines are made lighter and more compact, civil structures become higher and slender. Consequently, more flexible mechanical systems are created which are susceptible to unacceptable vibration levels. To protect these mechanical systems, an auxiliary structure is attached, called a dynamic vibration absorber. It typically consists of a linear mass-spring-damper system. The linear DVA is able to mitigate a single frequency really well. However, it does so only in a narrow frequency band and as such, if the mechanical system has shifting vibration frequencies or multi-modal vibrations, the linear DVA fails to mitigate the vibrations down to an acceptable level. To increase the bandwidth of the DVA, a nonlinear energy (NES) sink has been proposed in literature [1]. The NES has a nonlinear connecting spring which typically has a cubic spring characteristic.

Resonance Capture Cascade with Mechanical NES

If a mechanical system is shock loaded, a free vibration ensues, consisting of several vibration modes. While a linear DVA is not able to decay all modes efficiently, a NES can engage in resonance capture cascade (RCC). During RCC, the NES mitigates the vibration modes sequentially, from high to low frequency [1]. More recently, the author of the current abstract [2] presented a thorough study of RCC and tuning of the NES to increase the speed of RCC. To introduce RCC, a mechanical system with 2 vibration modes is equipped with a NES, Figure 1a. The NES has the following dynamics:

$$m_{na}\ddot{x}_{na} + c_{na}(\dot{x}_{na} - \dot{x}_1) + k_{na}(x_{na} - x_1)^3 + k_{lin}(x_{na} - x_1) = 0 \quad (1)$$

with m_{na} the NES' mass, c_{na} the NES' damping, k_{na} the NES' nonlinear stiffness and k_{lin} the NES' linear stiffness. The bottom mass of the mechanical system is subjected to an initial speed of $\dot{x}_1(0) = 1$. The RCC is seen in the NES vibrations, Figure 1c, with the shifting vibration frequency best seen on its wavelet transform Figure 1d. At first, the NES vibrates with the frequency of the second mode. Then, after about 25 s, the NES shifts its frequency to the first vibration mode. After about 120 s, the NES is barely moving. The vibration in the mechanical system, Figure 1e are mitigated over the 120 s where the NES is active, with the second mode decaying first, and then the first mode. A small amount of residual energy is left after RCC.

Resonance Capture Cascade with Electrical NES as Piezo Electric Shunt

By bonding piezoelectric (PE) material to a vibrating mechanical system, the vibration energy can be transferred to electrical energy. Similar vibration mitigation performance as with mechanical DVAs can be achieved by shunting the electrodes of the PE with a suitable circuits. Because of the similar dynamical equations in mechanical and electrical domain, a NES shunt was proposed in [3]. However, no attempt thus far has been made to achieve RCC. The dynamics of a NES is highly similar to the nonlinear shunt:

$$L\ddot{q} + R\dot{q} + \frac{1}{C_3}q^3 + \frac{1}{C_1}q + V = 0 \quad (2)$$

with V the voltage over the PE electrodes, generated by the vibrations, and $q = \int Idt$ the charge. A numerical investigation now shows that RCC occurs in the electrical NES. The vibrating mechanical systems are two cantilever beams with tip masses, connected at the tip with a spring, Figure 1c. The proposed mechanical system has two dominant modes and is easy to construct experimentally. The PE patch is shunted with a NES. The electrical vibrations in the current are shown on Figure 1f and Figure 1g. The behavior is identical to the mechanical NES. The second mode is mitigated first, followed by the first mode. This can be seen as well in the tip displacement of the beam, Figure 1h.

Conclusions

Resonance capture cascade (RCC) is the unique feature of nonlinear energy sinks (NESs) that can be exploited to mitigate transient multi-modal vibrations. During RCC, vibration modes of a vibrating mechanical system are sequentially mitigated, from high to low frequency. This feature is associated with mechanical NES. In this abstract it is shown that this unique feature of the NES is also possible in shunted piezoelectric patches.

Summary. The possibility of controlling of oscillations of overhead transmission lines by a nonlinear absorber is studied. We consider a linear beam with elastic boundaries conditions in displacement and rotation under harmonic excitations. After complexification of the system variables, we study the system at different time scales. The fast time scale provides the SIM (Slow invariant Manifold). Then, a stability study of the SIM is performed. Studying the slow time scale leads to detection of equilibrium and singular points of the system. Finally, we compare the analytical results with numerical solution obtained with the finite element method (FEM)(Code_Aster).

Introduction

Galloping of overhead transmission lines brings large amplitude at low frequency oscillations [1]. This phenomenon occurs when there is an aerodynamic instability on iced conductors [1]. Since the 1930s several researchers work on a better understanding of this phenomenon and to predict the amplitude of oscillation depending on the wind parameters [2]. Some devices have been designed to mitigate the amplitude of oscillations caused by galloping. Torsion pendulum have been designed to reduce galloping vibrations [3]. Interphase spacers have been developped to avoid shot circuits and collisions between conductors [4]. On the other hand, there are some nonlinear dampers that can reduce aeolian vibration like Hydro-Quebec damper [6]. However, galloping mitigation with a nonlinear energy sink (NES) [5] have not been studied yet. The NES has a small mass in comparison with the primary system and the two systems are coupled by a nonlinearity [7]. Hence, the main objective of this study is the behaviour of a cable coupled with a NES. We will locally modelise the cable with a linear beam with elastic boundary conditions in displacement and rotation. We conduct an analytical study of the system at different time scales. Complexification method of Manevitch [8] is used to understand the asymptotic behaviour of the system. We will validate the analytical results by comparison with the numerical solution obtained from the finite element method (FEM) Code_Aster.

Linear beam with elastic boundary conditions coupled to a NES

We consider the system of a beam with elastic boundary conditions coupled with a nonlinear oscillator. We can see on figure 1a the boundary conditions in translation k_0 , k_L and rotation k_{R0} , k_{RL} . The nonlinear oscillator is coupled to the beam at the distance l_n from the extreme left part of the beam. One can see on figure 1b the restoring forcing function of the non-smooth NES. Only one modal coordinate of the beam will be taken into account, for instance the coordinate of the first mode. The system is under external sinusoidal excitations $F_1(t)$, $F_2(t)$. We will consider the vertical displacement of the beam $v(x, t)$ and the vertical displacement of the oscillator $u(t)$. The effects of gravity are neglected.

Figure 1: a) Linear beam with elastic boundary conditions coupled to a NES; b) non-smooth NES restoring forcing function.

The system behaviour around a 1:1 resonance is studied. We project the governing equations of the system on the first mode. The variables of Manevitch are introduced to study the envelope response of the system [8]. Different time scales are introduced and the system behaviour at each time scale is detected. By studying the dynamics at fast time scale we obtain the slow invariant manifold (SIM) [9]. One can see on figure 2 the SIM curve for cubic and non-smooth NES. Then, we study the dynamics at a slow time scale and we obtain the equilibrium points depending on the excitation parameters namely, frequency and the amplitude [10]. On figure 3 one can see the equilibrium point depending on σ the normalised excitation frequency.

Figure 2: The SIM of the system for a) cubic NES; b) non-smooth NES, N_1 and N_2 stand for energies related to the mode and the NES, respectively.

Figure 3: Equilibrium points in three dimensions (N_2, σ, N_1) for a) cubic NES; b) non-smooth NES, σ is the detuning parameter from studying the behaviour around a 1:1 resonance.

Finally, we can validate our theoretical results with numerical integration with RK4 method and compare with FEM solution obtained with Code_Aster. The FEM enables to detect system response for a given σ and to compare its envelope with the analytical prediction. The developpements provide design tools for tuning parameters of the NES.

**Technical University of Berlin, Berlin, Germany*

† *Peter the Great St.Petersburg Polytechnic University, St.Petersburg, Russia*

Summary. Thermal grating technique is a promising method for direct measurement of transient anomalous heat conduction. This work analyses approaches for theoretical description of this experiment. Kinetic and dynamical approaches to problem of initial sinusoidal perturbation are found to be handfull. Behavior of amplitude decay calculated from these models plays a role of a signature of heat conduction regime. Decay of amplitude is analyzed using analytical, and molecular dynamics approaches. A comparison with available literature is presented.

Experimental studies confirm that in ultrapure materials heat can propagate ballistically (non-diffusively), which leads to the phenomenon of thermal superconductivity [1, 2, 3, 4]. This fact opens up broad perspectives for the practical applications of ultrapure crystals for design of new materials with unique properties and devices constructed with use of these materials [4].

The difficulty in study of ballistic thermal processes in real materials lies in the fact that it occurs at very high speeds (speed of sound in crystals, e.g., > 10 km/s for graphene [5]). Moreover, since the process is fundamentally different from Fourier's law, it lacks the thermal conductivity coefficient as a material parameter. However, even when the Fourier's law does not hold, in an experimental setting and molecular dynamic simulations when a steady non-equilibrium temperature gradient is applied to the specimen, it turns out that it is convenient to use the mathematical formulation of Fourier's law and to observe the size dependence of thermal conductivity as a signature of anomalous regimes [6, 7, 8, 9]. Thus, experimental methods, which have now already become a standard, have been developed to determine the thermal conductivity coefficient from Fourier's law [10]. These methods, however, cannot describe transient processes. A promising alternative of steady methods is the thermal grating technique which is a direct measurement of transient anomalous heat conduction [11].

In this work we focus on the theoretical description of transient thermal grating experiment [11]. In this experiment a sinusoidal periodic temperature excitation is created on a surface of the sample. Thus, a two dimensional heat transport occurs. Since the sinusoidal initial profile is excited along one axis, the heat transport remains quasi one dimensional. Let us consider initial temperature distribution as a periodic harmonic function along the spatial coordinate x .

$$T(x, 0) = e^{iqx}, \quad (1)$$

where $q = \frac{2\pi}{L}$ is a wavenumber, L is the period of initial excitation. Let us assume that the evolution of this excitation remains periodic in space and has the form

$$T(x, t) = A_1(t)e^{iqx}, \quad (2)$$

where $A_1(t)$ is the amplitude which depends on time t .

The solution for function $A(t)$ can be found using different approaches and methods. Let us first consider the model where the heat transport is modeled using the particles – heat carriers which are called phonons [12]. Probability density function $f(x, y, t, u, v)$ describing distribution of these particles is governed by the Boltzmann transport equation

$$\frac{\partial f}{\partial t} + u \frac{\partial f}{\partial x} + v \frac{\partial f}{\partial y} = f^{scat}, \quad (3)$$

where f^{scat} is the function describing scattering between the particles. Let us for simplicity first consider the case when $f^{scat} = 0$, i.e., when the particles propagate without scattering – ballistically. In the one dimensional case the equation then takes the form

$$\frac{\partial f}{\partial t} + u \frac{\partial f}{\partial x} = 0, \quad (4)$$

and f is not deendent of y : $f = f(x, t, u, v)$. Let us consider isotropic “grey” medium, i.e., medium where all the particles propagate in all directions with the same absolute velocity. Let us suppose that the distribution function corresponds to Eqs. (1), (2) and has the form

$$f(x, 0, u, v) = f^0(u, v)e^{iqx}, \quad f(x, t, u, v) = A_2(t)f^0(u, v)e^{iqx}. \quad (5)$$

Substitution of this anzatz (5) into (4) yeilds a linear diferential equation for A_2

$$\frac{\partial A_2}{\partial t} + iquA_2 = 0, \quad (6)$$

and solving the this equation yeilds

$$A_2(t) = e^{-iqu t}. \quad (7)$$

Thus the solution for f has the form $f(x, u, v, t) = f_0(u, v)e^{i(qx - qut)}$. Initial distribution over velocities for a case of grey medium, i.e., all the particles has constant absolute velocities and uniformly distributed random directions, may be written in the form

$$f_0(u, v) = \frac{1}{\pi} \delta(u^2 + v^2 - c^2), \quad (8)$$

where c is the absolute velocity of particles, and the factor $1/\pi$ arises from normalizing condition $\int \int f_0(u, v) du dv = 1$. Density of particles given in a chosen point of space in time $\rho(x, t)$ is found by integration over all velocities

$$\rho(x, t) = \frac{1}{\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \delta(u^2 + v^2 - c^2) e^{i(qx - qut)} du dv. \quad (9)$$

We are interested in the decay of the amplitude and not in the spatial dependency e^{iqx} . From (9) it is seen that amplitude is described by

$$A_3(t) = \frac{1}{\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \delta(u^2 + v^2 - c^2) e^{-iqut} du dv. \quad (10)$$

Change of variables to the polar coordinates in integration in (10) $u = r \sin \theta$, $v = r \cos \theta$, $du dv = r dr d\theta$ yields

$$A_3(t) = \frac{1}{\pi} \int_0^{2\pi} \int_0^{\infty} \delta(r^2 - c^2) e^{-iqrt \cos \theta} r dr d\theta = \frac{1}{2\pi} \int_0^{2\pi} e^{-iqct \cos \theta} d\theta = J_0(cqt), \quad (11)$$

where J_0 is a Bessel function of the first kind. Molecular dynamical simulation performed to check analytical prediction, Eq. (11). Simulation results confirm analytical predictions.

We would like to note that Bessel function has a power decay of amplitude $\sim 1/\sqrt{t}$, thus, obtained result contradicts with results obtained from the dynamical approach in [13] and solution of BTE from the kinetic approach [14]. The study of this discrepancy is a direction for further research.

^{*}Department of Electrical Engineering, National Taiwan University, Taipei, Taiwan

^{**}Department of Mechanical Engineering, National Taiwan University, Taipei, Taiwan

Summary.

The piezoelectric bimorph (PZT) was adopted as an energy harvester for a newly underwater application basing on the combination of piezoelectricity and flow induced vibration. The shape of piezoelectric energy harvester was optimized through the theoretical simulation code, ANSYS. Then, the energy harvesters with seven different types of tail fins were tested in flow field experiments with a large hydraulic recirculating flume from 0.6 to 5.37 m/sec. We discover there are two main regions of oscillating frequencies for PZT and the spectrum modes depend on three swing modes for this underwater energy harvester. The amount of power generation does not only positively correlate with the increase of flow rate, but also depend on the oscillating frequencies of PZT. When it produces an obvious and unique oscillating frequency, there is a larger amount of power it can get.

Abstract

Piezoelectric Materials are recently adopted as energy harvesters besides sensors or switches. Especially there is recently a new energy harvesting concept proposed to convert hydraulic kinetic energy into useable electrical energy with piezoelectric bimorph. This concept is based on the combination of piezoelectricity and flow induced vibration. In the research, we propose an innovative fixation method, hyperplastic adhesive, resolved fracture and waterproof for piezoelectric component (PZT-brass-PZT). And we also conduct a thorough theoretical simulation and a full-scale flow field experiments to optimize the energy harvester and analyze the relevance between power generation and oscillating frequencies of piezoelectric energy harvester from hydraulic flow rate 0.6 to 5.37 m/sec.

The designed energy harvester includes three structures, the bluff body, the piezoelectric material and the tail fin. A three-dimensional simulation code, ANSYS, based on the finite element numerical calculation was used to simulate dynamic state of fluid field through the bluff body with/without a tail fin to identify the optimal shape to be “the triangle prism with a tail fin” (Figure 1).

Then, the energy harvesters with seven different types of tail fins were tested in flow field experiments with a large hydraulic recirculating flume (Figure 2). A giant venturi tube was customized to increases the hydraulic flow rate 9 folds from 0.6 to 5.37 m/sec which was the highest record in Taiwan on piezoelectric energy harvesting researches. In addition, a customized micro-power rectifier and counter module was applied to accurately evaluate on the electromechanical transferring energy.

From the flow field experiments, based on fluid characteristic the hydraulic flow rate 0.6 to 5.37 m/sec can be separated into three regions - Low Flow Rate Region(below 3.1m/sec), Transition Region(3.1 ~ 4.2m/sec) and High Flow Rate Region(above 4.2m/sec). We discover there are two main regions of oscillating frequencies for PZT and the spectrum modes depend on three swing modes. The ratio of magnitude under the two frequency regions changes with flow rate (Figure 3). This means, the energy harvester can measure the real-time flow rate by PZT plate oscillating frequencies. Another discovery is that the amount of power generation does not only positively correlate with the increase of flow rate, but also depend on the oscillating frequencies of PZT. When it produces an obvious and unique oscillating frequency, there is a larger amount of power it can get (Figure 4).

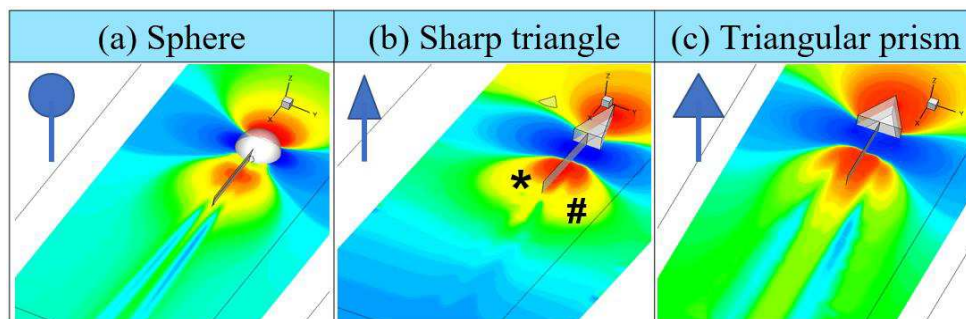

Figure 1. How bluff body shapes change the dynamic analysis of the flow field.

Figure 2. Flow field experimental equipment (a) Giant venturi tube, (b) Recirculating flume with giant venture

Figure 3. Oscillating frequencies in various flow rates with different system models. (a) Swing oscillation frequencies in Low Flow Rate Region. The smooth flow field produces an obvious and unique oscillating frequency. (b) Swing oscillation frequencies in Transition Region. The flow field starts to produce voids, it becomes unstable and complicated, and the oscillation frequency range becomes more irregular. (c) Swing oscillation frequencies in High Flow Rate Region. There are slug voids. The oscillating frequency resembles that of the low flow rate region, but the range in oscillation frequency from 4 - 15 Hz is significantly larger.

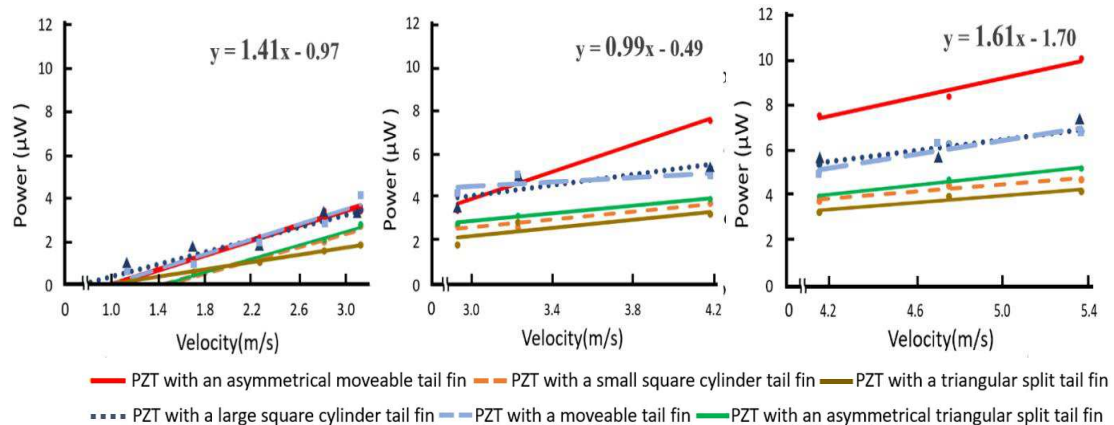

Figure 4. Comparison of power generation with different tail fin structure designs.

Summary. This work investigates the influence of holed gear blanks on the nonlinear dynamic behaviour of a flexible gear train. The system is excited by a multiharmonic internal excitation, namely a time-varying mesh stiffness and the static transmission error. This presentation will summarise the numerical procedure that has been developed to study such systems. A reference configuration without holes is used to give insight into the underlying dynamics and to highlight the effects of holed gear blanks. A thorough parametric study then addresses the robustness of the forced response curves and bifurcation structure to changes in gear blank topology.

Introduction

Weight reduction is a recurring concern in the design of modern mechanical systems. One of the most widespread solution to design lightweight gears is to resort to adding holes in the gear blanks. An accurate prediction of the dynamic behaviour of gears remains challenging due to the functional backlash, necessary to allow for assembly and operation, which can lead to contact loss and a strongly nonlinear response [1]. We herein propose an algorithm based on the harmonic balance method to investigate the dynamics of such systems. The proposed approach is able to take into account the internal excitation associated to geared systems. This excitation consists of the static transmission error (STE), whose origin lies in the teeth deflection under load, manufacturing defects and potential tooth profile modifications, and the time-varying mesh stiffness expressed as the derivative of the transmitted load relative to the STE [2].

Dynamic model

The proposed dynamic model [3] considers a reverse spur gear pair (same number of teeth on the input and output gears) modelled as lumped inertias and masses denoted I_1 and m_1 for the input gear and I_2 and m_2 for the output gear. Because both gears have the same number of teeth the shafts rotate at a fundamental frequency Ω . The shafts are modelled by torsional stiffnesses K_1 and K_2 and are supported by bearings of stiffness K_b . The input and output are modelled by two lumped inertias I_{in} and I_{out} , respectively. The gears are connected by a nonlinear element consisting of a time-varying

Figure 1: Dynamic model of the flexible transmission considered in this study.

piecewise linear stiffness. It includes the backlash $2b$ and the static transmission error as a gap function $g(t)$:

$$\mathbf{f}_{nl}(\mathbf{q}) = \mathbf{G}k_m(t) \left(\mathbf{G}^T \mathbf{q} - g(t) \right) \mathcal{H} \left(\mathbf{G}^T \mathbf{q} - g(t) \right) + \mathbf{G}k_m(t) \left(\mathbf{G}^T \mathbf{q} + g(t) \right) \mathcal{H} \left(-\mathbf{G}^T \mathbf{q} - g(t) \right) \quad (1)$$

Here, \mathcal{H} is the Heaviside step function and \mathbf{G} is a 6×1 column vector allowing for the projection of the displacements in the global reference frame on the line of action. The gap function $g(t)$ is expressed as

$$g(t) = b + q_s(t) - \frac{F_s}{k_m(t)} \quad (2)$$

where $q_s(t)$ is the static transmission error, $k_m(t)$ the mesh stiffness and F_s corresponds to the transmitted load. There exists a number of methods to compute the static transmission error. However this work considers gears with holes which warrants the use of a multibody analysis.

Numerical methods

Due to the functional backlash, the equations of motions of the above described systems are strongly nonlinear. The harmonic balance offers an efficient framework to compute the nonlinear response in the frequency domain. The equation of motion takes the general form

$$[\mathbf{M}] \ddot{\mathbf{q}} + [\mathbf{C}] \dot{\mathbf{q}} + [\mathbf{K}] \mathbf{q} + \mathbf{f}_{nl}(\mathbf{q}, \dot{\mathbf{q}}) = \mathbf{f}_{ex} \quad (3)$$

where \mathbf{q} contains the generalised displacement of each DoF and $[\mathbf{M}]$, $[\mathbf{C}]$, $[\mathbf{K}]$ are respectively the mass, damping and stiffness matrices. \mathbf{f}_{ex} is the vector of external periodic forcing and \mathbf{f}_{nl} the vector of nonlinear forces, i.e. the mesh force caused by contact, or lack thereof, between gear teeth. The terms in equation (3) are thus expanded as truncated Fourier series. More specifically, the generalised displacements are expressed as

$$\mathbf{q} \approx \sum_{k=0}^H \mathbf{a}_k \cos(k\Omega t) + \mathbf{b}_k \sin(k\Omega t) = [\mathbf{T} \otimes [\mathbf{I}_n]] \tilde{\mathbf{q}} \quad (4)$$

where \mathbf{T} contains the harmonic base functions up to the truncation order H , \otimes is the Kronecker tensor product, $[\mathbf{I}_n]$ the identity matrix of size n and $\tilde{\mathbf{q}}$ is the vector in which the Fourier coefficients are stored. The nonlinear forces are treated by the well-known alternating frequency/time procedure [4]. An arc-length continuation method is coupled with the HBM to build the frequency response curves. Hill's method [5] is used to assess the stability of the computed points and a number of test functions are defined to locate smooth [6, 7] and grazing bifurcations.

Numerical example

Figure 2: Forced response curve (a) and grazing bifurcation diagram (b). Dashed lines indicate unstable regions and solid lines indicate stable regions. Saddle-node, Neimark-Sacker and grazing bifurcations are represented with circle, triangle and diamond markers, respectively.

Conclusion

A numerical methodology has been developed to study the influence of gear topology discontinuities on the dynamics of geared systems. Results show that holes have a beneficial effect in curtailing the frequency range where the system exhibits vibro-impacts, both at low and high torques.

Experimental investigation of Circular Cylindrical Shell with non newtonian fluid

Antonio Zippo*, Giovanni Iarriccio* and Francesco Pellicano*

* *Università degli Studi di Modena e Reggio Emilia, Dipartimento di Ingegneria Enzo Ferrari, Centre InterMech - MO.RE.*

Summary. In the presented study the nonlinear vibrations of a fluid-filled circular cylindrical shell under base excitation is investigated. A PET thin shell with an aluminium top mass is harmonically excited through an electrodynamic shaker in the neighbourhood of the natural frequency of the first axisymmetric mode. The dilatant fluid is composed of a cornstarch-water mixture with 60% cornstarch and 40% water of total weight. The preliminary results show a strong non-linear response due to the coupling between the fluid and structure and the shaker-structure interaction that leads to a very interesting dynamic response of the system.

Introduction

The behaviour of thin-walled structure dynamics is always of high attention from the scientific community due to the extensive number of applications that can be found in engineering from macro to nanoscales (propellant tanks, micro-electro-mechanical systems, nanotubes, etc.).

In literature, it is possible to find several references where the response of thin-walled structures subjected to external forcing has been analyzed in presence of fluid-structure interaction [1-3], extreme temperature conditions [4-5] or interaction with electrodynamic shakers [6]. With the purpose of analyzing the response of the shell in presence of multiple interactions, an experimental study on the nonlinear vibrations of a fluid-filled cylindrical shell carrying a top mass has been carried out: the test setup is described, and preliminary results of the bifurcation analysis are presented.

Experimental setup and tests procedure

The specimen is a polymeric circular cylindrical shell, see Figure 1: an aluminum cylindrical mass is glued on the shell top edge; conversely, the bottom edge of the shell is clamped to a shaking table.

The following sensors have been adopted: three triaxial accelerometers placed on the top mass at 120°, a monoaxial accelerometer at the base of the shell, a laser vibrometer to measure the lateral velocity on the mid-height of the shell.

The test article has been excited in the axial direction through a harmonic load, with a step-sweep controlled output, the voltage signal sent to the shaker amplifier is closed-loop controlled; to avoid interaction between the control system and the specimen under study, no controls have been used for controlling the shaker base motion.

The harmonic forcing load consists of a stepped-sine sweep of frequency band 100-500 Hz with a step of 2.5 Hz. All the tests have been performed with the shell full filled with quiescent fluid.

Figure 1: fluid-filled polymeric circular cylindrical shell with a top mass

Preliminary results

In this section, a short overview of the preliminary results, obtained from the postprocessing of the experimental data, is shown. In figure 2 the amplitude frequency diagrams shown a transfer of energy to the lateral motion at increasing of the excitation. The bifurcation diagram of the radial velocity (figure 3a) and top acceleration (figure 3 b) of the downwards test at 0.48 Volt and the bifurcation diagram of the radial velocity (figure 3c) of the upwards test at 0.34 Volt shows clearly that the dynamic scenario of the shell is strongly nonlinear.

Figure 2: amplitude frequency diagram of (a) base acceleration (b) top acceleration (c) lateral velocity

This remark is confirmed by the Poincaré maps of the vertical acceleration of the top mass and the radial velocity of the shell: a 4-period subharmonic (Figure 3d) to chaotic states at 250Hz(Figure 3e) confirmed by the time history of the velocity (figure 3f) , and in the case of upwards at 0.34 Volt a period-doubling with amplitude modulation at 292.5 Hz: Poincaré maps (figure 3g) and spectrum of lateral velocity normalized respect to the forcing frequency at 292.5Hz (figure 3h) has been observed in the experimental analysis.

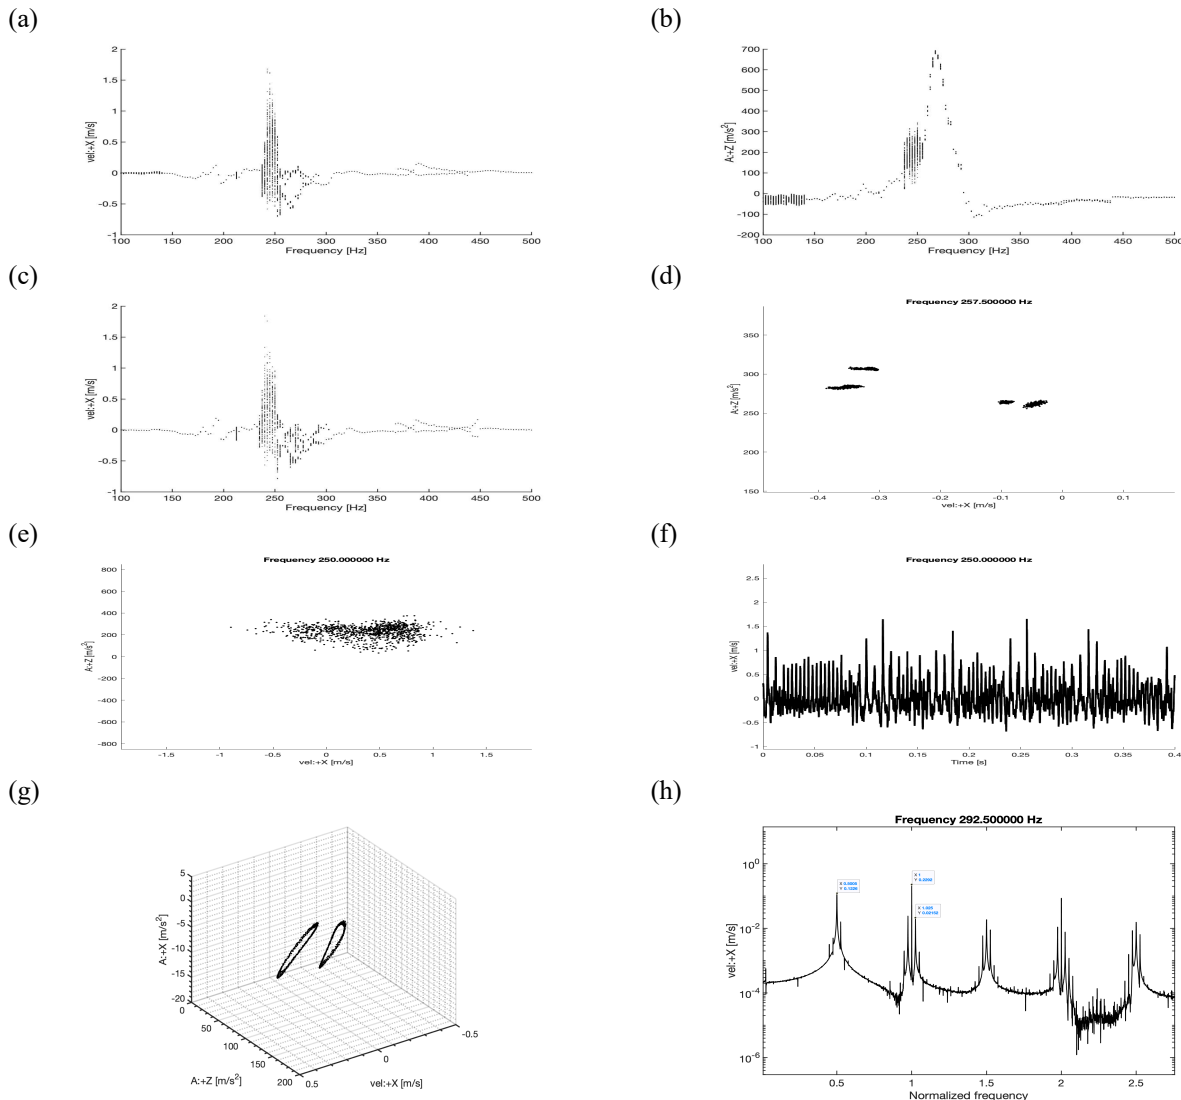

Figure 3: Bifurcation diagram and Poincaré maps of the fluid-filled shell response: experimental bifurcation diagram of the lateral velocity (a), top mass acceleration in axial direction (b) downwards 0.48V and lateral velocity upwards case at 0.34 V(c) , 4-period subharmonic response (d), chaotic motion: Poincaré maps(e) and time history (f), period-doubling with amplitude modulation: Poincaré maps (g) and spectrum of lateral velocity (h)

Reconfigurable Feedback Control of a Flexible Structure with a Nonstationary Backlash via a Digital-Twin Framework

Yoav Vered* and Stephen J. Elliott *

*Institute of Sound and Vibration Research, University of Southampton, Southampton, United Kingdom

Summary. The following work portrays a method to adaptively reconfigure a nonlinear controller to ensure the asymptotical stability of a position control mechanism that exhibits nonlinear and nonstationary backlash. The presented approach utilises a remote-based digital twin to perform the reconfiguration. Thus, the digital controller can be implemented locally using simple hardware. At the same time, the reconfiguration process takes place on a remote server that uses the acquired signal and dynamical models to perform simulations and calculations at a high rate. The proposed approach is demonstrated based on a numerical simulation of a three degrees-of-freedom structure coupled to an electrical DC motor via a lead screw. The lead screw exhibit backlashes whose characteristic width grows during the normal operation of the mechanism. Such system loses their closed-loop stability when the backlash becomes large. A nonlinear dead zone is used to restabilise the closed-loop system. The dead zone parameter is tuned based on a digital twin to ensure the closed-loop asymptotical stability and to avoid over-conservative design. Finally, the successful use of the proposed methodology is presented based on the simulation results.

Introduction

When a feedback-controlled mechanical system characteristic changes over time, the original design of the controller can lead to instabilities [1]. Wear and tear lead to such changes by introducing, for example, a nonlinear backlash. Although backlash is present in most mechanical position control systems [2], its effect on the linear feedback law is frequently neglected. However, even when the backlash is considered when formulating the identification and control problem [2, 3], its characteristics are usually modelled as a time-invariant. However, these time-invariant models are not applicable when wear and tear processes occur [4], in which case the characteristics of the backlash change over time.

To account for the time dependence of the backlash, an adaptive controller [3] can be used. However, the downside of doing so is that the controller's structure is complex, and its implementation is not straightforward. Therefore, in this work, a PID controller [5] is considered, with the addition of a dead zone to overcome the limit cycles introduced by the backlash and maintain minimal control effort minimal in the backlash gap [3]. The dead zone parameter is estimated asynchronously using a remotely-based digital twin [6] to monitor the changing backlash.

The core purpose of the digital twin is to create a fusion between physical and data-based models. Most research on digital twins is concerned with utilising them for decision-making and structural health monitoring, with only a few remarks on the use of digital twins in control, using classical ideas like controller scheduling [7]. This is in contrast to the past developments in digital signal processing, which have led to a more profound understanding of advanced control methodologies [8, 9]. Therefore, this work tries to pave the way and demonstrate the capabilities of incorporating digital twins into system control by employing the digital twin as an asynchronous estimator, resulting in a simple structure of the digital controller. This idea is not, by any means, a demonstration of the full capabilities of digital twins but only acts as a stepping stone towards a fuller understanding of digital twins' potential use in feedback control.

Control problem formulation

PID Feedback controllers are widely used for position control of flexible structures [5]. The schematics of a position controller of a flexible mechanism are presented in Figure 1(a). The mechanism is composed of 3 lumped masses con-

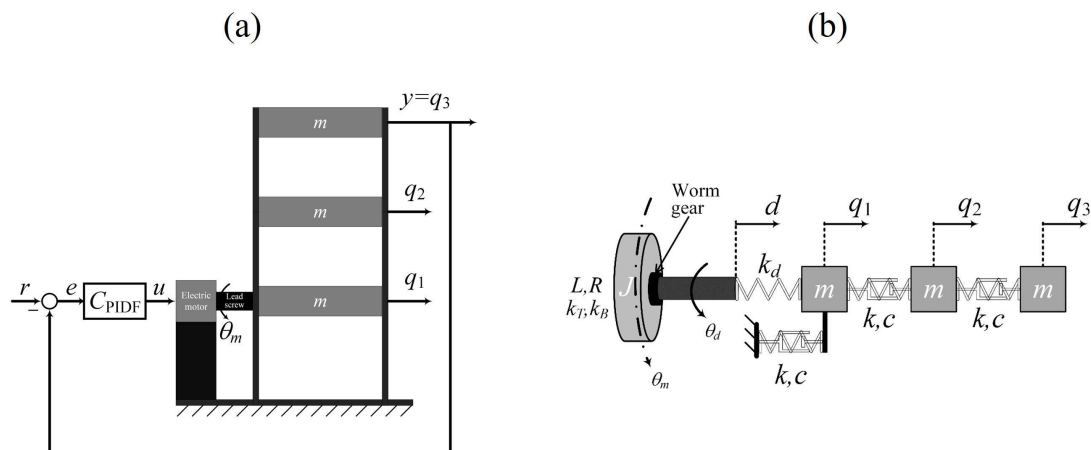

Figure 1: The position control system models. (a) – Schematic of the feedback position control. (b) – Lumped elements model.

nected via flexible beams. An electrical motor that is connected via a lead screw to the bottom mass is used to drive the system. The system's lumped model shown in Figure 1(b) is used for the numerical simulation. In the lumped model of Figure 1(b), L and R denote the electrical motor's inductance and resistance, respectively, J its lumped inertia, k_B and k_T are the torque and back-emf motor's constants, θ_m the angular position, and ω_m the angular velocity. The motor is connected to the lower mass via a lead screw, whose angle is denoted as θ_d , and its end position, d , is related to its angular position via

$$d = p\theta_d, \quad (1)$$

where p denotes the lead screw's pitch. The lead screw elasticity is modelled using a linear spring k_d , which in the following simulation is assumed to be infinitely rigid. m , k , and c denote the lumped mass of each platform and the connecting beams' elasticity and dissipation, which are assumed to be linear. Finally, q_i $i = 1, 2, 3$, denote the horizontal position of each platform. The physical values used throughout the paper are given in Table 1.

Table 1: Physical properties and values used in the numerical simulation of the three DOF with the DC electrical motor

Symbol	Value, units	Symbol	Value, units	Symbol	Value, units
m	5.2, kg	J	$5 \cdot 10^{-6}$, kg · m ²	p	$10^{-3}/2\pi$, m/rad
k	10^4 , N/m	L	10^{-3} , H	k_T	0.8, (N·m)/A
c	36.9, N/(m·s)	R	12, Ohm	k_B	0.1, V/(m/s)

Linear models and controller

Assuming that the inertial loading of the structure is negligible compared to the motor's torque, a single direction coupling model can be used to represent the motor and platform dynamics. The motor's input-output relation under these assumptions can be written as

$$\theta_m = \frac{1}{s} \frac{k_T}{JLs^2 + JRs + k_Bk_T} u, \quad (2)$$

where u denotes the input voltage to the motor. The top platform and the lead screw positions are related via:

$$q_3 = \frac{c^2s^2 + 2cks + k^2}{m^2s^4 + 3cms^3 + (c^2 + 3km)s^2 + 2cks + k^2} d. \quad (3)$$

When the lead screw backlash is neglected, i.e., $\theta_d = \theta_m$, the static relation of Eq. (1) can be used to couple the two systems' dynamics.

To control the motion and position of the top platform such that it follows a stepwise constant reference signal, r , a feedback PID controller of the following form

$$C_{PID}(s) = K_p + K_i \frac{1}{s} + K_d \frac{s}{T_f s + 1}, \quad (4)$$

is introduced, where K_p , K_i , and K_d are the proportional, integral, and differential gains, respectively, and T_f is the differential filter time constant. Such that the motor's input voltage u is obtained from the tracking error $e = r - q_3$ as

$$u = C_{PID}(s)e. \quad (5)$$

The PID was designed to achieve a zero steady-state error, a bandwidth frequency of 10 rad/s, and a minimum phase margin of 10 deg.

Nonlinear backlash model

Since the positioning mechanism is based on a lead screw, it might exhibit backlash in practice, mainly as it wears. A simple model for backlash, which is a nonlinear dynamic element, is by introducing a dynamic dead zone of known width whenever the velocity changes sign [3].

The following nonlinear model can be used to relate the motor and lead screw angular velocities:

$$\omega_d = \begin{cases} \omega_m & (\text{sign}(\omega_m) > 0 \text{ and } \theta_m - \theta_d \geq \theta_b/2) \text{ or } (\text{sign}(\omega_m) < 0 \text{ and } \theta_m - \theta_d \leq -\theta_b/2) \\ 0 & \text{Otherwise} \end{cases}, \quad (6)$$

where θ_b denotes the backlash gap angle.

A time-invariant backlash model, with a constant backlash gap angle θ_b , is readily available with many simulation software. However, since the backlash gap angle is time-varying here, a separate procedure for the state transition was used, based on the model of Eq. (6). To illustrate its response, Figure 2 shows the output of the backlash model for a gap angle of $\theta_b = 40$ degrees, and for an amplitude changing sinusoidal input of the following form:

$$\theta_m(t) = (1 + t/10) \sin(2\pi t).$$

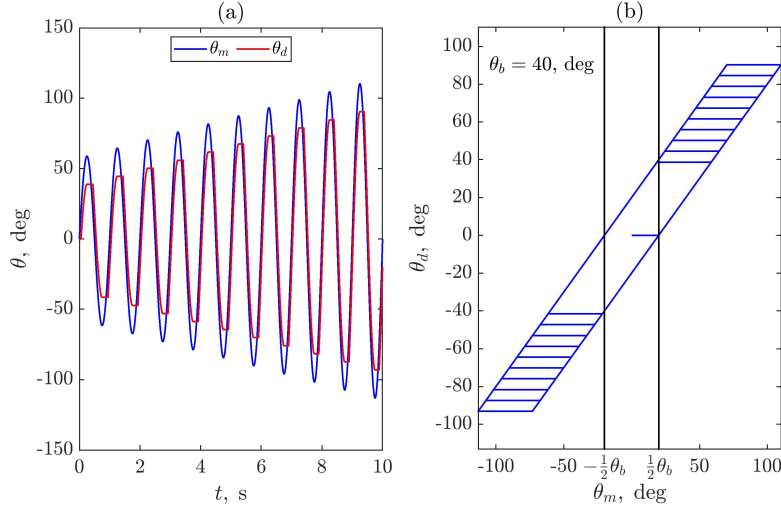

Figure 2: Simulation results for the backlash model for an amplitude-modulated sinusoidal input.

Figure 3: Simulation results for the linear controller with a nonstationary backlash.

The lost motion between θ_m and θ_d can be seen in Figure 2(a), which shows their two waveforms, whereas the nonlinear characteristics of the backlash are more transparent in Figure 2(b), which plot one against the other.

The simulation results of the feedback position control mechanism with a predetermine backlash's gap angle profile are shown in Figure 3. When the width is small, the position control is applied successfully to the system, and the top mass position does converge to the required reference position. However, a limit cycle is observed when the width becomes more significant, and the system can no longer be considered asymptotically stable.

Switched dead zone controller

A dead zone of a prechosen width is incorporated into the controller to capture and maintain the backlash's effect and restabilise the system [3]. The controller input-output relation can now be read as:

$$u_{dz} = \begin{cases} C_{PID}(s)e_{dz} & |e| > \varepsilon_{dz} \\ 0 & \text{Otherwise} \end{cases}, \quad (7)$$

where

$$e_{dz} = \begin{cases} e & |e| > \varepsilon_{dz} \\ 0 & \text{Otherwise} \end{cases}, \quad (8)$$

and the dead zone tolerance, ε_{dz} , is given by:

$$\varepsilon_{dz} = p\hat{\theta}_b, \quad (9)$$

$\hat{\theta}_b$ being the backlash gap angle estimation.

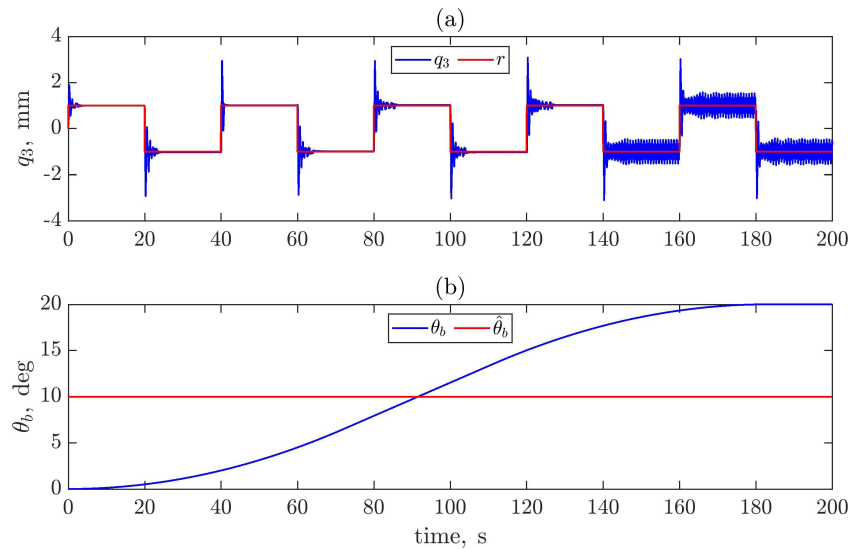

Figure 4: Simulation results for the dead zone controller with a nonstationary backlash and a constant backlash gap angle estimation.

If the controller's dead zone width is tuned too conservatively, i.e., $\hat{\theta}_b$ is chosen large, a significant bias is introduced between the required and actual position. Moreover, no force is applied to the structure inside the dead zone, and its response decays similarly to its initial condition response. Thus, the desired damping levels of the designed controller are lost, and the settling time can become significantly longer.

A second simulation was carried out using the same backlash's width profile with the dead zone switched controller. In the simulation, the backlash gap angle estimator was chosen as the mean value, i.e., $\hat{\theta}_b = 10$ deg. The simulation's results are shown in Figure 4. It is clear that the system again loses stability when the real backlash's gap angle is significantly larger than the modelled one. Moreover, when the actual backlash's gap angle is smaller, the settling time does get longer as anticipated. An estimation of the backlash is proposed to ensure the closed-loop stability and reduce the amount of conservative used for choosing the dead zone width. The backlash's gap angle estimation is done via a remote digital twin to avoid overflowing the controller and to enable, in the future, the use of more sophisticated estimation and designing methods.

Digital twin reconfigurable controller

Figure 5: Schematics of the digital twin based reconfigurable controller.

The digital twin is a modern concept in engineering. At its core, the digital twin aims to create a fusion between meaningful physical models of a system, combined with measured data collected from different sensors throughout the physical system's operation [6]. The digital twin as a concept has so far been used during several stages of a product's life-cycle: designing, manufacturing, and condition monitoring. However, the use of a digital twin is not as common in control theory [7], specifically motion control. Although many systems for which digital twins are considered, like wind turbines and aircraft [6], depend on motion controllers for their smooth operation. The idea put forward in this work is to use a simple model of a digit twin to monitor the backlash's width and reconfigure the dead zone feedback controller. The block diagram of Figure 5 represents the physical system (physical twin and feedback controller) on the left-hand side and the simulated system (digital twin and controller design) on the right-hand side. The main difference between the use of a digital twin framework and adaptive control [1, 8], is the asynchronous nature of the communication and the ability to

use highly detailed simulations. Therefore, ensuring that the digital feedback controller will operate properly, where the states' and controller's estimation and reconfiguration occur on a remote server.

Backlash gap angle estimation

It is assumed that the control signal, u , and the top platform position, q_3 , are measured and are sent to the digital twin asynchronous. After each data transmission, the digital twin can be used to simulate the internal signals of the feedback system. It is desired to estimate both the output and input of the backlash and compare them to estimate the backlash angle. The input of the backlash, the motor's angle, is estimated using the measured control signal, which is fed to the discretised dynamical model of Eq. (2), assuming a zero-order hold and an ideal sampler. The output of the backlash, the lead screw's angle, is estimated using the measured top platform position and a digital-based delayed inverse of the dynamical model of Eq. (3). An impulse invariant discretisation algorithm is used [9] to ensure that the sampled system remains minimum phase, up to the addition of zeros at the origin. Then the inverse filter of the sampled system can be calculated. A discrete modelling delay of N samples is added to the sampled system inverse filter to ensure causality. The minimal value of N required for causality is equal to the pole excess of the sampled system. Since N step delay is added to the backlash output, a similar delay is added to the digital-sampled motor's dynamics. The estimators of the motor and lead screw's angles, $\hat{\theta}_m$ and $\hat{\theta}_d$, are thus the output of the following two sampled time linear systems:

$$\hat{\theta}_m = z^{-N} \hat{G}_1(z)u, \quad (10)$$

$$\hat{\theta}_d = z^{-N} \hat{G}_2^{-1}(z)y, \quad (11)$$

where $\hat{G}_1(z)$ and $\hat{G}_2(z)$ are the discretised dynamical model of Eq. (2) and Eq. (3), respectively.

To estimate the backlash angle, θ_b , the difference between the angles is calculated. It follows from the backlash definition that if $\omega_d \neq 0$, then $\theta_m - \theta_d = \Delta\theta_{\pm}$, where the plus or minus are chosen based on the sign of ω_m . Therefore, it follows that

$$\theta_b = \Delta\theta_+ - \Delta\theta_-, \quad (12)$$

Equation (12) is accurate up to measurement and estimation errors. Therefore, a threshold is used for the lead screw's angular velocity criteria to overcome these errors. In addition, based on the previous simulation of Figure 4, it seems safer to use a slight overestimation of the backlash gap angle. Consequently, the estimated values which correspond to the angular velocity threshold are rounded up to the nearest scaled-integer degree, and the mean is taken as the estimator. If degree units are used, then the estimator is:

$$\hat{\theta}_b = \frac{1}{N_{\Delta\theta_+}} \sum_{t_s \in t_+} \lceil \Delta\theta_+ \rceil_{l/2} - \frac{1}{N_{\Delta\theta_-}} \sum_{t_s \in t_-} \lfloor \Delta\theta_- \rfloor_{l/2}, \quad (13)$$

where t_+ represents the sampling times when $\omega_d \neq 0$ and $\omega_m > 0$, similarly, t_- represents the sampling times when $\omega_d \neq 0$ and $\omega_m < 0$, $N_{\Delta\theta_+}$ and $N_{\Delta\theta_-}$ denote the number of elements in each time subset, and the ceil l and floor l operators are defined as:

$$\lceil x \rceil_l := l \cdot \text{ceil}(x/l), \lfloor x \rfloor_l := l \cdot \text{floor}(x/l). \quad (14)$$

Figure 6: Post-processing identification of the time-varying backlash angle.

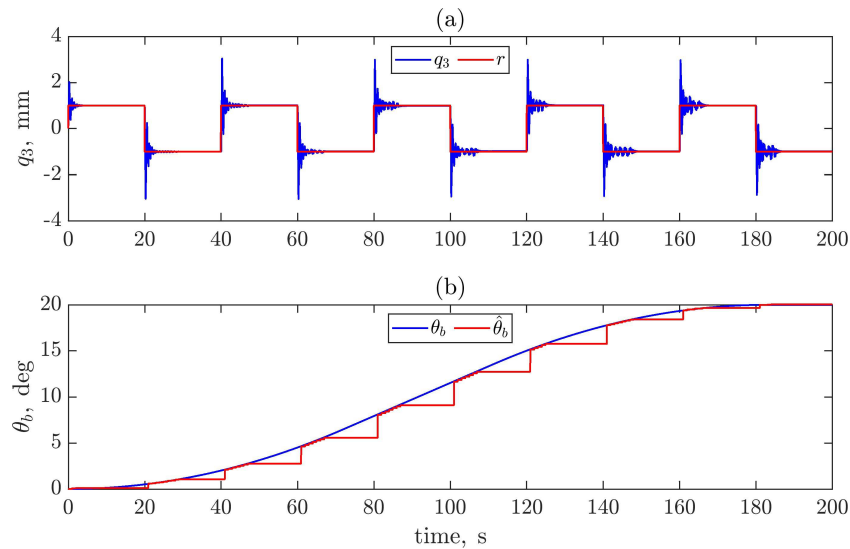

Figure 7: Simulation results for the digital twin reconfigurable controller with a nonstationary backlash.

To check the estimation algorithm and help tune the angular velocity threshold, the simulation data in Figure 4 was post-processed. A 5000 Hz sampling frequency was used, the angular velocity threshold was set to $\varepsilon_b = 0.1$ rad/s, the number of discrete delays added to the digital sampled inverse system $N = 2$, and the rounding factor was chosen as $l = 1/10$. Figure 6(a) shows the command and output signals, and Figure 6(b) shows the actual and estimated backlash angles obtained using the proposed estimation algorithm. When the input to the digital sampled inverse system is constant (The top mass is at rest following a step change), the estimated lead screw's angle matches the measured one. However, if the input is not constant, a small phase and gain delay are present. This is due to the dynamics of the inverse filter. Consequently, the actual and estimated angles differ whenever the lead screw angular velocity is nonzero. However, as seen in Figure 6(b), the estimation algorithm successfully identifies the backlash angle, even though the two angles differ slightly. The results of Figure 6 were obtained based on noncausal signal post-processing, so the backlash angle estimation has no delay. In the following subsection, the real-time use of a digital twin is simulated, including this processing delay, to include its effects in restabilising the system.

Real-time simulation

A third simulation was carried out based on the block diagram of Figure 5, the dead zone PID controller, and the backlash estimation method. The backlash gap angle estimator was initialised to be zero. To account for the communication delay between the physical and digital twin, a 1-second delay was added.

Figure 7 shows the results of the digital twin reconfigurable dead zone controller. Note that unlike the previous simulation results (Figure 4), the reconfigurable controller now restabilises the nonlinear feedback system at all times. Even though a bias in the final position of each step is present, the worst bias is under 2% of the required reference amplitude. The lead screw's angle estimation procedure yields a sufficiently accurate estimation for stable control, and the delay due to the data transfer does not significantly affect the estimation and control. These results show that the backlash's estimation is accurate and that the closed-loop system remains stable throughout the entire manoeuvre.

Conclusions

This paper puts forward the idea of utilising a digital twin to estimate the nonstationary characteristics of a nonlinear mechanism and, in turn, reconfigure a feedback controller to stabilise the system. The advantage of using a digital twin over classical adaptive control is using asynchronous communication and utilising the server's high computation power. Doing so ensures that the digital controller will operate without introducing additional delays or overflows. Moreover, elaborate models can be used for the inverse estimation problems associated with the signal estimation procedure. Finally, the numerical simulation results are an indication of future possibilities. Mainly, by employing the digital twin, evolved nonlinear mechanisms characteristic can be identified, and a simulation-based design of a reconfigurable controller.

Summary. Although not studied extensively, adaptive frequency oscillators (AFOs) could have many useful applications. AFOs possess the capability of synchronizing their oscillating frequency with their input frequency. Here, the noise-influenced dynamics of the Hopf Adaptive Frequency Oscillator (HAFO) are analyzed in a probabilistic manner. By adding a stochastic forcing term to the ordinary differential equations (ODEs), the resulting stochastic differential equations (SDEs) are integrated using the Euler-Maruyama (EM) method to obtain direct numerical solutions and the probabilistic dynamics of the oscillator. Additionally, a hardware circuit realization of the HAFO is fabricated, and the experimental results and the simulation results are compared. Efforts are made to quantify the working capability of the oscillator, which is limited by nonideal electrical components. The influence of noise on the HAFO circuit will also be investigated and compared with the results obtained through the Euler-Maruyama simulations.

Hopf Adaptive Frequency Oscillator

The Hopf Adaptive Frequency Oscillator is capable of synchronizing its oscillating frequency to an oscillatory input signal. The HAFO with the capability of learning the frequency of any rhythmic inputs are widely used for robotic locomotion control, by using the HAFOs as central pattern generators to tune the walking patterns in a cooperative way [1, 2]. The HAFO is an augmented form of the Hopf oscillator [3], which has an additional state related to the frequency:

$$\begin{aligned}\frac{dx}{dt} &= (\mu - r^2)x - \omega y + kF(t) \\ \frac{dy}{dt} &= (\mu - r^2)y + \omega x \\ \frac{d\omega}{dt} &= -\text{sgn}(y)kF(t)\end{aligned}\quad (1)$$

where $r = \sqrt{x^2 + y^2}$, k is the amplitude of the deterministic forcing function, μ is a constant related to the limit cycle amplitude, and $F(t)$ is a sinusoidal forcing function. The first two equations are the typical version of the Hopf oscillator, while the $\frac{d\omega}{dt}$ equation allows frequency adaptation. The learning process is embedded into the dynamical system, and there are not any pre- or post-processing procedures needed to accomplish the frequency synchronization. This behavior may be observed in Fig. 1.

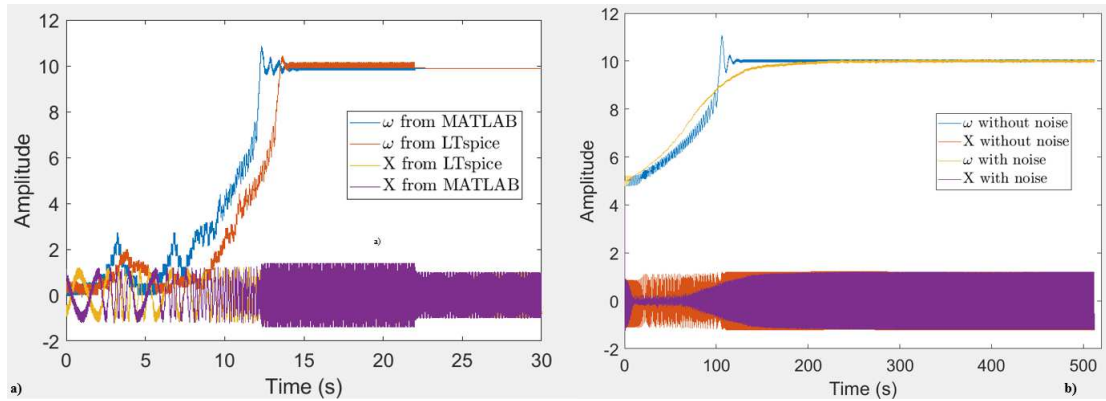

Figure 1: a) MATLAB simulation and LTspice simulation of eqs. 1. The sinusoidal forcing causes the HAFO to adapt. After the forcing is set to zero at $t = 22$ s, the HAFO “remembers” the input frequency. Additionally, the x output from both simulations overlaps with each other when the frequency adaptation is accomplished. b) MATLAB simulation of eqs. 2 by the Euler-Maruyama method. The noise amplitude is 10% of the amplitude of the sinusoidal forcing function. With the addition of noise, the frequency adaptation takes a longer time, but there is no overshoot. The x output from both cases overlaps with each other after the transient response.

Influence of Noise

Previously, the stochastic response of the HAFO was approximated by using a Fokker-Plank formulation [4]. As noise can change the dynamic stability of nonlinear systems [5, 6], it is important to further explore the effects of noise on the HAFO. To consider the effects of noise on the HAFO, the sinusoidal function, $F(t)$, is replaced with $\hat{F}(t) + \frac{\sigma}{k}\dot{W}(t)$. Here, $\hat{F}(t)$ is a sinusoidal function, $\dot{W}(t)$ is white Gaussian noise, and σ is the amplitude of the noise. Making this replacement, the stochastic differential equations are:

$$\begin{aligned}\frac{dx}{dt} &= (\mu - r^2)x - \omega y + k\hat{F}(t) + \sigma\dot{W}(t) \\ \frac{dy}{dt} &= (\mu - r^2)y + \omega x \\ \frac{d\omega}{dt} &= -\text{sgn}(y)k\hat{F}(t) - \text{sgn}(y)\sigma\dot{W}(t)\end{aligned}\quad (2)$$

This set of SDEs can then be simulated using the Euler-Maruyama method, depicted in Fig. 1.

Circuit Realization

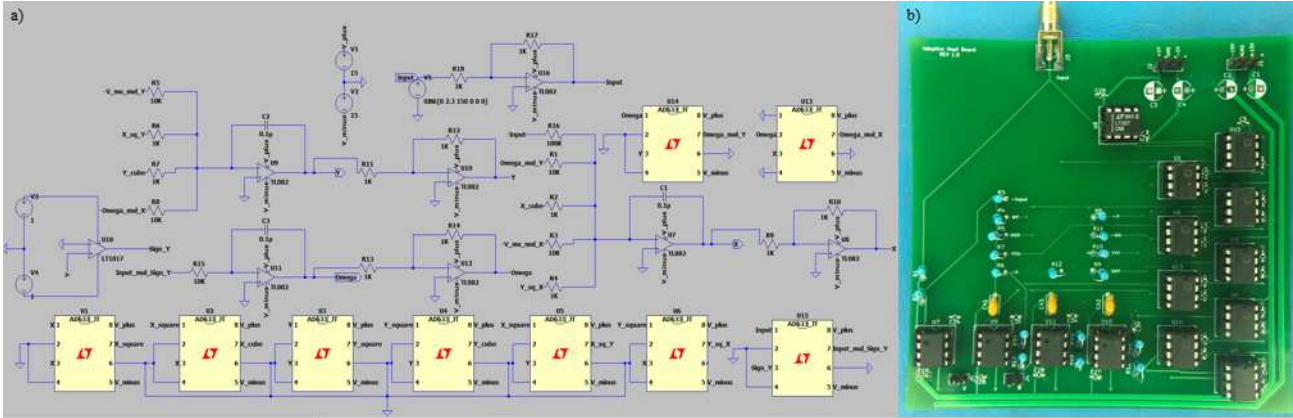

Figure 2: a) The circuit diagram in LTspice. b) A printed circuit board (PCB) of the HAFO.

The circuit design (Fig. 2) was inspired from [7], which presents an electronic implementation of the Lorenz chaotic oscillator for radar applications. To make the hardware circuit easier to implement, the original set of equations is modified, as in [8]:

$$\begin{aligned} \frac{dx}{dt} &= (\mu - r^2)x - \omega y + kF(t) \\ \frac{dy}{dt} &= (\mu - r^2)y + \omega x \\ \frac{d\omega}{dt} &= -\frac{y}{\sqrt{x^2 + y^2}} kF(t) \end{aligned} \quad (3)$$

The modification of eqs. 1 does not change the frequency adaptation property. However, it does affect the length of the transient response and the error (the difference between the steady-state frequency of the oscillator and the frequency of the input signal). In Fig. 3, a comparison between the experimental circuit and the LTspice simulation is shown. Filtering was performed on the experimental data in MATLAB. Nonideal electronic components cause discrepancies between the experimental circuit and the simulated circuit. The voltages reported in the figure must be converted to find the frequency in Hertz.

Conclusions

AFOs could prove to have useful properties for mechatronics. To gain better understanding of their dynamics, numerical simulations of the deterministic and stochastic system are pursued, while a PCB implementation provides experimental insight. In Fig. 3, the experimental frequency was recorded with an oscilloscope, and LTspice was used to simulate the HAFO circuit. The variation between the experimental results and the numerical results is lower than 5%. The modeling of the HAFO on the hardware circuit achieved by the PCB is practical and inexpensive. Further work will be pursued to determine their efficacy as analog controllers.

Summary. The past decade has witnessed renewed interests to nonlinear model reduction and many differently motivated techniques are proposed, including nonlinear normal modes (NNMs), direct multi-scale method (dMSM, full-basis), normal form (NF), sub-spectral manifolds (SSMs), quadratic manifolds (QM, using a mode derivative concept), low-order elimination technique (LOE). There is indeed demand for unified perspectives on the whole nonlinear model reduction matter, aiming at a better understanding of subtle connections among all these reduction methods.

In this talk, the recent low-order elimination (LOE) technique using a passive pattern concept will be first discussed, and then used to outline some unified perspectives on nonlinear model reduction, which are developed based upon two different basic problems, i.e., truncation order and truncation degree. The former refers to the common reduced dimension or number of dominant modes, while the latter refers to truncation degree of polynomials employed to approximate invariant manifold/transformation/passive pattern.

An explicit theoretical correspondence among these reduction methods will be detailed, placing in particular NNMs/dMSM/NF/LOE within a unified framework in the sense of refined finite mode truncation, which justifies various claims/observations in literature that all these refined reduction methods correct the routine/flat Galerkin (say, single-mode) truncated model.

Another unified perspective is built by focusing on various reduced-order models (ROMs) of general quadratic/cubic nonlinear structures, produced by different reduction methods with two-, three-, and four-degree truncations. It turns out that all the truncations produce valid and equivalent, but seemingly different, ROMs. Through translating invariant manifolds and nonlinear transformation terminology into low-order elimination language using passive patterns, we frame various reduction approaches within the same formulation and finally give a unified elucidation of distinct reduction methods in the sense of truncation degree.

Model truncation issues

We take a quadratic/cubic nonlinear structure as an archetypical model

$$\partial^2 w / \partial t^2 + L[w] = N_2[w] + N_3[w] + \dots \quad (1)$$

with boundary conditions $B_0[w] = B_1[w] = 0$. Here $w(x, t)$ is the displacement, $L[\cdot]$, $N_2[\cdot]$ and $N_3[\cdot]$ are the structure's linear, quadratic and cubic spatial operators, respectively. Using single-mode truncation (m -th mode is assumed to dominate asymptotic dynamics), we deduce routine Galerkin model for model (1)

$$\ddot{q}_m + \omega_m^2 q_m = \langle \phi_m, N_2[\phi_m, \phi_m] \rangle q_m^2 + \langle \phi_m, N_3[\phi_m, \phi_m, \phi_m] \rangle q_m^3 + \dots \quad (2)$$

where $\langle \phi_i, \phi_j \rangle = \delta_{ij}$, $\langle \phi_i, L[\phi_j] \rangle = \omega_i^2 \delta_{ij}$, with ω_i and ϕ_i being i -th modal frequency and shape. However it is often criticized due to completely neglecting non-essential modes $q_l, l \neq m$, which leads to possible error predictions.

Truncation order problem: refined finite mode truncation

(1) The NNMs method introduces the following invariant manifolds

$$q_l = g_l(q_m, \dot{q}_m) \sim O(q_m^2, \dot{q}_m^2), \quad \dot{q}_l = h_l(q_m, \dot{q}_m) \sim O(q_m^2, \dot{q}_m^2), \quad l \neq m \quad (3)$$

to enslave the non-essential modes ($l \neq m$) to the dominant one, satisfying manifold equations (say, up to second order)

$$\frac{\partial g_l}{\partial q_m} \dot{q}_m + \frac{\partial g_l}{\partial \dot{q}_m} (-\omega_m^2 q_m) = h_l, \quad \frac{\partial h_l}{\partial q_m} \dot{q}_m + \frac{\partial h_l}{\partial \dot{q}_m} (-\omega_m^2 q_m) = -\omega_l^2 g_l + \langle \phi_l, N_2[\phi_m, \phi_m] \rangle q_m^2 \quad (4)$$

(2) The full-basis or direct perturbation method designs a 'ladder-type' expansion scheme like

$$O(\varepsilon): D_0^2 q_{m1} + \omega_m^2 q_{m1} = 0, \quad O(q_{l1}) \ll O(q_{m1}), \quad l \neq m \quad (5)$$

$$O(\varepsilon^2): D_0^2 q_{m2} + \omega_m^2 q_{m2} = \langle \phi_m, N_2[\phi_m, \phi_m] \rangle q_{m1}^2, D_0^2 q_{l2} + \omega_l^2 q_{l2} = \langle \phi_l, N_2[\phi_m, \phi_m] \rangle q_{m1}^2, \quad l \neq m \quad (6)$$

to dynamically condense the non-essential modes ($l \neq m$) to the dominant one q_m, \dot{q}_m (satisfying Eq.(6) at $O(\varepsilon^2)$)

$$q_{l2} = \frac{\langle \phi_l, N_2[\phi_m, \phi_m] \rangle}{0^2 + \omega_l^2} \left(\frac{q_m^2}{2} + \frac{\dot{q}_m^2}{2\omega_m^2} \right) + \frac{\langle \phi_l, N_2[\phi_m, \phi_m] \rangle}{-4\omega_m^2 + \omega_l^2} \left(\frac{q_m^2}{2} - \frac{\dot{q}_m^2}{2\omega_m^2} \right), \quad l \neq m \quad (7)$$

(3) The (simplified) normal form method introduces the following nonlinear near-identity transformations

$$q_l = p_l + \hat{G}_l(p_m, \dot{p}_m), \quad \dot{q}_l = \dot{p}_l + \hat{H}_l(p_m, \dot{p}_m), \quad l = 1, 2, \dots \quad (8)$$

to reformulate the original full-basis discretized Galerkin model as

$$\begin{aligned} \ddot{p}_l + \omega_l^2 p_l = 0 &+ 2 \langle \phi_l, N_2[\phi_m, \phi_m] \rangle p_m \hat{G}_m \\ &+ \sum_{j=1, j \neq m}^{\infty} \langle \phi_l, N_2[\phi_j, \phi_m] + N_2[\phi_m, \phi_j] \rangle \hat{G}_j p_m + \langle \phi_l, N_3[\phi_m, \phi_m, \phi_m] \rangle p_m^3 \end{aligned} \quad (9)$$

satisfying the simplified homological equations (say, up to second order)

$$\nabla_Y \hat{M}_l [\Lambda_m] Y - [\Lambda_l] \hat{M}_l = \left[0, \langle \phi_l, N_2 [\phi_m, \phi_m] \rangle p_m^2 \right]^T, \hat{M}_l \triangleq [\hat{G}_l, \hat{H}_l], Y = [p_m, \dot{p}_m]^T, \nabla_Y \triangleq [\partial/\partial p_m, \partial/\partial \dot{p}_m] \quad (10)$$

(4) The *low-order elimination* technique [1] designs a new displacement decomposition augmented by passive patterns

$$w(x, t) = \phi_m(x) q_m(t) + \sum \Phi_{\Omega_k}(x) P_{\Omega_k}(t) \quad (11)$$

where $(\phi_m, q_m \sim e^{i\omega_m t})$ is the dominant mode and $(\Phi_{\Omega_k}, P_{\Omega_k} \sim e^{i\Omega_k t})$ is the k -th passive pattern produced by low-order quadratic source terms, with $\Omega_p \triangleq \{0, 2\omega_m\}$, satisfying

$$\sum_{\Omega_k \in \{0, 2\omega_m\}} (-\Omega_k^2 I + L) \Phi_{\Omega_k}(x) P_{\Omega_k}(t) = N_2 [\phi_m, \phi_m] q_m^2, \quad B_0 [\Phi_{\Omega_k}] = B_1 [\Phi_{\Omega_k}] = 0 \quad (12)$$

$$P_0(t) = q_m^2/2 + \dot{q}_m^2/(2\omega_m^2), \quad P_{2\omega_m}(t) = q_m^2/2 - \dot{q}_m^2/(2\omega_m^2) \quad (13)$$

leading to so-called low-order elimination in the reference model

$$\left(\frac{\partial^2}{\partial t^2} + L \right) \phi_m q_m = \boxed{0} + \sum_{\Omega_k \in \Omega_p} (N_2 [\phi_m, \Phi_{\Omega_k}] + N_2 [\Phi_{\Omega_k}, \phi_m]) q_m P_{\Omega_k} + N_3 [\phi_m, \phi_m, \phi_m] q_m^3 + \dots \quad (14)$$

Quite interestingly, the four distinctly motivated reduction methods above are equivalent to each other, and a theoretical correspondence can be established [2].

Truncation degree problem

Due to the correspondence/equivalence above, the truncation degree problem in nonlinear model reduction is developed in the low-order elimination formulation using passive patterns. We consider full/non-full truncations of degree two

$$w(x, t) = \phi_m q_m + \Phi_0 P_0 + \Phi_{2\omega_m} P_{2\omega_m} + \dots, \quad w(x, t) = \phi_m q_m + \bar{\Phi}_0 P_0 + \bar{\Phi}_{2\omega_m} P_{2\omega_m} + \dots \quad (15)$$

and also full/non-full truncations of degree three

$$\begin{aligned} w(x, t) &= \phi_m q_m + \Phi_0 P_0 + \Phi_{2\omega_m} P_{2\omega_m} + \Phi_{\omega_m} P_{\omega_m} + \Phi_{3\omega_m} P_{3\omega_m} + \dots \\ w(x, t) &= \phi_m q_m + \bar{\Phi}_0 P_0 + \bar{\Phi}_{2\omega_m} P_{2\omega_m} + \bar{\Phi}_{\omega_m} P_{\omega_m} + \bar{\Phi}_{3\omega_m} P_{3\omega_m} + \dots \\ w(x, t) &= \phi_m q_m + \bar{\Phi}_0 P_0 + \bar{\Phi}_{2\omega_m} P_{2\omega_m} + \hat{\Phi}_{\omega_m} P_{\omega_m} + \hat{\Phi}_{3\omega_m} P_{3\omega_m} + \dots \end{aligned} \quad (16)$$

Note non-full truncation means the pattern shape functions $\bar{\Phi}_{\Omega_k}$ and $\hat{\Phi}_{\Omega_k}$ are incomplete with master components being skipped. It turns out that the NNMs method (invariant manifolds) can always be regarded as a non-full truncation (thus non-full elimination) technique, while the existing normal form method can be regarded as either a non-full three-degree truncation, or a full two-degree truncation with further third order simplification. Interestingly, for quadratic/cubic structures, all the reduction methods, either degree two or three, full or non-full, lead to equivalent third-order ROMs. Furthermore, in degenerate case, a four-degree truncation will be required [3].

The two unified perspectives on nonlinear model reduction are further illustrated in Fig.1 and the numerical results are obtained by applying the reduction methods above to a nonlinear foundation beam example.

Fig.1 Unified perspectives and numerical illustrations: (a) truncation order problem [2]; (b) truncation degree problem (degenerate dynamics) [3]

Summary. The state estimation problem for noisy nonlinear systems remains a difficult problem, particularly as the dimension of the state space grows large. This presentation will consist of a brief introduction to the problem as a diffusion process and its solution employing smooth particle hydrodynamics (SPH) to advance the estimator through the state space in time. Performance comparisons between the current algorithm, the particle filter, and the extended Kalman filter for Duffing systems of two and four dimensions will be presented.

Introduction

The effectiveness of a nonlinear estimator in a noisy environment depends on many factors, one being the accuracy with which it can predict the state dynamics of the underlying dynamical system between measurements. It is well known that a memoryless nonlinear dynamical system driven by additive and/or multiplicative Gaussian white noise can be represented by a system of D nonlinear stochastic differential equations of the Ito form, where D is the number of system states. The Bayesian optimal prior can be obtained by solving the corresponding Fokker-Planck Equation (FPE), governing the evolution of the transition probability density function of the system response over the state space [1]. The FPE is a degenerate, linear, elliptic-parabolic partial differential equation having D spatial dimensions, plus time, on an infinite spatial domain, for $t \geq 0$. To date, for the nonstationary (transient) problem, analytical solutions exist only for the scalar case, $D = 1$, the exception being the linear system subject to additive noise for which the analytical solution can be found for arbitrary D . Thus, although computational solutions of the nonstationary FPE for nonlinear systems of dimension $D = 3$ have been tractable since the mid-1980s, solution remains problematic for realistic systems with $D > 3$ due to scaling issues caused by the well-known “curse of dimensionality,” and it remains extraordinarily difficult and costly to achieve accurate solutions to higher dimensional problems over the entire state space [2,3].

This presentation is a summary of our recent work addressing a general nonlinear filter based on solving the nonstationary FPE in \mathbf{R}^D using Smooth Particle Hydrodynamics (SPH) at lower resolution which, for the limited number of four-dimensional systems studied, appears to result in reasonably accurate state estimation results. The filter is enabled by an efficient heuristic resampling scheme of the SPH solution, also briefly discussed. The resulting FPE-SPH filter appears able to replicate the accuracy of both the well-known, simulation-based Particle Filter (PF) and linearization-based Extended Kalman Filter (EKF) for lower dimensional systems, while being more robust than the EKF, at least for the several higher-dimensional systems examined [4].

In the limited time available, a short exposition of the underlying theory will be given, followed by a comparison of results obtained for two-dimensional and four-dimensional Duffing oscillators.

Background

Consider a system of stochastic differential equations of the form

$$d\mathbf{x} = \mathbf{f}(\mathbf{x}, t)dt + \mathbf{g}(\mathbf{x}, t)d\mathbf{W}(t) \quad (1)$$

$$\mathbf{y} = \mathbf{h}(\mathbf{x}, t) + \mathbf{v}(t) \quad (2)$$

where $\mathbf{x}, \mathbf{f} \in \mathbb{R}^D$, $\mathbf{g} \in \mathbb{R}^{D \times D_s}$, and $\mathbf{w} \in \mathbb{R}^{D_s}$, subjected to zero mean Gaussian white noise that defines a Wiener process $d\mathbf{W}(t) = \sqrt{t}d\mathbf{w}$, $E[\mathbf{w}(t)] = 0$, $E[\mathbf{w}(t)\mathbf{w}^T(t + \tau)] = \mathbf{Q}\delta(\tau)$. Also, \mathbf{y} is a state measurement process, where $\mathbf{y}, \mathbf{h} \in \mathbb{R}^{D_o}$ and $\mathbf{v} \in \mathbb{R}^{D_o}$ is a nonzero mean Gaussian white noise, and $E[\mathbf{v}(t)] = 0$, $E[\mathbf{v}(t)\mathbf{v}^T(t + \tau)] = \mathbf{R}\delta(\tau)$. There exists a corresponding Fokker-Planck-Kolmogorov equation which defines the evolution in time of the transition probability density function of the system states, which takes the form

$$\frac{dp}{dt} = -\sum_{i=1}^D \frac{\partial}{\partial x_i} (D_i^{(1)} p) + \frac{1}{2} \sum_{i=1}^D \sum_{j=1}^D (D_{ij}^{(2)} p) \quad (3)$$

subject to

$$p(\mathbf{x}, 0 | \mathbf{x}_0) = \prod_{i=1}^D \delta(x_i - x_{i0}) \quad (4)$$

where $D_i^{(1)}$ and $D_{ij}^{(2)}$ are the deviate moments derived from eq. (1).

Results and Conclusions

For systems with simpler dynamics, the FPE-SPH, PF and EKF filters perform very similarly when properly parameterized. Differences emerge for systems such as the Duffing where the double-well potential of the PDF can result in rapid changes in an individual transient trajectory. In an estimation context sufficient process noise, measurement noise, and/or time between update steps can result in extreme EKF divergence. The PF and FPE-SPH filters on the other hand are robust against these sudden switches, which can be seen in the single run history below in Figure 1 and 25 run NEES in Figure 2.

Figure 1: Example 2D Duffing estimated state histories (position, velocity) demonstrating EKF divergence.

Figure 2: 2D Duffing NEES (25 Monte-Carlo runs, different initial conditions, common seeds between filters)

Robustness of the FPE-SPH filter extends up to four-state systems where one of the oscillators possesses a Duffing term. The system parameters simulated are not severe enough to result in EKF divergence as with the two state Duffing, but the results confirm that the FPE-SPH Filter is an accurate estimator in higher dimensional systems. The RMS error is shown in Figure 3.

Figure 3: RMS Errors for 4D Nonlinear System, separated by degree of freedom (10 runs)

The FPE-SPH filter can accomplish this with only 5,000 particles using conservative runtime acceleration parameters compared to the PF's 100,000. Improvements to the underlying algorithm to better handle higher dimensional behavior and more aggressive parameterization to further prioritize run time might allow for further scaling to tackle systems with more than four states. Please refer to the references for information about the algorithms employed.

Coupled nonlinear oscillators: closed form solutions

Stefano Lenci*

**Department of Civil and Building Engineering and Architecture, Polytechnic University of Marche, Ancona, Italy*

Summary. The mathematical solution of a system of two coupled Duffing oscillators is obtained in closed form by extending to this 2 DOF system a technique previously used for 1 DOF systems. A parametric investigation is proposed to illustrate the usefulness of the exact solution to detect the main dynamical phenomena, in particular those related to the modal coupling which is the main characteristic of this archetypal system.

Introduction

A two Degrees of Freedom (DOF) nonlinear oscillator is an archetypal system that allow to detect, in a simple way, the modal coupling in nonlinear mechanical systems. It permits focusing on the main phenomena, without unessential mathematical developments that sometimes hide the main physical characteristics of interest. Furthermore, it is obtained when a two-mode reduced order model of any, even infinite dimensional, system is considered. It is the natural evolution of the study of simple 1 DOF archetypal systems, like Duffing, Helmholtz, van der Pool, etc., that have been largely studied in the past.

Although it looks a simple model, it is not yet fully investigated, even if several studies have been devoted to modal coupling of different, specific, engineering systems. Furthermore, all previous works used numerical simulations or approximated analytical methods, notably the multiple time scale method.

In this work, which is based on [1] and take advantage from the ideas of [2-4], we consider an exact, closed form, solution for a system of two Duffing oscillators, linearly and nonlinearly coupled. This permits a full parametric investigation and detection of “all” dynamical outcomes due to coupling.

Governing equations and solution

A system of two Duffing linearly and nonlinearly coupled oscillators is governed by the equations

$$\begin{aligned} M_x \ddot{x} + D_x \dot{x} + K_x x + K_{3x} x^3 + D_{xy} (\dot{x} - \dot{y}) + K_{xy} (x - y) + K_{3xy} (x - y)^3 &= G_x(t), \\ M_y \ddot{y} + D_y \dot{y} + K_y y + K_{3y} y^3 + D_{xy} (\dot{y} - \dot{x}) + K_{xy} (y - x) + K_{3xy} (y - x)^3 &= G_y(t), \end{aligned} \quad (1)$$

where M_i are the masses, D_i the damping coefficients, K_i the linear stiffnesses, K_{3i} the nonlinear stiffnesses and $G_i(t)$ the external forces. To obtain the closed form solution, the excitations are assumed to be in the form

$$\begin{aligned} G_x(t) &= D_x \dot{x} + D_{xy} (\dot{x} - \dot{y}) + K_{xy} (x - y) + K_{3xy} (x - y)^3 - S_x x - S_{3x} x^3, \\ G_y(t) &= D_y \dot{y} + D_{xy} (\dot{y} - \dot{x}) + K_{xy} (y - x) + K_{3xy} (y - x)^3 - S_y y - S_{3y} y^3, \end{aligned} \quad (2)$$

where S_x, S_{3x}, S_y, S_{3y} are parameters that can be chosen freely. Inserting (2) in (1) yields

$$\ddot{x} + (\omega_x^2 + W_x)x + (k_x + C_x)x^3 = 0, \quad \ddot{y} + (\omega_y^2 + W_y)y + (k_y + C_y)y^3 = 0, \quad (3)$$

where

$$\omega_x^2 = \frac{K_x}{M_x}, \quad W_x = \frac{S_x}{M_x}, \quad k_x = \frac{K_{3x}}{M_x}, \quad C_x = \frac{S_{3x}}{M_x}, \quad \omega_y^2 = \frac{K_y}{M_y}, \quad W_y = \frac{S_y}{M_y}, \quad k_y = \frac{K_{3y}}{M_y}, \quad C_y = \frac{S_{3y}}{M_y}. \quad (4)$$

Equations (3) are two uncoupled Duffing equations, for which the closed form solutions are

$$x(t) = A_x \text{cn}(a_x t, b_x), \quad y(t) = A_y \text{cn}(a_y t, b_y), \quad (5)$$

where

$$\begin{aligned} a_x^2 &= (\omega_x^2 + W_x) + (k_x + C_x)A_x^2, \quad b_x^2 = \frac{(k_x + C_x)A_x^2}{2a_x^2}, \\ a_y^2 &= (\omega_y^2 + W_y) + (k_y + C_y)A_y^2, \quad b_y^2 = \frac{(k_y + C_y)A_y^2}{2a_y^2}. \end{aligned} \quad (6)$$

and where “cn” is the Jacobian elliptic function. $x(t)$ and $y(t)$ are periodic with period

$$T_x = \frac{4K(b_x)}{a_x}, \quad T_y = \frac{4K(b_y)}{a_y}. \quad (7)$$

The solutions of interest are those for which $T_x = T_y (= T)$, i.e. both $x(t)$ and $y(t)$ oscillate with the same period (but not with the same amplitudes A_x and A_y). Actually, this is an equation linking A_x and A_y (e.g. $A_y(A_x)$), once all the other parameters are known. Then, from (7) one gets the period of the excitation $T_x = T(A_x)$ and $T_y = T(A_y)$. Inverting these expressions one obtains the frequency response curves $A_x(T)$ and $A_y(T)$. Further details, including how to determine its stability, can be found in [1].

An advantage of the proposed method is that it is possible to use the free parameters S_x, S_{3x}, S_y, S_{3y} to shape the excitation and to have it as close as possible to a desired target, still keeping the closed form expressions for the nonlinear oscillations.

An example

To shortly illustrate the previous findings we consider

$$\begin{aligned} \omega_x = 2.5, \quad W_x = -4.5, \quad k_x = 2, \quad C_x = 0, \quad \omega_y = 2.5, \quad W_y = 0, \quad k_y = -1, \quad C_y = 0, \\ M_x = 1, \quad M_y = 2, \quad D_x = 0.01, \quad D_{xy} = 0.02, \quad D_y = 0.03, \quad K_{xy} = 0.5, \quad K_{3xy} = 0.4, \end{aligned} \quad (8)$$

which corresponds to the perfect internal resonance ($\omega_x = \omega_y$) with the x mode hardening and the y mode softening. The solution of $T_x = T_y$ is reported in Fig. 1. For $A_x = 1$ one obtains $A_y = 1.9731$ and $T = 3.5009$. The corresponding excitations $G_x(t)$ and $G_y(t)$ and solutions $x(t)$ and $y(t)$ are illustrated in Fig. 2. In Fig. 3 it is shown how choosing $W_x = -4.47979443$, $C_x = 0.036619325$, $W_y = 0.14970754$, $C_y = 0.024427757$ allows to strongly reduce $G_y(t)$, by leaving practically unchanged $G_x(t)$. This is an example of shaping the excitation, which can be improved by using optimization algorithms. Much more results, including frequency response curves, are reported in [1].

Figure 1: The solution $A_y(A_x)$ for the parameter (8).

Figure 2: a) $G_x(t)$ (black) and $G_y(t)$ (red); b) $x(t)$ (black) and $y(t)$ (red). $A_x = 1$ and parameters (8).

Figure 3: As Fig. 2, but with $W_x = -4.47979443$, $C_x = 0.036619325$, $W_y = 0.14970754$, $C_y = 0.024427757$.

Phase - locked breathers in the damped driven granular chains

Margarita Kovaleva*, Yuli Starosvetsky**

*N.N. Semenov Federal Center for Chemical Physics, Russian Academy of Sciences, Moscow, Russia

**Faculty of Mechanical Engineering,
Technion Israel Institute of Technology, Haifa, Israel

Summary. Over the past few decades, dynamics of one-dimensional (1D) granular lattices has become a subject of immense theoretical and experimental research. In the present talk we will discuss the fundamental problem of nonlinear wave propagation in the damped-driven, granular lattice mounted on a linear elastic foundation which assumes the general type of strongly nonlinear, inter-site potential and subject to an external harmonic forcing in the form of a traveling wave. In the present work we will focus on the analysis of moving breather solution forming in the damped-driven chain.

Introduction

Of late, a special type of localized excitations forming in granular medium has become a subject of immense theoretical and experimental research. This special type of solutions is manifested by a spatial energy localization and time periodicity which are usually referred to in the literature as intrinsically localized modes (ILM) or Discrete Breathers (DB). To the best of authors knowledge the first theoretical study of the dynamics of localized modes in compressed granular chains has been reported in [1]. In fact as it was shown in this study, these localized modes are formed due to the presence of the mass defects. The first experimental study of the formation of long-lived, DB solutions in granular medium has been performed on the compressed, di-atomic granular crystal [2]. This groundbreaking experimental study of DBs has been followed by a systematic theoretical analysis of existence and stability of these spatially localized solutions [3]. All the DB solutions reported in [2-3] correspond to the bright breather solutions emerging in the di-atomic, essentially compressed granular chains. Additional theoretical and experimental study of compressed, mono-atomic granular crystal [4], have demonstrated the existence of dark breather solutions in these chains. These special nonlinear waves have also been reported in theoretical and experimental study of the damped, driven, compressed granular crystals [5]. In fact all the DB solutions existing in granular configurations reported in [2-5] have been considered solely for the pre-compressed state of granular medium. Therefore, when considering the uncompressed state of granular chains, one may wonder whether these spatially localized and time periodic nonlinear wave solutions exist. As a matter of fact, existence of discrete breathers in the un-loaded granular crystals, has been reported at first for one-dimensional, uncompressed granular chain subject to a linear on-site potential and an inter-particle Hertzian interaction [6]. In the same study, formation of static and traveling DBs has been demonstrated numerically. Passing to a small amplitude limit, authors derived the reduced model which has been coined a name of discrete p-Schrodinger (DpS) equation. This model can be regarded as a slow flow model, which approximates the slow (amplitude and phase) modulation of the low amplitude regimes of the original granular setup.

Model

Present study has been motivated by the earlier work by James et al. [8] who derived the analytical approximation for the moving breather supported by the DpS chain. In the present work we consider the DpS chain, subject to the external forcing and dry friction. As it has been shown by James the slow modulation of low amplitude oscillatory solutions can be efficiently described by the discrete p-Schrodinger equation which can be derived through the common multi-scale procedure [6-7]. Following same idea we consider p-Schrodinger equation with forcing and dry friction terms:

$$\frac{d\varphi_k}{dt_1} = \frac{i\sigma}{2}\varphi_k - \lambda \frac{\varphi_k}{|\varphi_k|} + \frac{iF}{2}e^{ik\gamma} + i\mu(\varphi_k - \varphi_{k-1})|\varphi_k - \varphi_{k-1}|^m + i\mu(\varphi_k - \varphi_{k+1})|\varphi_k - \varphi_{k+1}|^m \quad (1)$$

Asymptotic expansion

Assuming the following asymptotic scaling of forcing, damping and the power of non-linearity,

$$m = \nu^2, \quad F = \tilde{F}\nu^2, \quad \lambda = \tilde{\lambda}\nu^2, \quad \varphi_n = (-1)^n \rho_n e^{i\gamma n} \quad (2)$$

we proceed with the multiple-scale expansion,

$$\rho_n = \phi(\xi, \tau), \quad \xi = \nu(n - c_q \tau_1), \quad \tau = \nu^2 \tau_1. \quad (3)$$

Log – NLS equation

Proceeding to the multiple-scale technique we end up with the damped-driven Log – NLS equation

$$\phi_\tau = -\lambda \frac{\phi}{|\phi|} + \frac{iF}{2} + \frac{3i\beta \cos \gamma}{8} \phi_{\xi\xi} + \frac{3i\beta \Omega^2}{8} \phi \ln |\Omega \phi|, \quad \Omega = \sqrt{(2 + 2 \cos \gamma)} \quad (4)$$

Seeking for the stationary (in terms of the super-slow time scale) traveling soliton solution we obtain the following second order ODE.

$$\phi_{\xi\xi} + \frac{8i\lambda}{3\beta \cos \gamma} \frac{\phi}{|\phi|} + \frac{8F}{6\beta \cos \gamma} + \frac{\Omega^2}{\cos \gamma} \phi \ln |\Omega \phi| = 0 \quad (5)$$

Assuming the phase-locked solution (strictly locked phase $\phi = R(\xi)e^{i\vartheta}$, $R, \vartheta \in \mathbb{R}$, $\vartheta - \text{const}$) the complex ODE equation is split into the real and imaginary part:

$$R_{\xi\xi} = -\frac{8F}{6\beta \cos \gamma} \cos(\vartheta) - \frac{\Omega^2}{\cos \gamma} R \ln |\Omega R|; \quad (6a)$$

$$-\frac{8\lambda}{3\beta \cos \gamma} + \frac{4F}{3\beta \cos \gamma} \sin \vartheta = 0. \quad (6b)$$

The real part is the second order ODE which depicts the evolution of the amplitude, while the second imaginary part is an algebraic equation which defines the stationary phase of the breather solution:

$$\sin \vartheta = \frac{2\lambda}{F}; \cos \vartheta = \pm \sqrt{1 - \left(\frac{2\lambda}{F}\right)^2} \quad (7)$$

It can be easily inferred from the imaginary part we have two solutions which emerge through the typical saddle – node bifurcation. To illustrate better the dynamics of two distinct breather solutions on both branches we illustrate the following phase portraits.

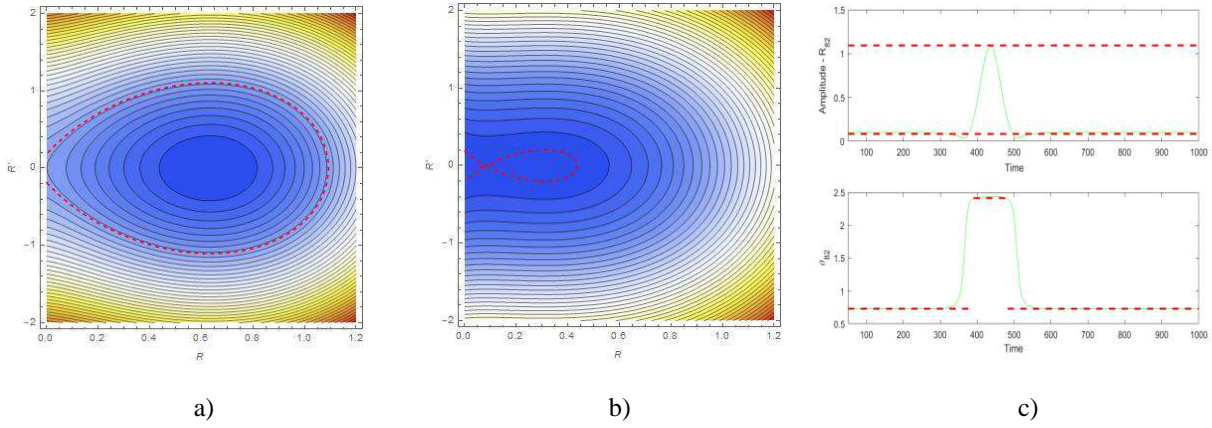

Figure 1: Phase planes of the two branches of the equation (a) First branch (b) Second branch (c) Time histories of the response of the DpS chain (Amplitude – upper panel, phase – lower panel), red-dashed lines stand for the phase locked approximation

Clearly the homoclinic orbit of the phase plane shown in the right panel corresponds to the phase locked solitons solution. However, this solution could not be reproduced in the extensive numerical simulations. We conjecture that this solution is unstable. Interestingly enough there exists an additional, phase locked, soliton solution which can be approximated using both phase planes. This solution emanates from the saddle of the right phase plane (Figure 1b) (to the left of the saddle) and continues along the unstable manifold of the saddle up to the point of zero amplitude. When reaching this point there is a jump to the second branch which means that the solution changes phase. Further evolution of the trajectory on the second branch is denoted with the red, dashed line on the left phase plane (Figure 1a). When it reaches again the point of zero amplitude there is a subsequent jump to the first branch and then it gradually converges to a saddle of the first branch along the stable manifold. Here we would like to emphasize that the proposed solution is just an approximation as there is no immediate jump in the phase for the true system solution. This can be clearly seen from the results of Figure 2 where the jump from the vicinity of one phase to the second one, occurs in the fast time scale. Using our analytical model and in particular the analysis of the phase planes, we predict the amplitude, the background and the speed of the traveling soliton. As for the phase of this solution we can clearly see the fast evolution of the phase in the true DpS from one state (first branch) to another (second branch). Obviously enough this transient evolution of the phase from one state to another cannot be captured by our phase locked approximation.

Conclusions

New family of traveling solitons in the forced-damped DpS chain has been observed. The original approach of the analysis of the breathers in the conservative system developed by James [8], allowed us to predict the possibility of formation of phase locked DB in the damped-driven DpS. These solutions can be depicted on the phase plane in the Log-NLS limit.

Summary. The nonlinear dynamics of a thin circular cylindrical shell subjected to thermal gradients and random excitation is experimentally investigated. The combination of broadband random loading and thermal conditions both at different homogenous temperature and with thermal gradients across the shell thickness. The phenomenon of synchronization is observed at particular thermal and loading conditions: a severe transfer of energy from a broadband excitation to an almost subharmonic out of band response is experimentally observed.

Introduction

In several applications like aerospace automotive and civil engineering the role of thin-walled structures have a key function, for example, bodywork panels, fuselage or aircraft and satellite panels together with storage tower.

A crucial factor in thin walled structures is the performance under random forcing whose dynamics, characterized by strong nonlinearity can give rise to unexpected complex phenomena that cannot be predicted by the traditional engineering tools and theories.

It is well known that chain of non-linear oscillators under intense periodic forcing could exhibit a "mode-locking" phenomenon that synchronizes the exciting load with the response. A similar phenomenon, which is much less investigated, can happen when a nonlinear system is excited with a broadband random forcing [1], for example when internal resonances are present; in such cases it has been proven the possibility of entrainment of regular harmonic responses by the system. This phenomenon is said "synchronization" of non-linear oscillators subjected to random forcing [2,7], it has been partly investigated proving the unusual phenomenon of conveying the random spectral energy to specific frequencies, determining remarkable vibration amplitudes.

In recent research published on Ref. [4, 5] it is proved that the effect of temperature greatly influences the instability regions and the vibration levels, moreover, it was pointed out that high environmental temperature leads to a more complex dynamics.

In the present work an experimental investigation of the synchronization phenomenon is carried out. A circular cylindrical shell made of polymeric material is considered; the shell is mounted on a shaking table, the shell axis is vertical, the bottom is clamped to the table, the top is closed with a rigid disk. The shaking table provides a base motion in the direction of the shell axis. The temperature is controlled inside and outside the shell. Several random excitation level and types are considered (different frequency bands) as well as several internal and internal temperatures.

Experimental setup and results

The experimental test consists of a specimen mounted on an electrodynamic shaker coupled with a climate chamber and monitored by accelerometers, laser vibrometer and a telemeter. The specimen is a thin cylindrical shell made of Polyethylene terephthalate (P.E.T.), a thermoplastic polymer, a top mass, made of aluminum alloy, is glued with special epoxy glue, resistant to high temperature, on the top of the specimen. The bottom of the shell is clamped to the fixture through a shaft collar that guarantees a uniform connection to the vibration table adapter (VTA), i.e. a clamped-clamped boundary condition is guaranteed on the bottom and the top.

Figure 1 shows the experimental setup including the control system, the shaker and the climate chamber. Inside the shell, a cartridge heater is mounted and is used to adjust the temperature inside the shell and to obtain the desired thermal gradient across the shell wall, see Figure 2; a mirror periscope has been used to allow the laser beam measuring the lateral vibration of the shell. An accelerometer located on the base of fixture, for control purposes, three triaxial accelerometers are located equally spaced on the top disk.

A random controlled broadband base excitation is applied at the base through the electrodynamic shaker. Each test is carried out at different bandwidth and different overall RMS.

The forcing is a band limited random (900-1500 Hz), see figure 3, with a 28°C thermal gradient from 48°C in the inner surface and 20°C in the outer surface, the Power Spectral Density is shown. In figure 3a the pink box identifies the electrical flat spectrum of the random signal provided to the shaker and controlled by the electronic controller, no out of band electric power is provided out of band. On the base the spectral energy is uniform in the band (900-1500 Hz) which is controlled; there is an energy transfer to superharmonics, where evident spikes are present; such spikes are due to the shaker-shell nonlinear interaction; therefore, the base motion contains a strong deterministic component (harmonic). On the top disk a clear deterministic (subharmonic) response takes place in correspondence of the first axisymmetric mode of the shell (467Hz) and, similarly to the base spectrum, high frequency out of band spikes are present.

The novelty of the present paper consists in the experimental evidence of the synchronization phenomenon: when the nonlinear system is excited with random forcing a strong transfer of energy to specific harmonics can take place. It is worthwhile to point out that the phenomenon appears only for certain environmental and forcing conditions.

Summary. This study investigates the intermodal targeted energy transfer (IMTET) concept for passive mitigation of a model of large-scale twenty-story steel structure subjected to seismic excitation. This is achieved by introducing strategically placed, local strong nonlinearities, in the form of vibro-impacts of the floors of the building with a relatively light, yet stiff, auxiliary core structure. These impacts rapidly, robustly and irreversibly redistribute the input seismic energy within the modal space of the structure through extremely rapid IMTET from low-to-high frequency structural modes, yielding drastically enhanced mitigation of unprecedented effectiveness, right from the very first cycle of the structural response. Moreover, when optimized, this new concept can be realized fully passively, without the need to adding any mass to the building, and with minimal increase in the resulting floor accelerations and local stresses. Therefore, the IMTET methodology for seismic mitigation has the potential to be truly transformative in the field of hazard mitigation of civil infrastructure.

Introduction

The dynamical responses of structures subjected to extreme loads (such as blast, earthquakes, shock) poses a significant challenge and has attracted great interest among researchers and engineers [1]. One of most important issues here is rather limited suppression achieved for the first few (but most intensive and dangerous) cycles of the structural response to the excitation. Consequently, many new and innovative structural protection fully passive concepts have been proposed, developed, and even implemented, being classified as linear, and nonlinear passive mitigation strategies [1, 2]. Specifically, load mitigation based on irreversible (directed) passive nonlinear vibration energy transfers, known as targeted energy transfers (TETs) has been widely explored for passive vibration control and energy harvesting purposes. This approach is based on transferring energy from a directly excited primary structure to a set of secondary strongly nonlinear structures (referred to as nonlinear energy sinks – NESs), where it is localized and locally dissipated without scattering back to the primary structure [2]. The dynamical mechanisms governing such TET mechanism are isolated or multiple (i.e., cascades of) transient resonance captures. However, such resonant energy transfers to the NESs are achieved through relatively slow modulations of the structural modal amplitudes, which, for some applications involving extreme loads, e.g., blast or seismic excitations, prove not to be fast enough.

Recent studies [3, 4], however, has shown that nonlinear resonance is not the only fundamental mechanism for achieving TET, since it can also be realized through a non-resonant fast scale mechanism involving non-smooth effects. This has been employed to explore the concept of intermodal targeted energy transfer (IMTET) to mitigate the effect of blast loading on a nine-story steel structure [4]. In this study, we explore the implementation of the IMTET strategy for seismic passive protection of tall buildings (in particular, twenty-story) subject to strong earthquakes.

Model description

The primary structure considered here is the benchmark 20-story steel building designed by Brandow & Johnston Associates for the SAC Phase II Steel Project, and its geometrical and physical properties are given in details in [5]. To achieve seismic mitigation using the IMTET concept, a flexible internal core structure is introduced, with distributed clearances with respect to the floors of the primary twenty-story building, as shown in Figure 1.

Figure 1: Seismically excited 20-story primary building with internal flexible core structure: Schematic of (a) the integrated building-core, and (b) the flexible core structure

Denoting by \mathbf{M} , \mathbf{K} , \mathbf{C} , and \mathbf{M}_{cs} , \mathbf{K}_{cs} and \mathbf{C}_{cs} , the mass, stiffness and damping matrices of the primary building and the core structure, respectively, the equations of motion are given by:

$$\begin{aligned} \mathbf{M}\ddot{\mathbf{u}} + \mathbf{C}\dot{\mathbf{u}} + \mathbf{K}\mathbf{u} - \mathbf{f}^{NL}(\dot{\mathbf{u}}, \mathbf{u}, \dot{\mathbf{v}}, \mathbf{v}, \Delta) &= -\mathbf{M}\mathbf{\Gamma}\ddot{u}_g \\ \mathbf{M}_{cs}\ddot{\mathbf{v}} + \mathbf{C}_{cs}\dot{\mathbf{v}} + \mathbf{K}_{cs}\mathbf{v} + \mathbf{f}^{NL}(\dot{\mathbf{u}}, \mathbf{u}, \dot{\mathbf{v}}, \mathbf{v}, \Delta) &= -\mathbf{M}_{cs}\mathbf{\Gamma}\ddot{u}_g \end{aligned} \quad (1)$$

where \ddot{u}_g is ground acceleration, \mathbf{u} and \mathbf{v} the displacement vectors of the building floors and core contact points, respectively, $\mathbf{\Gamma}$ the influence vector for base motion, and Δ the vector of clearance gaps. Uniaxial seismic excitation is assumed, along the weak direction of the primary building (Figure 1(a)). The vector $\mathbf{f}^{NL}(\dot{\mathbf{u}}, \mathbf{u}, \dot{\mathbf{v}}, \mathbf{v}, \Delta)$ contains the inelastic Hertzian contact interactions, and its j th element is given by:

$$f_j^{NL}(\dot{\mathbf{u}}, \mathbf{u}, \dot{\mathbf{v}}, \mathbf{v}, \Delta) = k_c \left[[v_j - u_j - \Delta_j]_+^{\frac{3}{2}} - [u_j - v_j - \Delta_j]_+^{\frac{3}{2}} \right] \left(1 + \frac{3(1-r)}{2(\dot{u}_j^- - \dot{v}_j^-)} (\dot{u}_j - \dot{v}_j) \right) \quad (2)$$

where $k_c = \frac{2E\sqrt{R}}{3(1-\nu^2)}$ is a stiffness coefficient (Hunt and Crossley, 1975), assuming that the impact is between a semi-sphere of radius R on the core structure and a contact point on a flat plane on the primary building, with the contacting bodies having the same Young's modulus E and Poisson's ratio ν . Also, \dot{u}_j^- and \dot{v}_j^- are the contact velocities of the j th floor just before the impact, and r is a restitution coefficient. The subscript (+) indicates that only non-negative values of the arguments in the brackets should be taken into account, with zero values being assigned otherwise.

Preliminary results

The computational results provide a preliminary demonstration of the effectiveness of IMTET for rapid seismic mitigation of the primary building response subjected to Kobe (1995) ground motion. Figure 2(left) shows an extremely rapid attenuation of the overall structural response, compared to the linear case of no core (i.e., infinite gaps). The governing nonlinear mechanism responsible for the drastic enhancement in seismic mitigation is shown in Figure 2(right), where the percentage of input seismic energy eventually dissipated by the inherent (modal) dissipation of each of the ten leading structural modes of the primary building (with no core) is depicted. Indeed, compared to the linear case of no core – where the energy dissipation is dominated by the fundamental structural mode in the case of optimized clearance gaps the seven leading modes participate in energy dissipation. Hence, there is a noteworthy, rapid, and irreversible nonlinear targeted energy transfer (or IMTET) from the low structural modes to the higher ones, causing rapid reduction of the structural response.

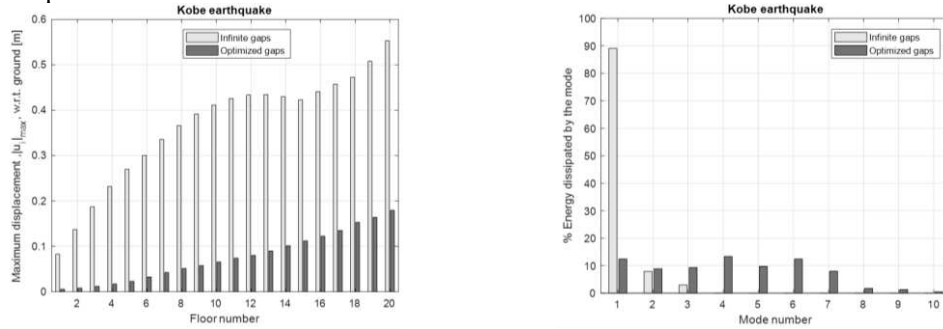

Figure 2: Primary building with optimized core and no core subject to the Kobe earthquake: Maximum floor displacement (left); Input seismic energy (%) dissipated by the inherent damping of the leading modes of the primary building (right)

Conclusions

In this work, a radically new concept for seismic mitigation of civil infrastructure is discussed, based on extremely rapid nonlinear scattering of seismic energy from low-to-high frequency modes of a building through strong local nonlinearities, which is referred to as intermodal targeted energy transfer (IMTET). The results show that the overall level of system vibration is reduced not by adding extra dissipative elements but rather by redistributing energy from lower to higher frequencies where the vibration amplitudes decrease. Moreover, the dissipative capacity of the system itself is radically enhanced since a much larger set of vibration modes (especially high-frequency ones) participate in the response, which can greatly enhance the rate of energy dissipation. Hence, IMTET provides a new approach to passive energy management.

Non-linear dynamic stability of mono-symmetric thin walled beams under random excitation

Sajad Haji Tayebi*

*Department of Civil Engineering, Imam Khomeinie International University, Qazvin, Iran

Summary. The focus of my presentation is to study the non-linear dynamic stability of a viscoelastic thin walled beam with cross section having one axis of symmetry and subjected to a dynamical axial compressive load $P(t)$ (generally eccentric). The equations of motion is derived and the method of stochastic averaging is used to decoupled the governing equations into Itô equations. For small damping and weak stochastic fluctuation, the expressions are derived for the moment Lyapunov exponent.

Introduction

Thin walled beams are widely used in construction, aircraft, ship building, etc. Also, with the increasing use of materials, there exists the need for analyzing viscoelastic structures under dynamic loading. Therefore, there are lots of works in both deterministic and stochastic domains. The general theory of thin walled beams was investigated by Vlasov [1] and the dynamic instability of elastic system was explained by Bolotin [2]. Stratonovich formulated the method of stochastic averaging [3] and it mathematically proved by Khasminskii [4]. There are the overwhelming number of papers in the literature. The modern theory of stochastic dynamic stability is founded on Lyapunov exponents and moment Lyapunov exponents [5]. Also for distinguishing among the different cases of resonances, the method of multiple scales is used.

Formulation

The flexural-torsional vibration of a thin walled beam with mono-symmetric I-section is presented in Fig.1. In the present article, the boundary condition is considered as both ends simply supported.

Figure 1

The equations of motion is defined as [1]. In these equations, we can see inertia components Δq , ΔM , ΔN which are nonlinearly related to the principal displacements u and ϕ . By locating a mass on the movable end [2] and adding the viscous damping and also replacing the elastic modulus by the Volterra operators $E(1-H)$ [5], the governing partial differential equations become:

$$\begin{aligned}
 & E(1-H) J_y \left(\frac{\partial^4}{\partial z^4} u(z, t) \right) + P(t) \left(\frac{\partial^2}{\partial z^2} u(z, t) \right) + P(t) (a_y - e_y) \left(\frac{\partial^2}{\partial z^2} \phi(z, t) \right) + m \left(\frac{\partial^2}{\partial t^2} u(z, t) \right) \\
 & + D_u \left(\frac{\partial}{\partial t} u(z, t) \right) + m a_y \left(\frac{\partial^2}{\partial t^2} \phi(z, t) \right) \\
 & + \left(\frac{\partial^2}{\partial z^2} \Delta M(z, t) \right) \phi(z, t) + 2 \left(\frac{\partial}{\partial z} \Delta M(z, t) \right) \left(\frac{\partial}{\partial z} \phi(z, t) \right) + \Delta M(z, t) \left(\frac{\partial^2}{\partial z^2} \phi(z, t) \right) + \left(\frac{\partial}{\partial z} \Delta N(z, t) \right) \\
 & \left(\frac{\partial}{\partial z} u(z, t) + a_y \left(\frac{\partial}{\partial z} \phi(z, t) \right) \right) \\
 & + \Delta N(z, t) \left(\frac{\partial^2}{\partial z^2} u(z, t) + a_y \left(\frac{\partial^2}{\partial z^2} \phi(z, t) \right) \right) = 0
 \end{aligned}
 \tag{1}$$

$$\begin{aligned}
 & P(t) (a_y - e_y) \left(\frac{\partial^2}{\partial z^2} u(z, t) \right) + E (1 - H) J_\omega \left(\frac{\partial^4}{\partial z^4} \phi(z, t) \right) \left[P(t) (r^2 + 2 \beta_y e_y) - T (1 - H) J_d \right] \left(\frac{\partial^2}{\partial z^2} \phi(z, t) \right) \\
 & + m r^2 \left(\frac{\partial^2}{\partial r^2} \phi(z, t) \right) + m a_y \left(\frac{\partial^2}{\partial r^2} u(z, t) \right) + D_\phi \left(\frac{\partial}{\partial t} \phi(z, t) \right) \\
 & + \left(\frac{\partial}{\partial z} \Delta N(z, t) \right) \left[r^2 \left(\frac{\partial}{\partial z} \phi(z, t) \right) + a_y \left(\frac{\partial}{\partial z} u(z, t) \right) \right] + \Delta N(z, t) \left[r^2 \left(\frac{\partial^2}{\partial z^2} \phi(z, t) \right) + a_y \left(\frac{\partial^2}{\partial z^2} u(z, t) \right) \right] \\
 & + \Delta M(z, t) \left(\frac{\partial^2}{\partial z^2} u(z, t) \right) - 2 \beta_y \left(\left(\frac{\partial}{\partial z} \Delta M(z, t) \right) \left(\frac{\partial}{\partial z} \phi(z, t) \right) + \Delta M(z, t) \left(\frac{\partial^2}{\partial z^2} \phi(z, t) \right) \right) \\
 & - \Delta q(z, t) a_y \phi(z, t) = 0
 \end{aligned}
 \tag{2}$$

With the aid of the Galerkin method, (1) and (2) can be converted into two ordinary differential equations. To show that damping, viscoelasticity and excitation are small, a parameter $0 < \varepsilon \ll 1$ is introduced. The axial thrust $P(t)$ is assumed to be a stationary stochastic process.

Stochastic averaging

To apply the averaging method, one should consider first the unperturbed system which can be solved by the method of operators. The solutions are:

$$u_1 = a_1 \cos(\omega_1 t + \phi_1) + a_2 \cos(\omega_2 t + \phi_2), \quad u_2 = \alpha_1 a_1 \cos(\omega_1 t + \phi_1) + \alpha_2 a_2 \cos(\omega_2 t + \phi_2)
 \tag{3}$$

The method of variation of parameters is applied to determine the solutions of the perturbed system. Here, in the present article, because of the nonlinearities, there is a difference in the applying of this method with the other papers.

By averaging the responses over one period, we can expect to obtain accurate results. This may be done by applying the method of stochastic averaging. Through the method of stochastic averaging, the system can be approximated by Itô stochastic differential equations.

Moment Lyapunov exponents

To have a complete picture of dynamic stability, it is important to investigate both the moment and almost-sure stability which is the topic of the present work.

However, the stability of the p th moment of the solution of system is governed by the p th moment Lyapunov exponent defined by:

$$\Lambda(p) = \lim_{t \rightarrow \infty} \frac{1}{t} \log E[\|u\|^p]
 \tag{4}$$

If the Λ is negative, the p th moment is asymptotically stable; otherwise, it is unstable [5]. One can obtain the largest Lyapunov exponent (5) through its relation with moment Lyapunov exponents (6).

$$\lambda = \lim_{t \rightarrow \infty} \frac{1}{t} \log \|u\|
 \tag{5}$$

$$\lambda_{\max} = \Lambda'(0) = \lim_{p \rightarrow 0} \frac{\Lambda(p)}{p}
 \tag{6}$$

In this article, I use the moment Lyapunov exponents for analyzing the dynamic stability of system.

Summary. In this work an efficient tool is presented to numerically solve stochastic delay differential equations by transforming them to stochastic differential equations. This approach allows the use of methods originally implemented for stochastic differential equations, while algorithms specialized to delay problems can be also included. The convergence and stability of the numerous solver methods are investigated through Monte-Carlo simulations for different case studies.

Introduction

In scientific computing to analyze the behavior of dynamical systems a widely used approach is to numerically integrate the corresponding differential equation (DE). For a large number of problem classes (e.g., ordinary DEs (ODEs), delay DEs (DDEs), stochastic ODEs (SODEs or SDEs)), there is a wide range of official integrator solutions to choose from, both open-source and commercial [8]. However, for stochastic delay DEs (SDDEs) there exists no such solver, despite that there are algorithms already introduced since the late 90's [1, 5, 3] along with proof of convergence for SDDEs with point delays.

The goal of this work is to introduce a feature rich and “easy-to-use” open source tool to solve stochastic delay differential equations. These features include but are not limited to parallelized Monte-Carlo calculations, use of arbitrary precision numbers or the automatic differentiation of the solution w.r.t. to the parameters of the SDDE. This solver is available as a Julia package under the name of StochasticDelayDiffEq.jl and is part of the DifferentialEquations.jl [7] ecosystem.

Stochastic Delay Differential Equations as SODEs

Consider the Itô stochastic delay differential equation (SDDE)

$$dx(t) = f(x(t), x_t, t)dt + g(x(t), x_t, t)dW(t), \quad x(\theta) = \varphi(\theta), \quad -\tau \leq \theta \leq 0, \quad (1)$$

where $f, g : \mathbb{R}^d \times C([- \tau, 0], \mathbb{R}^d) \times \mathbb{R} \rightarrow \mathbb{R}^d$ are smooth functions, $x_t(\theta) = x(t + \theta) \in \mathbb{R}^d, \theta \in [- \tau, 0]$ defines the state at time t (segment of the solution), $W(t)$ is an \mathcal{F}_t -measureable standard Wiener process and the initial state $\varphi : [- \tau, 0] \rightarrow \mathbb{R}^d$ is sufficiently nice and \mathcal{F}_0 measureable. Note that the present state $x(t)$ is separated from the solution segment x_t and this study is restricted to systems with J number of point delays, namely $0 < \tau_1 < \tau_2 < \dots < \tau_J := \tau$, since distributed delays can be approximated as point delays using e.g. shifted Dirac delta distributions [4] or via Clenshaw-Curtis quadrature [9].

Since all values of the interval x_t are available at time t , the SDDE (1) can be rewritten as a SODE:

$$dx(t) = \hat{f}(x(t), t)dt + \hat{g}(x(t), t)dW(t). \quad (2)$$

The transformation is performed by dynamically embedding the initial φ and current x_t states into the functions \hat{f} and \hat{g} as a time dependent inhomogeneity, namely

$$\hat{f}(x(t), t) = f(x(t), \phi_t, t), \quad \hat{g}(x(t), t) = g(x(t), \phi_t, t), \quad (3)$$

where

$$\phi_t(\theta) = \begin{cases} \varphi(t + \theta) & t + \theta \leq 0 \\ x(t + \theta) & t + \theta > 0 \end{cases}. \quad (4)$$

This representation is similar to the method of steps [2], however it allows uninterrupted integration (with discontinuity handling) and the utilization of the solver algorithms and features of the already existing SODE ecosystem from StochasticDiffEq.jl [6].

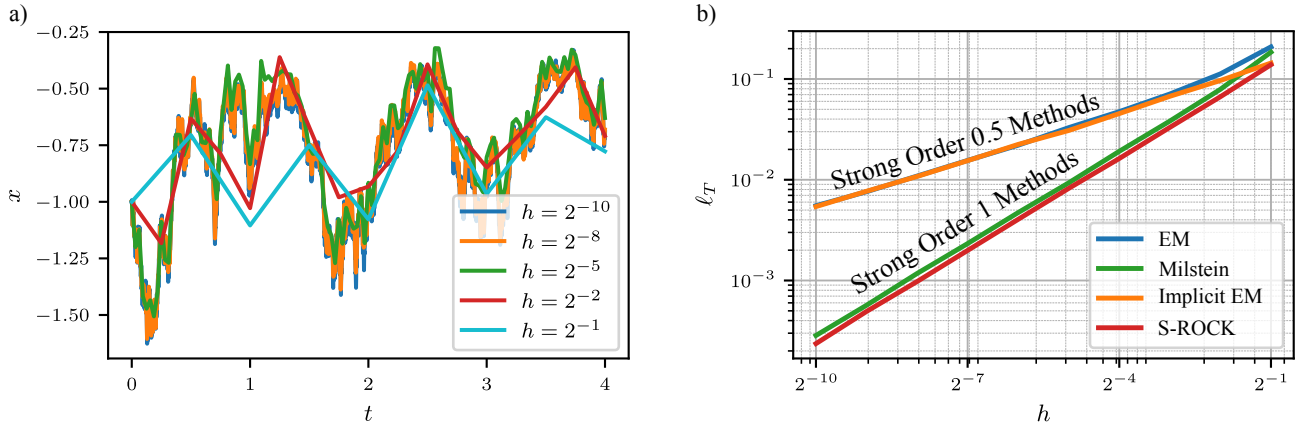

Figure 1: Demonstration of the convergence of multiple methods for $f(x(t), x(t-1), t) = x(t) - \sin(x(t-1))$, $g(x(t), x(t-1), t) = \sin(x(t))$ and $\varphi(t) = t - 1$. The sample trajectories in a) are calculated with the Euler-Maruyama method using multiple time resolutions h , and with delay $\tau = 1$, while the trajectories are integrated up to time $T = 4$. For the convergence plots in b) the ℓ_T measure is used, defined in Eq. (7).

Convergence tests

As an example, if the general SDDE (1) has a single point delay it can be rewritten in the form

$$dx(t) = f(x(t), x(t-\tau), t)dt + g(x(t), x(t-\tau), t)dW(t). \quad (5)$$

If the Euler-Maruyama method is chosen from the package as the integrator algorithm with time step $h = \tau/N_h$, where $N_h \in \mathbb{N}^+$, the approximation of the value $x_{n+1} \approx x(t_{n+1} = (n+1)h)$ inherently reduces to:

$$x_{n+1} = x_n + f(x_n, x_{n-N_h}, t_n)h + g(x_n, x_{n-N_h}, t_n)\xi_n\sqrt{h}, \quad \xi_n \sim \mathcal{N}(0, 1), \quad (6)$$

which is shown to be convergent to the solution of (5) in [1]. The presented solver package can help to show the strong and weak convergence of other methods from the *StochasticDiffEq.jl* as well as newly created methods for SDDEs. Some examples are shown in Fig. 1, where numerical Monte-Carlo experiments were used to approximate the convergence of the solution at the final time point T by studying

$$\ell_T(h) = \mathbb{E}(\|x^h(T) - x^{h_{\text{ref}}}(T)\|_2), \quad (7)$$

where x^h is the solution of the SDDE (1) approximated with time resolution h and $h_{\text{ref}} = 2^{-15}$ is the reference time resolution.

Summary. The stability properties of the single track vehicle model with proportional, delayed feedback control are investigated in the presence of measurement noise. The moment stability and the stationary behavior of the resulting stochastic system is analyzed using the stochastic semi-discretization method and numerical simulations are conducted to verify the results.

Introduction

The stabilization of path following is a fundamental element of numerous autonomous driving functions from lane keeping to self-driving. The focus of this work is to investigate the effects of measurement noise in the feedback loop of a path following controller with time delay, leading to a system of stochastic delay differential equations (SDDE's).

A number of important results have been developed over the years for the analysis of such systems. The moment stability of the solution in the linear case was presented in [1]. In [2], an approximate Fokker-Planck equation was introduced for the stationary solutions of nonlinear SDDE's with small delays. The stability of linear control systems with time delay was investigated in [3] using the Lyapunov exponent approach. The Taylor expansion of the control force was used in [4] and [5] to investigate the control of stochastic time delay systems in the linear and the non-linear case, respectively.

In this paper, the stochastic semi-discretization method [6] is used in order to determine the second moment of the stationary solution of a path following controller with time delay and measurement noise. Due to the so-called autonomous stochastic resonance phenomenon, the effects of the noise excitation may be amplified close to the stability boundaries, leading to an exceedingly large variance of the system response even if the control gains are selected from the stable parameter domain. The stochastic semi-discretization method generates a mapping of the discretized second moment, which can be used to assess the stability properties and the steady state solution of the second moment dynamics. As a result, specific regions of the control gains can be established within the stable domains that correspond to a given maximum allowable variance of the solution.

The rest of the paper is organized as follows: the mathematical model of the closed-loop system is introduced first. The second moment of the stationary solution is analyzed along the stable domain of control parameters with the help of the stochastic semi-discretization method and the results are verified by numerical simulations of the linear system. Next, the effects of a cutoff frequency in the measurement noise are investigated, then numerical simulations are also performed on the non-linear system by applying filtered white noise.

Figure 1: The single track vehicle model

Vehicle model

The mechanical model of our analysis is based on the single track vehicle model (see Fig. 1) with linear tire characteristics, according to [7]. Linearizing the system around the rectilinear motion along the x axis leads to the linear system $\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{B}\delta_s(t)$, where the state vector $\mathbf{x} = [y \ \psi \ \sigma_1 \ \sigma_2]^T$ includes the lateral position, yaw angle, lateral velocity

Table 1: Parameter values used for stability maps and simulations

f (m)	d (m)	m (kg)	J_z (kgm ²)	C_F (N/rad)	C_R (N/rad)	V (m/s)	τ (s)	σ_y (m)	σ_ψ (rad)
2.7	1.35	1430	2500	45000	45000	20	0.5	0.1	0.005

and yaw rate of the vehicle, respectively. The steering angle is denoted by δ_s , while the system and input matrices are

$$\mathbf{A} = \begin{bmatrix} 0 & V & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & A_{33} & A_{34} \\ 0 & 0 & A_{43} & A_{44} \end{bmatrix} \quad \text{and} \quad \mathbf{B} = \begin{bmatrix} 0 \\ 0 \\ B_3 \\ B_4 \end{bmatrix} \quad (1)$$

with the elements

$$\begin{aligned} A_{33} &= -\frac{B_3}{V} - \frac{C_R(J_z + md^2)}{mVJ_z}, \quad A_{34} = -B_3\frac{f}{V} - V, \quad B_3 = \frac{C_F(J_z + md(d-f))}{mJ_z}, \\ A_{43} &= -\frac{B_4}{V} + \frac{C_R d}{VJ_z}, \quad A_{44} = -B_4\frac{f}{V}, \quad B_4 = \frac{C_F(f-d)}{J_z}. \end{aligned} \quad (2)$$

The vehicle parameters include the mass m , the yaw moment of inertia J_z (with respect to the center of gravity), the wheelbase f , and the distance d between the rear axle and the center of gravity. V denotes the longitudinal speed of the vehicle (assumed to be constant), and the tire cornering stiffnesses are denoted by C_F (front axle) and C_R (rear axle). The control goal is to reach stable rectilinear motion along the x axis, therefore the steering angle is generated by the delayed feedback of the vehicle's lateral position y and its yaw angle ψ : $\delta_s(t) = \mathbf{K}\mathbf{x}(t-\tau) = -P_y y(t-\tau) - P_\psi \psi(t-\tau)$, where $\mathbf{K} = [-P_y \quad -P_\psi \quad 0 \quad 0]$ includes the control gains. The time delay τ consists of sensor and communication delays, processing times, as well as the dynamics of the steering mechanism.

In order to represent measurement noise in the control loop, the above model is extended by adding an additive noise component to the feedback signal of both y and ψ . This may include effects from environmental noise or the slight jumps in the estimation results of the lane detection system in each frame in case of a vision-based solution. The noise is modeled as a one-dimensional Langevin force excitation Γ_t [9], with the intensities σ_y and σ_ψ collected in $\mathbf{D}_m = [\sigma_y \quad \sigma_\psi \quad 0 \quad 0]^T$. Overall, the resulting linear, stochastic, time delay system can be written as

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{B}\mathbf{K}\mathbf{x}(t-\tau) + \sigma\Gamma_t, \quad \text{where} \quad \sigma = \mathbf{B}\mathbf{K}\mathbf{D}_m. \quad (3)$$

Since the Langevin force excitation Γ_t is defined such that its integration leads to the Wiener process W_t [9], Eq. (3) can be rewritten into the incremental form

$$d\mathbf{x}(t) = (\mathbf{A}\mathbf{x}(t) + \mathbf{B}\mathbf{K}\mathbf{x}(t-\tau))dt + \sigma dW_t. \quad (4)$$

Stability analysis

The system may lose its stability in two ways: at $P_y = 0$, a static loss of stability occurs, which corresponds to a real characteristic root crossing the imaginary axis. At the rest of the stability boundaries, a complex conjugate pair of roots moves to the right half-plane, leading to an oscillatory loss of stability. The analytical derivation of these stability boundaries for the deterministic system using the D-subdivision method is detailed in [7].

In order to investigate the stability properties of the stochastic delay differential equation (4), the stochastic mapping $\mathbf{y}_{n+1} = \mathbf{F}\mathbf{y}_n + \mathbf{g}$ is defined by discretizing the system with respect to the delayed term [6, 8]. The size of \mathbf{y}_n depends on the resolution of the discretization; \mathbf{F} is based on the deterministic part of Eq. (4) (\mathbf{A} and $\mathbf{B}\mathbf{K}$), and \mathbf{g} is calculated from σ . For the exact definition of the above mapping, the reader is referred to [6].

The stability of the mean dynamics is determined by \mathbf{F} (leading to the results presented in [7]), while the second moment stability is analyzed according to [6]. Note that first moment stability is required for the stability of the second moment process, therefore it is sufficient to check only the latter. Moreover, since there is no multiplicative noise term in our model, stability analysis of the first and second moment dynamics leads to the same results. In other words, the introduction of additive sensor noise does not influence the stability boundaries of the system. However, due to the autonomous stochastic resonance effect, the steady-state second moment values may start to increase near the stability boundaries. This means that even though the control gains are chosen from the stable parameter domain, the variance of the steady state solution may become unacceptably large.

In order to check this, the first order stochastic semi-discretization method was applied with the help of the corresponding Julia package [6]. A discretization step of 0.05 s was used and the vehicle parameters were selected according to Table 1. The effect of autonomous stochastic resonance is illustrated in Fig. 2 (a), where the steady state second moment of y (denoted by $M_{st,y}$) is plotted along the stable parameter domain of the control gains. The sections of the stability map were chosen according to the control gains that lead to the most highly damped response of the deterministic system ($P_y = 0.00077 \text{ m}^{-1}$, $P_\psi = 0.0805$).

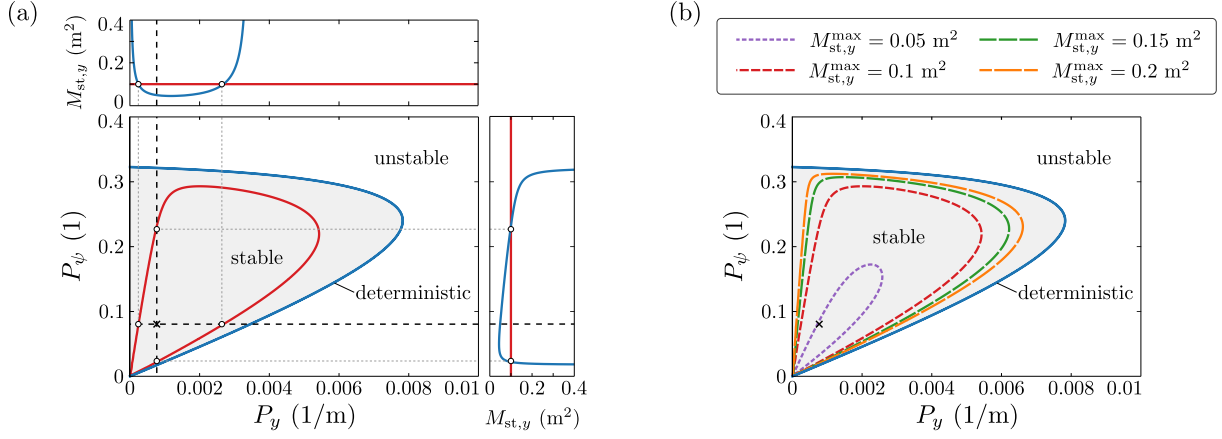

Figure 2: (a) The effect of sensor noise on the steady state second moment of y ; (b) regions of the stability map corresponding to different limits on $M_{st,y}$; the deterministic optimum is denoted with a cross

Figure 2 (b) shows a practical stability map that demonstrates how the usable domain of control parameters shrinks if we want to limit the steady state second moment of y . Notice that the minimum of $M_{st,y}$ does not fall into the deterministic optimum (that is based on the eigenvalues of \mathbf{F}). Instead, it depends on the values of σ_y and σ_ψ , and the amplification due to the control gains.

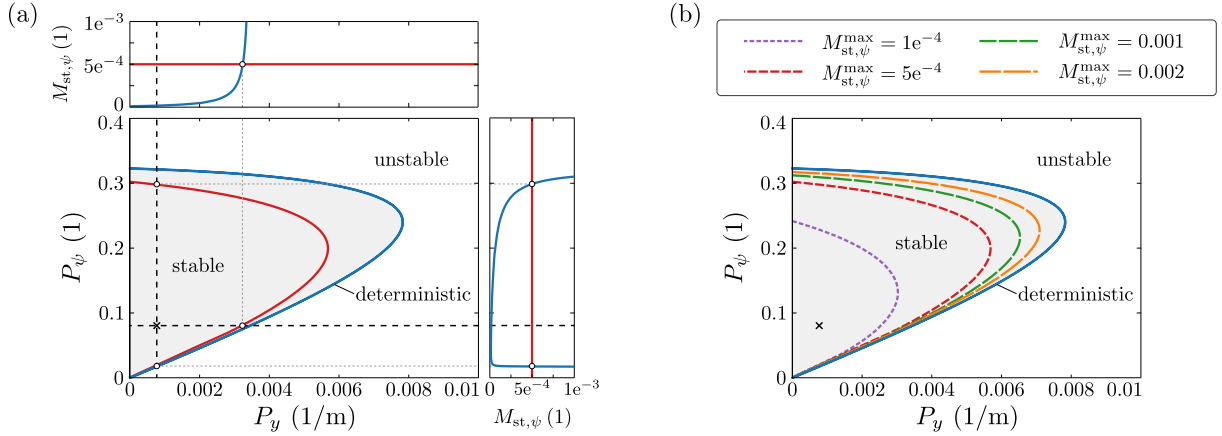

Figure 3: (a) The effect of sensor noise on the steady state second moment of ψ ; (b) regions of the stability map corresponding to different limits on $M_{st,\psi}$; the deterministic optimum is denoted with a cross

Figure 3 shows similar practical stability maps with regards to the steady state second moment of the yaw angle ψ . Note the different shape of the contour lines compared to those in Fig. 2. As P_y is decreased, the vehicle takes much longer to reach the equilibrium (in terms of mean dynamics), since the position error is very weakly compensated (at $P_y = 0$, a static loss of stability occurs, where the vehicle path diverges). This also means that the steering action does not suppress the stochastic jumps around the equilibrium as effectively once the steady state is reached, leading to an increase in $M_{st,y}$ (as seen in Fig. 2 (a)). On the other hand, the control action related to ψ is not affected as P_y is decreased, which explains why there is no increase in $M_{st,\psi}$ in Fig. 3 (a) (note that $M_{st,\psi}$ does not reach zero at $P_y = 0$). Another effect to keep in mind, however, is that decreasing the gains not only decreases the control action, but it also suppresses the noise amplitude that appears in δ_s . Therefore decreasing the control gains directly leads to decreased noise gains, which means that the second moments are generally lower near the origin of the stability maps (unless of course stochastic resonance effects appear due to the proximity of a stability boundary).

In order to verify the results, 1000 Monte-Carlo simulation runs were conducted using the Euler-Maruyama method [10]. The control gains were chosen according to the deterministic optimum, and an initial condition of $y(t \leq 0) = 3$ m was used (while the rest of the initial state values were set to zero), representing a lane change manoeuvre. The simulations were run for 100 seconds, with a time step of 0.005 s. In order to calculate the stationary second moment, the first 30 seconds of the simulations were cut to ensure proper decay of the transients. There is good accordance between the numerically determined stationary second moment and the result of the stochastic semi-discretization method (see the first two columns of Table 2). This is also illustrated in Fig. 4, where the square root of the stationary second moment according to the semi-discretization method (shown in red) matches the sample standard deviation of the Monte-Carlo runs (shown in blue; note that the expected value of the stationary solution is zero).

Figure 4: Simulation results of 1000 Monte-Carlo runs of the linear system. Black lines show the sample mean and blue lines denote the standard deviations of the samples. An arbitrarily chosen single realization is shown in light gray, while the red dashed lines represent the square root of the stationary second moments calculated using stochastic semi-discretization.

Table 2: Stationary second moment values determined using different methods

	Stochastic SD	Linear simulation	Non-linear simulation
$M_{st,y} \text{ (m}^2\text{)}$	0.04867	0.04783	0.04896
$M_{st,\psi} \text{ (rad}^2\text{)}$	1.8642e-5	1.8553e-5	1.8741e-5

Colored noise, simulation of the nonlinear system

A possible extension of the previously detailed model is the use of colored noise in the form of a first order Markov process [11]. This approach incorporates a cutoff frequency ω_c to limit the bandwidth of measurement noise due to e.g. digitization. The noise processes corresponding to the feedback signal of y and ψ are

$$\dot{w}_y = -\frac{1}{T_y}w_y + \sigma_y^c \Gamma_t, \quad \dot{w}_\psi = -\frac{1}{T_\psi}w_\psi + \sigma_\psi^c \Gamma_t, \quad (5)$$

where w_i ($i \in \{y, \psi\}$) denote the state of the noise process and the time constants T_i determine the correlation time of the noise and the corresponding cutoff frequency ($\omega_c = 1/T_i$). This time constant is assumed to be equal for both measurement signals.

As opposed to the previous section, the Langevin force excitation Γ_t is now used to generate the colored noise process, instead of directly acting on the feedback signal. Its intensity σ_i^c is chosen such that the energy content of the colored noise process (at low frequency levels) matches the corresponding white noise process used in the previous section, leading to

$$(\sigma_i^c)^2 = \frac{\sigma_i^2}{T_i^2}, \quad i \in \{y, \psi\}. \quad (6)$$

Using the above noise processes, the closed-loop system is of the form

$$\dot{\mathbf{x}}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{BK} \left(\mathbf{x}(t - \tau) + \mathbf{D} \begin{bmatrix} w_y \\ w_\psi \end{bmatrix} \right), \quad \mathbf{D} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix}^T. \quad (7)$$

Combining Eq. (5) and Eq. (7), the system can be turned to a similar form as Eq. (3)

$$\dot{\mathbf{X}}(t) = \left[\begin{array}{c|cc} \mathbf{A} & \mathbf{BKD} \\ \hline \mathbf{0}_{2,4} & -1/T_y & 0 \\ & 0 & -1/T_\psi \end{array} \right] \mathbf{X}(t) + \left[\begin{array}{c|c} \mathbf{BK} & \mathbf{0}_{4,2} \\ \hline \mathbf{0}_{2,4} & \mathbf{0}_{2,2} \end{array} \right] \mathbf{X}(t - \tau) + \left[\begin{array}{c} \mathbf{0}_{4,2} \\ \hline \sigma_y^c & 0 \\ 0 & \sigma_\psi^c \end{array} \right] \Gamma_t \quad (8)$$

using the augmented state vector

$$\mathbf{X} = [y \quad \psi \quad \sigma_1 \quad \sigma_2 \quad w_y \quad w_\psi]^T. \quad (9)$$

$\mathbf{0}_{i,j}$ represents the zero matrix of size $i \times j$.

The stability maps in Fig. 5 demonstrate how the cutoff frequency of the measurement noise affects the previously shown robust stability maps. At the boundary of dynamic loss of stability (the so-called D-curve), a complex conjugate pair of characteristic roots crosses the imaginary axis at $i\omega$. The value of ω continuously increases along the stability boundary from $\omega = 0$ at the origin to approximately $\omega = 2$ rad/s where the D-curve crosses the vertical axis slightly above $P_\psi = 0.3$. The line style of the deterministic boundary in Fig. 5 shows the relation between the selected cutoff frequency and the system dynamics. The section of the stability boundary where the imaginary part of the corresponding characteristic roots is below the cutoff frequency is shown in blue, while the sections plotted in dashed gray are above ω_c .

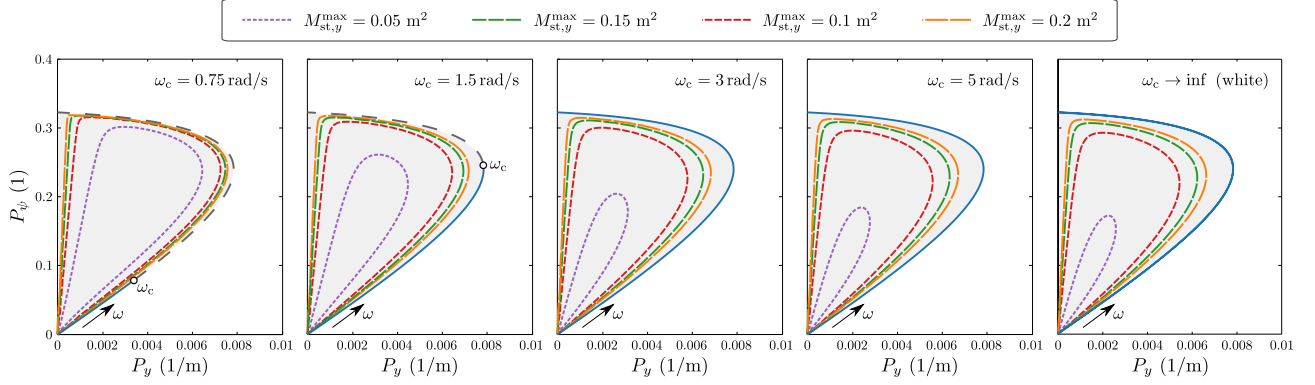

Figure 5: Robust stability maps in terms of the steady state second moment of y while increasing the cutoff frequency of the sensor noise (ω_c). The styling of the deterministic boundary shows the relation between the frequency component ω of the critical characteristic roots at the boundary and the cutoff frequency ω_c (blue: $\omega < \omega_c$, gray dashed: $\omega > \omega_c$).

It can be seen that as long as only a small section of the stability boundary (and therefore the corresponding dynamics) is excited, the stochastic resonance effect is not very strong, the stationary second moment of y remains small throughout the majority of the stable parameter domain, and there is not much difference between the deterministic and the robust stability boundaries. However, as the cutoff frequency is increased, the stochastic excitation has a stronger effect on the dynamics, and the contour lines of $M_{st,y}$ start tending towards those shown for white noise excitation. Since the vehicle model acts as a low-pass filter with relatively slow dynamics, the colored sensor noise also has to have a very low cutoff frequency in order to show a meaningful difference in terms of the steady-state dynamics of the system compared to a white noise excitation. Therefore there is not much benefit in taking into account the cutoff frequency of the sensor noise in most practical cases, where ω_c is typically at least 10 Hz.

Figure 6: Simulation results of 1000 Monte-Carlo runs of the non-linear system. Black lines show the sample mean and blue lines denote the standard deviations of the samples. An arbitrarily chosen single realization is shown in light gray, while the red dashed lines represent the square root of the stationary second moments calculated using stochastic semi-discretization.

On the other hand, a possible advantage of modeling the additive sensor noise as a first order Markov process is that this approach allows the numerical simulation of the non-linear system too (the non-linear system equations can be found in [7]). In spite of feeding back the measurement noise through non-linear functions, the overall system remains driven by an additive, white noise source, which is easy to handle mathematically.

The results in Fig. 6 and Table 2 show that there is minimal difference in the observed stationary second moments between performing simulations on the linear and the non-linear system. This is mainly due to the fact that only geometrical non-linearities are considered, which do not have a strong effect in the performed lane change manoeuvre, especially once the steady state is reached. Even though there is constant steering action due to the stochastic effects, the steering and side-slip angles all remain small enough that the system stays well within the linear regime. Nevertheless, this still provides a useful example of simulating a non-linear system with direct feedback of measurement noise.

Conclusion

The stability and steady-state dynamics of a path tracking controller were investigated in the presence of time delay and measurement noise. It was shown how the choice of control parameters influences the steady-state dynamics. Due to the autonomous stochastic resonance effect, it is possible to choose control gains from the linearly stable parameter domain that still lead to unacceptably large variance in the steady-state solution. The included robust stability maps aim to provide guidelines about which regions of the stable domain should be avoided for this reason. The results determined using the stochastic semi-discretization method were verified by numerical simulations. The simulation of the non-linear stochastic system was achieved by using filtered white noise. A possible extension of the present study is to also consider the effects of road excitation as another noise source in the system.

The Relevance of Spectral Submanifolds and Slow Manifolds for Randomly Excited Mechanical Systems

Thomas Breunung*, Florian Kogelbauer† and George Haller*

* *Institute for Mechanical Systems, ETH Zürich, Zürich, Switzerland*

Summary. Invariant manifolds, such as nonlinear normal modes, spectral submanifolds and normally hyperbolic invariant manifolds are the key to understand the dynamical behavior of nonlinear mechanical systems and serve as natural candidates for model-order reduction. While numerous related invariant manifold results are available for unforced and periodically forced nonlinear mechanical systems, the case of random external forcing has not been studied from this perspective. Here, we clarify the role of deterministic invariant manifolds in the case of small white noise excitation and demonstrate our results on explicit mechanical systems.

Introduction

To account for parameter uncertainty, unmodeled degrees of freedom or unknown disturbances in realistic engineering structures, the use of statistical methods is unavoidable [1]. Gaussian white noise is commonly considered to account for such random perturbations. Whether the deterministic invariant manifolds, such as nonlinear normal modes, spectral submanifolds or normally hyperbolic invariant manifolds, are of relevance under uncertainties or random external excitation has, however, remained unclear.

Various definitions of nonlinear normal modes have been proposed in the literature (cf. [2] for a review) and multiple computational algorithms for the unforced or periodically forced nonlinear mechanical systems have been developed [3]. Recently, Haller and Ponsioen [4] identified the smoothest nonlinear continuation of a spectral subspace of the linearization as spectral submanifold (SSM). While spectral submanifolds have proven valuable for model-order reduction, the related computational tools assume a completely deterministic nature of the system. This assumption, however, does not generally hold for structures which are subject to parameter uncertainties and external (unmodeled) disturbances.

Counterparts to deterministic dynamical features, such as normally hyperbolic invariant manifolds or stable/center manifolds of fixed points, for randomly perturbed mechanical systems are intricate to establish mathematically. Berglund and Gentz [5] assume an idealized slow-fast decomposition in the deterministic system, while the stable and center manifolds established in [6] generally depend on the realization of the random process. Therefore, each realization results in a different reduced-order model, which is computationally costly and limits relevance of the reduced-order model significantly. In contrast, the probability density function (PDF) is independent of the realization. In the case of Gaussian white noise excitation, the time evolution of the probability density is governed by the Fokker-Planck equation [7]. Explicit solutions of the Fokker-Planck equation, however, are only available in specific cases, and approximate numerical methods discretizing the Fokker-Planck equation or Monte Carlo simulations are computationally expensive [8].

Recently, Haller et al. [9] derived tools to identify material diffusion barriers, including material surfaces that extremize the diffusive transport of the PDF in the phase space. By the definition of these barriers, the transport of the PDF across them is purely driven by small stochastic perturbations of the otherwise deterministic system. Specifically, *perfect barriers* block the transport at leading order completely and thereby demarcate regions of the phase space that trajectories generally not penetrate. Similarly, ridges of the diffusion barrier strength (DBS) highlight surfaces with strong diffusive transport, i.e., regions where trajectories accumulate. Both identifiers (perfect barriers and DBS) can be computed from purely deterministic quantities associated with the dynamical system and hence computationally expensive numerical methods such as Monte-Carlo approximations can be avoided.

Set-up

In this talk, we apply the methods from [9] for diffusive transport in fluids to mechanical systems excited by Gaussian white noise with small intensity. Specifically, we consider N -degree-of-freedom mechanical systems of the form

$$\mathbf{M}\ddot{\mathbf{q}} + \mathbf{C}\dot{\mathbf{q}} + \mathbf{K}\mathbf{q} + \mathbf{S}(\mathbf{q}) = \sqrt{\nu}\mathbf{f}(\mathbf{q})d\mathbf{W}, \quad \mathbf{q} \in \mathbb{R}^N, \quad (1)$$

where \mathbf{M} , \mathbf{C} and \mathbf{K} are the mass, damping and stiffness matrices. The geometric nonlinearity $\mathbf{S}(\mathbf{q})$ is a nonlinear function of the position, such that $\mathbf{S}(\mathbf{q}) = \mathcal{O}(|\mathbf{q}|^2)$. The vector $d\mathbf{W}$ collects M independent one-dimensional Brownian motions and the matrix $\mathbf{f}(\mathbf{q}) \in \mathbb{R}^{N \times M}$ prescribes their directions. Since \mathbf{f} can depend on the coordinates \mathbf{q} (cf. eq. (1)), our formulation also covers parametric random excitations.

After transforming system (1) into first order, we introduce the probability density function $\rho(\mathbf{q}, \dot{\mathbf{q}}, t)$ depending on the phase space location and time, both of which are suppressed in our notation for simplicity. The time evolution of ρ is then governed by the classic Fokker-Planck equation [7], which can be recast in the advection-diffusion form

$$\frac{D\rho}{Dt} = \frac{\nu}{2} \nabla \cdot (\nabla \cdot \mathbf{f}(\mathbf{q})\mathbf{f}^\top(\mathbf{q})) + k\rho. \quad (2)$$

The constant k in equation (2) depends on the damping \mathbf{C} and $D\rho/Dt = \partial\rho/\partial t + \mathbf{v} \cdot \nabla\rho$ denotes the material derivative. The results of Haller et al. [9] on transport barriers can be applied to equations of the form (2). These results yield

invariant manifolds of an associated, deterministic barrier equation. The manifolds obtained in this fashion are barriers to the diffusive transport of the PDF of the original mechanical system (1).

Results

We numerically investigate whether distinguished transport extremizers align with known deterministic slow manifolds or fast stable manifold of stable fixed points. More specifically, we investigate the modified Shaw-Pierre example [10]

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \ddot{\mathbf{q}} + \begin{bmatrix} c_1 + c_2 & -c_2 \\ -c_2 & c_1 + c_2 \end{bmatrix} \dot{\mathbf{q}} + \begin{bmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_1 + k_2 \end{bmatrix} \mathbf{q} + \begin{bmatrix} \kappa q_1^3 \\ 0 \end{bmatrix} = \sqrt{\nu} \begin{bmatrix} 0 \\ 1 \end{bmatrix} dw, \quad (3)$$

where the intensity ν is a small parameter ($\nu \ll 1$) and dw indicates Gaussian white noise. Further, we investigate the classical Duffing oscillator [11]

$$q + cq + kq + \kappa q^3 = \sqrt{\nu} dw. \quad (4)$$

(a) Duffing oscillator (4)

(b) Shaw-Pierre example (3).

Figure 1: Diagnostics from [9] applied to the Shaw-Pierre Example (3) and Duffing oscillator (4).

For systems (3) and (4), we plot the diagnostics for transport barriers from [9] in Fig. 1. In the case of the stochastically forced Duffing oscillator (4) the slow manifold connecting the saddle type fixed point at the origin with the stable node at $q=1$ is successfully identified as a DBS ridge (cf. Fig. 1a). For the Shaw-Pierre example (3), the fast stable submanifold is successfully identified as a perfect barrier for the stochastically excited nonlinear system (cf. Fig. 1b).

Conclusion

We demonstrate that the methods developed in [9] link classic deterministic normally hyperbolic manifolds or stable submanifolds of nonlinear mechanical systems to the stochastic dynamics arising under small random perturbations to the deterministic system. Our analysis is based on purely deterministic quantities and thereby avoids computationally expensive methods, such as Monte-Carlo approximations.

Summary. The noisy dynamics of the system called the smooth and discontinuous (SD) oscillator in its frequency domain is studied. The nonlinearity is smooth (continuous) or nonsmooth (discontinuous) depending on the value of the smoothness parameter α . It was observed that the hysteretic region decreases with a higher correlation in noise. Furthermore, an increase in the smoothness parameter in the presence of noise also has the effect of reducing the hysteretic region.

Introduction

The study of discontinuous nonlinear systems subjected to stochastic excitations using non-smooth transformations, approximate analytical methods, numeric-analytical methods and numerical methods are few [1]. Most of these studies were carried out with the assumption of noise being uncorrelated in nature. However, white noise is a mathematical abstraction and the noise occurring in real physical systems often has a finite bandwidth. Furthermore, the problem is more involved in the vicinity of a bifurcation as the presence of a subcritical bifurcation in a deterministic dynamical system leads to the formation of a pair of stable solutions separated by an unstable branch, thus creating a hysteretic loop when a forward and a backward bifurcation is carried out. The dynamics follows a particular bifurcation branch until the critical value of a control parameter is reached, followed by a sudden transition to another branch. However, if the integration is carried out using the varying the same control parameter in the reverse manner, the critical transition occurs at a different value. Noise has the potential to influence these critical parameters [2]. The dependence of the size of the hysteresis loop on the intensity and correlatedness of noise is thus important to demarcate the stability regime of the dynamical system. The complexity of the problem is increased when there is an interplay of nonsmoothness in the dynamical system. To decipher the underlying dynamics of such noise-induced transitions, an archetypal snap-through truss oscillator has been considered. The dynamics of the system can be considered to be smooth or non-smooth depending on the smoothing parameter α in the problem. The non-dimensionalized equations of motion of this system are given by Eq. 1. In the smooth regime, the system is observed to bear significant resemblance to the Duffing oscillator, exhibiting the standard dynamics governed by the hyperbolic structure associated with the double well. At the discontinuous limit however, the dynamics diverges substantially. The loss of local hyperbolicity leads to a jump in the velocity flow when crossing from one well to another. The system has coexisting attractors in the presence of damping and external excitations.

$$\ddot{x} + 2\zeta\dot{x} + x\left(1 - \frac{1}{\sqrt{x^2 + \alpha^2}}\right) = f_0 \cos \omega t + n\lambda(t), \quad (1)$$

where ζ is the damping coefficient, f_0 is the amplitude of forcing and ω is the corresponding forcing frequency. $\lambda(t)$ depicts the Ornstein Uhlenbeck noise and n denotes its intensity.

Results and discussions

The results of direct numerical simulations using forward integration has been shown in Fig. 1. It can be observed that in the presence of noise, the upper branch near $\omega \simeq 0.8$ is continued for a larger magnitude of frequency before there is a transition to the lower amplitude branch. The transition is depicted by a saddle-node bifurcation of limit cycles, leading to the creation of a stable and unstable branch of bifurcations [4]. It is also observed that the lower amplitude branch has a marked increase in the observed maximum amplitude of oscillations post the saddle-node bifurcation. Thereafter, the effect of correlatedness in noise on the transition to the lower branch is studied. The intensity of noise, mean and variance are kept constant at 0.5, 0 and 0.1 and the mean reverting speed is varied, here denoted by θ . The system is assumed to be ergodic and the maximum amplitude is computed with one simulation from an ensemble of realizations where a long time history of 10^3 cycles is considered. It was observed that the transition occurred for a lower magnitude of frequency when the mean reversion speed of the Ornstein Uhlenbeck process was higher *i.e.* higher correlatedness in noise led to a proponent of transition to the lower amplitude branch when a forward numerical integration is carried out; see Fig. 2.

Furthermore, the effect of varying the smoothing parameter in the SD oscillator on the transition to the lower branch is studied. Fig. 3. is a depiction of the variation of nonlinear restoring force as a function of α . It can be observed that the restoring force becomes stiff as α decreases and is discontinuous at $\alpha = 0$ [3]. Fig. 4 depicts the variation in the control parameter leading to the occurrence of the nonsmooth saddle-node bifurcation. As α decreases, the bifurcation is delayed to a higher parameter of ω . Also, a corresponding increase in the maximum amplitude of the response has been observed post occurrence of the bifurcation. For the simulations, the intensity of noise n is kept constant at 0.5 and the process parameters of the Ornstein Uhlenbeck process are 0, 0.5, 0.3 respectively. The step size of integration is fixed at 0.001.

Figure 1: The frequency response of the SD oscillator for $\alpha = 1.1, f_0 = 0.25, \zeta = 0.0141$ using numerical integration with stochastic Runge-Kutta method when $\sigma = 0, 0.1$.

Figure 2: The frequency response of the SD oscillator with Stochastic Runge-Kutta method with different correlated noises.

Figure 3: Nonlinear restoring force for different values of α .

Figure 4: The frequency response of the SD oscillator with Stochastic Runge-Kutta method with different values of the smoothing parameter α .

A systematic semi-analytical and numerical approach to determine the effect of additive noise on the region of co-existence of attractors in a SD oscillator is currently under investigation. The noise is appended to the harmonic excitation in the system. The effect of the degree of nonlinearity given by α , the intensity of noise n , correlatedness of noise $\lambda(t)$, damping ζ are explored.

Summary. Acoustic Black Hole (ABH) is a new passive technique for vibration damping of thin-walled structures such as beams and plates. It consists of a local decrease in the thickness profile, associated to the deposit of a thin viscoelastic coating in the thinnest region. One of the common feature for this technique is that it is very efficient in the high frequency range, but it is less optimal in the low frequency range. To overcome this limitation, we propose to investigate the benefit brought by different types of nonlinear dampers into the system. The effect of a Tuned Mass Damper (TMD), a Nonlinear Energy Sink, and a Bistable Nonlinear Energy Sink are respectively considered and compared. The dynamics of these systems are numerically solved using a modal approach with an energy conserving scheme. Then, by defining some frequency indicators, the low frequency performance of each aforementioned strategy is characterized. It is demonstrated that, if appropriately designed, all the proposed methods can effectively reduce the low frequency resonance peaks in the ABH structure, and hence improve the average performance of an ABH.

Introduction

The Acoustic Black Hole (ABH) effect has become an increasingly popular technique for passive noise and vibration control. Its one dimensional implementation (i.e its implementation in a beam structure) consists of a local decrease of the thickness according to a power law profile associated to the adding of a thin viscoelastic damping layer in the tapered area [1]. Existing theoretical, numerical and experimental papers show that Acoustic Black Holes induce significant localization of the bending waves, and have a strong damping effect in the middle and high frequency ranges [1]. Some design rules based on the analysis of the wave scattering induced by an ABH termination have been proposed [2] to achieve high modal damping coefficients, the underlying mechanism being interpreted using the critical coupling concept [3]. However, a significant limitation of the ABH effect leads in the fact that it is effective in the mid-high frequency range. A cut-on frequency has been defined [4], for representing the critical frequency threshold below which the ABH loses its efficiency. To overcome this issue, the idea of associating the ABH effect with some other nonlinear effects has emerged: geometrical nonlinearities due to vibrations with large amplitudes have been exploited [5], as well as strong nonlinearities induced by vibro-impacts [6].

In this paper, the interest of adding three different types of vibration absorbers to a beam ABH termination are tested in order to meet the requirement of a broadband passive energy mitigation. A classical tuned mass damper (TMD) is first considered, which consists of a linear device that has been proven to be a very reliable passive mitigation strategy in a large number of contexts [7, 8]. It could be awaited that once a TMD is attached to an ABH beam and tuned to one of its resonant modes below the cut-on frequency, where the ABH effect is ineffective, the peak response reduced [9], and the average performance of the ABH could hence be improved.

Considering the known major drawback that TMD is only effective in a narrow frequency band, a more broadband nonlinear vibration absorber consisting of an NES with cubic nonlinearity [10] is also proposed. Unlike a linear system, a unique nonlinear phenomenon called targeted energy transfer [11] could be observed for effective broadband vibration mitigation [12, 13]. A third proposition of absorber consists of a recently studied Bistable Nonlinear Energy Sink (BNES), for which the targeted energy transfer can be activated with a lower energy barrier [15, 16].

The purpose of this paper is thus to use the aforementioned three types absorbers in order to improve the performance of the ABH below its cut-on frequency, and to compare their performances. The numerical modeling of all the considered systems will be formulated in Section 2. Section 3 is mainly devoted to the numerical results, the performance of each methods will be discussed, before the conclusion given in section 4.

Equations of motion

Let us consider an ABH beam coupled to a single vibration absorber consisting in an elementary 1-DOF oscillator (see Fig. 1). The absorber is located at $x = x_c$. Its mass m is assumed to be small compared to that of the beam. It is characterized by its linear stiffness k_l , its cubic nonlinear stiffness k_n , and its damping coefficient 2σ . Considering such parameters, the three different types of absorbers can be modeled by varying k_l and k_n . More precisely, a linear TMD [7, 8] is obtained by setting $k_l > 0, k_n = 0$; while the classical NES [11] with cubic nonlinearity corresponds to the arrangement of $k_l = 0, k_n > 0$. Finally, the case of a BNES [15, 16] can be obtained for $k_l < 0, k_n > 0$.

The ABH beam is supposed to have a constant thickness h_0 in the region $x \in [0, x_{abh}]$. An ABH profile is assumed in the right hand region $x \in [x_{abh}, L]$: The thickness $h_b(x)$ is decreasing with respect to the variable x , in the form of the

power-law function

$$h_b(x) = \begin{cases} h_0, & \text{for } x \in [0, x_{abh}] \\ h_0 \left(\frac{x - x_{end}}{x_{abh} - x_{end}} \right)^2, & \text{for } x \in [x_{abh}, L] \end{cases} \quad (1)$$

The cross-section of the ABH beam is assumed to be rectangular and with width b , such that the cross-section area $A(x)$ and the inertia moment $I(x)$ writes respectively $A(x) = bh_b(x)$ and $I(x) = bh_b(x)^3/12$. Finally, a viscoelastic layer is added in the ABH region in consideration of ensuring the damping for a practical ABH with an inevitable truncation thickness h_t .

Figure 1: The layout of the considered system consists of an ABH beam coupled to a lightweight oscillator located at x_c . A thin damping layer (red) of thickness h_l is added along the ABH profile.

Let $u(x, t)$ be the transverse displacement of the beam, and $v(t)$ the motion of the absorber. The governing equation for the system can then be written as

$$\rho(x)A(x)\frac{\partial^2 u}{\partial t^2} + \frac{\partial^2}{\partial x^2} \left(D(x)\frac{\partial^2 u}{\partial x^2} \right) + f\delta(x - x_c) = p\delta(x - x_F), \quad (2a)$$

$$m\ddot{v} = f, \quad (2b)$$

$$f = k_l w + k_n w^3 + 2\sigma \dot{w}, \quad (2c)$$

$$w = u(x_c, t) - v, \quad (2d)$$

where $\rho(x)$ is the material density of the beam, and $D(x) = E(x)I(x)$ is the bending stiffness, $p = p(x, t)$ stands for the pointwise external force induced at the position $x = x_F$. The force $f = f(x, t)$ is the restoring force of the oscillator written in form of the relative motion $w = u(x_c, t) - v$. The mass ratio ϵ defined by $\epsilon = m/m_{beam}$ is supposed to be small (m is the mass of the absorber and m_{beam} is the total mass of the beam). As for the boundary conditions, the beam is considered to be clamped at $x = 0$ and free at $x = L$.

The damping induced by the viscoelastic layer is modelled with the Ross-Kerwin-Ungar method [2], in which a complex bending stiffness $D^*(x)$ is introduced and can be expressed as,

$$D^*(x) = \begin{cases} E_b I_b(x) (1 + j\eta_b), & \forall x \in [0, x_{abh}], \\ E_b I_b(x) \left[(1 + j\eta_b) + \frac{E_l}{E_b} \left(\frac{h_l}{h_b(x)} \right)^3 (1 + j\eta_l) + \frac{3 \left(1 + \frac{h_l}{h_b(x)} \right)^2 \frac{E_l h_l}{E_b h_b(x)} (1 - \eta_b \eta_l + j(\eta_b + \eta_l))}{1 + \frac{E_l h_l}{E_b h_b(x)} (1 + j\eta_l)} \right], & \forall x \in [x_{abh}, L], \end{cases} \quad (3)$$

where j is the imaginary unit, E_b , I_b , and η_b stand respectively for the bending stiffness, the Young's modulus, the moment of inertia and the loss factor of the beam alone, while E_l and η_l are the Young's modulus and the loss factor of the viscoelastic layer. In addition, a modification on the thickness $h(x) = h_b(x) + h_l$ and material density $\rho(x) = (\rho_b h_b + \rho_l h_l)/h$ at the ABH area are also performed due to the added mass of the damping layer.

A modal approach, whose implementation details are given in [6], is applied to numerically solve the problem described in 2 in the time domain. A special emphasize on the added new dof introduced by the nonlinear damper will be further explained here. First of all, the beam displacement is written as $u(x, t) = \sum_{k=1}^{N_m} \phi_k(x) q_k(t)$, where $q_k(t)$ is the modal

coordinate associated to mode $\phi_k(x)$, and N_m is the number of modes kept in the expansion. Introducing the modal expansion into (2), and projecting the dynamics onto each mode yields :

$$\ddot{q}_k + 2\xi_k\omega_k\dot{q}_k + \omega_k^2q_k = p\phi_k(x_F) - f\phi_k(x_c), \quad (4a)$$

$$m\ddot{v} = f, \quad (4b)$$

$$f = k_l w + k_n w^3 + 2\sigma\dot{w}, \quad (4c)$$

$$w = \sum_{k=1}^{N_m} q_k \phi_k(x_c) - v, \quad (4d)$$

where ω_k and ξ_k are respectively the eigenfrequency and the modal damping ratio associated to each mode k . Hence, the original problem with PDE is transferred to a set of ODEs with time variables only. Before solving Eqs. (4), a eigenvalue problem should be solved to determine $\phi_k(x)$, ω_k , and ξ_k for each mode. Such eigenvalue problem is written from Eq. (2a), considering that $f = p = 0$. A finite difference method with a non-uniform grid is applied to discretize the variable thickness of the ABH beam. All the complete details are given in [2]. They are skipped here for conciseness. Once the eigenvalue problem solved, the last step of the numerical model consists in the time integration of Eqs. (4). It is done using the exact energy conserving numerical scheme developed in [17].

Let $t_n = n\Delta t$, with n the step index and Δt the time step. The specific feature of the numerical integrator developed in [17] is to use the modal approach for the linear part, whereas the contact force are computed in the physical space. To that purpose, the relationship between the modal space and the physical space needs to be explicit. We introduce $\mathbf{S}_F = [\phi_1(x_F), \phi_2(x_F), \dots, \phi_{N_m}(x_F)]$, as the modal matrix containing the first N_m beam modes at x_F , and $\mathbf{S}_c = [\phi_1(x_c), \phi_2(x_c), \dots, \phi_{N_m}(x_c)]$ the modal matrix at point x_c . The relationship with the modal expansion allows one to write $u(x_c, n\Delta t) = \mathbf{S}_c \mathbf{q}$, and $u(x_F, n\Delta t) = \mathbf{S}_F \mathbf{q}$. With these definitions, Eqs. (4) can then be written at each time step n as:

$$\mathbf{q}^{n+1} = \mathbf{C}\mathbf{q}^n - \tilde{\mathbf{C}}\mathbf{q}^{n-1} + \Delta t^2 (\mathbf{S}_F^T p^n - \mathbf{S}_c^T f^n), \quad (5a)$$

$$m\delta_t v^n = f^n, \quad (5b)$$

$$f^n = k_l w^n + k_n (w^n)^2 \mu_t w^n + 2\sigma \delta_t w^n, \quad (5c)$$

$$w^n = \mathbf{S}_c \mathbf{q}^n - v^n. \quad (5d)$$

where p^n and f^n are respectively the external and restoring forces at time step n . The matrices \mathbf{C} and $\tilde{\mathbf{C}}$ are two diagonal matrices whose expressions could be found in [17], δ_t is a centred time difference reading $\delta_t w^n = (w^{n+1} - w^{n-1}) / 2\Delta t$, and μ_t is an averaging operator: $\mu_t w^n = (w^{n+1} + w^{n-1}) / 2$. The advantage of this particular choice stems from the consideration of ensuring the energy conserving properties and avoid numerical dispersion. It should be noted that before the numerical analysis, a convergence study should first be performed on the sampling frequency $F_s = 1/\Delta t$ and the number of modes N_m , in order to appropriately select the numerical parameters. It was demonstrated that an arrangement with $N_m = 20$ and $F_s = 16\text{kHz}$ is sufficiently enough for obtaining accurate results in our studies.

Nonlinear dampers attached to a uniform beam

The first results and comparisons of the three selected methods (TMD, NES and BNES) have been first tested numerically on a simply supported uniform beam. goal is here to suppress one targeted single resonance of the beam using each of the three selected methods. Fig. 2 provides two simulation results: 1/ the optimization of the nonlinear cubic stiffness k_c and the location x_c of a NES is performed using the energy dissipation E_{diss} cost function (see Fig. 2(a)). 2/ The performance of the system subjected to a harmonic excitation at the circular frequency ω_F in the vicinity of the fundamental frequency of the beam ω_1 is illustrated in Fig. 2(b).

It can be seen that with a appropriate design, each strategy, either a TMD, a NES, or a BNES can effectively suppress the resonance peak of the beam which confirms their efficiency. For the next step, the three methods will then be applied to the ABH beam in order to improve the low frequency performance, with comparisons and optimizations for each of the three mentioned method.

Nonlinear dampers attached to an ABH beam

Parameters of the ABH beam and linear performance

The geometrical and material parameters for the selected ABH beam used in our simulations are listed in Table 1. These choices are related to the experimental beam used in the previous works in[2]. The first line in Table 1 defines also a uniform beam of constant thickness, which will be used subsequently as reference in order to draw out comparisons.

The driving mobility defined as the ratio between the velocity spectrum and the input force spectrum at x_F , is compared in Fig. 3 between the reference (naked) beam and the ABH beam. It could be found that the ABH effect is particularly noticeable on the high-frequency part of the mobility. The cut-on frequency of the ABH effect is evaluated at $f_c = 500\text{ Hz}$,

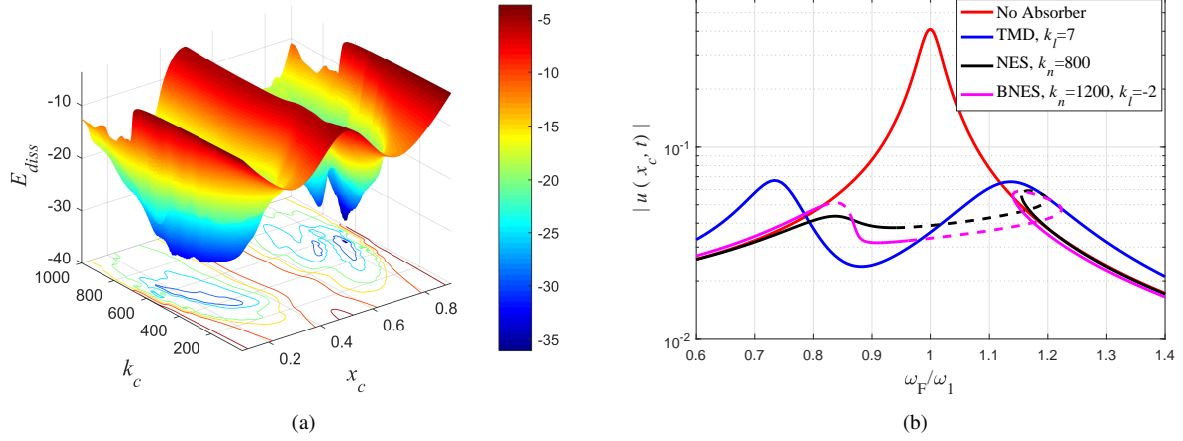

Figure 2: (a): Dissipated Energy E_{diss} of a NES having a purely nonlinear cubic stiffness k_c and located at x_c . (b): Frequency response of the beam under a harmonic excitation in the vicinity of the first resonance frequency ω_1 . Comparisons among the optimized TMD, NES and BNES configurations, with the same damping $\sigma = 0.1$. $|u(x_c, t)|$ refers to the beam displacement at the attached point, the dashed lines indicate that the periodic solution is unstable.

Table 1: Geometrical and material parameters selected for the studied ABH beam.

above which excellent damping properties in the ABH beam with strong attenuation of the sharp resonance peaks (more than 20dB) could be observed. However, at the frequency range below 500Hz, sharp resonance peaks still exist, the ABH almost has no effect. Therefore, in the next sections, our goal will be to improve the damping properties of the ABH effect in the frequency range $[0, 500]$ Hz, by associating the ABH with a special vibration absorber: TMD, NES or BNES.

Figure 3: Comparison of the driving mobilities of the ABH and the uniform beam given in Table 1. Excitation and measurement point are fixed at $x_F = 24$ cm. The excitation is a white noise excitation on $[0, 5000]$ Hz, with amplitude 1 N.

Effect of vibration absorbers on ABH beam

To investigate in the effect of the adding vibration absorber on the performance of the ABH beam, a white noise excitation in the frequency band $[0, 500]$ Hz is considered. Four different cases including the ABH beam without damper (the reference case), the ABH with an attached TMD, the ABH coupled to a NES with pure cubic stiffness, the ABH coupled to a BNES with both cubic stiffness and negative linear stiffness, are then discussed and compared. Fig. 4 shows the output velocity spectrum at the excitation point for each case. Clearly enough, each method could be able to reduce the resonant responses in the targeted low frequency range, while for this typical simulation, the performance is significant for the first 4 modes but less important for the others. More precisely, for mode 2, a 15-25dB reduction could be observed,

and for mode 3, this reduction is around 10-20dB. Thus, by using a linear or nonlinear absorber, the average performance of the ABH beam at the low frequency range is considerably improved. On the other hand, the spectra above the 500Hz indicate that while not significant, the nonlinearity of the NES and BNES brings some transfer of the energy from the low frequency to the high frequency, whereas the TMD shows a linear behaviour without such energy transfer.

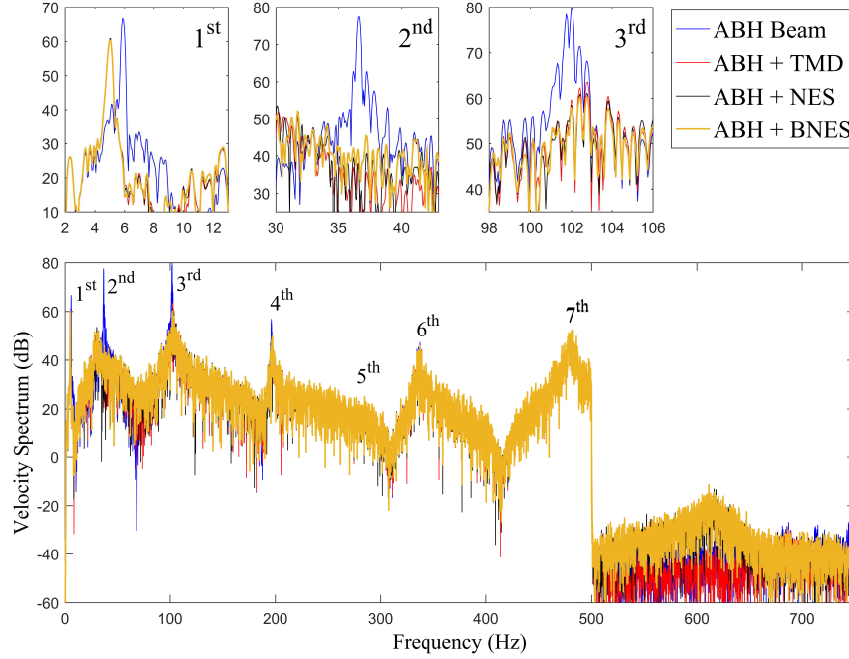

Figure 4: Reduction of the resonance peaks of an ABH beam by using a TMD with $k_l = 800$ N/m, a NES with $k_n = 3 \times 10^9$ N/m³, and a BNES with $k_l = -300$ N/m, $k_n = 3 \times 10^9$ N/m³. For all cases, $\sigma = 0.5$ N · s/m, $x_c = 0.72$ m. The beam is excited with a white noise of $[0, 500]$ Hz, with an amplitude $A = 5$ N and a location $x_F = 0.24$ m. The dynamics are simulated up to 10s.

A performance indicator is proposed for a more quantitative comparison :

$$I = 10 \log_{10} \left(\frac{\int_{f_0}^{f_{end}} V_c^2 df}{\int_{f_0}^{f_{end}} V_{ref}^2 df} \right), \quad (6)$$

where V stands for the power spectrum of velocity at the exciting point, with subscript c or ref referring respectively to the current case and the reference case (*i.e.* the ABH beam without attachment). This indicator allows one to assess the improvements brought by each method over an arbitrary frequency band $[f_0, f_{end}]$. Having in mind the purpose that we want to compare the performances of the three vibration absorbers in the low frequency range below the cut-on frequency of the ABH, some useful indicators can thus be defined in Tab. 2. Here, I_{ω_1} to I_{ω_3} are the indicators quantifying the reduction in the vicinity of each eigenfrequencies ω_1 to ω_3 , while I_{ave} provides an evaluation for the average performance at the low frequency band $[0, 500]$ Hz of the ABH beam.

Indicators	I_{ω_1}	I_{ω_2}	I_{ω_3}	I_{ave}
$\omega_i/2\pi$ (Hz)	5.9	36.7	101.9	/
$[f_0, f_{end}]$ (Hz)	[0, 15]	[30, 45]	[95, 110]	[0, 500]

Table 2: Frequency bands used for defining the performance indicators

The performance indicators for all the cases considered in Fig. 4 are reported in Fig. 5. Considering the fact that the chosen excitation signal is random, a single simulation result may not give an accurate value for the indicators, hence a average values over 20 random selections for each indicator I_{ω_1} to I_{ave} , together with the standard variations is depicted in Fig. 5. One can see that the variations brought by the randomness of the excitation is significant. For I_{ω_1} , a worst fluctuation at around ± 6 dB is observed. At the higher frequencies, the indicators are less prone to variations. As a result, there finally exists a variation at around ± 1.5 dB for the average performance I_{ave} . Thus, a single simulation is not sufficient enough to provide accurate values for each indicator. A Monte Carlo method for obtaining convergence results has then been performed. It is shown that, by make the average value of at least 5 times of simulation samples, I_{ave} can be converged to to a very small variation of less than 0.2dB. In this paper hereafter, for each case, we will repeat 10 times each simulation, and we will take the average value for computing the indicators.

Figure 5: Histograms of indicators I_{ω_1} to I_{ave} calculated for the four cases given in Fig. 4. Average values and standard deviation are computed from 20 randomly generated white noise excitations with amplitude 5N and frequency band $[0, 500]$ Hz.

It should be emphasized that the parameters associated to each method are randomly selected, hence their performances are not really optimized currently but discussed thanks to the help of the indicators. It allows to propose some guidelines for an optimal design.

Tuning the vibration absorbers: parametric study

This section is devoted to the parametric tuning and the optimization of the different vibration absorbers. The interested parameters are the linear and nonlinear stiffnesses k_l and k_n , the damping coefficient σ , and the location x_c . For all the simulations, the external force is a white noise excitation limited to the low frequency band $[0, 500]$ Hz, with amplitude $A = 5$ N and location $x_F = 0.24$ m.

Since the linear and nonlinear stiffnesses play an important role in the energy transfer between the ABH and the vibration damper, their effects are first investigated. Fixing $x_c = 0.72$ m, $\sigma = 0.5$ Ns/m, and $\epsilon = 0.1$ and varying k_l and k_n , the values of different indicators are depicted in Fig. 6 for the three vibration absorbers.

As the linear stiffness k_l in the TMD increases, I_{ω_1} , I_{ω_2} , I_{ω_3} , and I_{ave} show a similar trend, with different minimum values for each indicator (see Fig. 6(a)). For example, I_{ω_1} meets its optimal value of $I_{\omega_1} = -15$ dB for $k_l = 20$ N/m, showing that the best reduction is obtained for the resonance peak of the first mode. For I_{ω_2} and I_{ω_3} , the optimal stiffnesses are $k_l = 500$ N/m and $k_l = 5000$ N/m, respectively. Each optimal stiffness is just consistent with the eigenfrequency of the correspond mode, which is also the key rule in the classical frequency tuning of TMD. Nevertheless, the combined effects reported by the average indicator I_{ave} show that a global minimum can be found for k_l around 1000N/m.

For the case of an attached NES, trends similar to the TMD case can be observed (see Fig. 6(b)). The optimal performance for the reduction of the resonance peaks of modes 1-3 could be found respectively for $k_n = 10^7$ N/m³, $k_n = 10^9$ N/m³, and $k_n = 3 \times 10^{10}$ N/m³, with indicators respectively equal to $I_{\omega_1} = -15$ dB, $I_{\omega_2} = -23$ dB, $I_{\omega_3} = -20$ dB. Besides, for the average performance, $k_n = 2 \times 10^9$ N/m³ gives the optimal tuning.

In Fig. 6(c-d), the effect of the negative stiffness k_l shows quite different trends for different values of k_n . For a relatively small value of $k_n = 10^6$ N/m³, the effect of varying k_l is important. The optimal performance can be easily observed for each single mode 1-3 as $k_l = -10$ N/m, $k_l = -300$ N/m, and $k_l = -2000$ N/m respectively, and the optimal average performance is obtained within $k_l \in [300, 500]$ N/m. However, for higher values of k_n , for example $k_n = 2 \times 10^9$ N/m³ (see Fig. 6(d)), where the nonlinear stiffness has been tuned to the optimal value found for the pure cubic NES, the effect of k_l become much less noticeable: varying k_l does not bring an evident improvement and the indicators remain stable on a wide range of k_l . In this case, the dynamical behaviour is dominated by the nonlinear stiffness. Consequently, the effect of having a (now small) linear negative stiffness is negligible and the dynamics of the damping mechanism is dominated by that of a classical NES with targeted energy transfer. Finally, as testified by the abrupt increase of I_{ave} for $k_l < -1000$, one can remark that when the negative linear stiffness becomes too large, the performance is largely reduced.

The influence of the damping σ on the performance of each vibration damper is depicted in Fig. 7. In each case, as damping increases, the performance improves at first and then decreases, hence for effective vibration suppression, neither too large nor too small value of damping is appropriate. This conclusion could be explained by the fact that when the damping is too small, the absorber might be insufficient to damp out the energy, while an inappropriately too large value on the other hand reduces also the relative motion the energy transfer between the beam and the absorber becomes more difficult. As a result, a damping coefficient of $\sigma = 3$ N · s/m could be selected for the best suppression. Note the difference among the absorbers, one can conclude that at low damping level, NES and BNES generally show a much better behaviour than the TMD due to their strong nonlinearity. However, the difference becomes less significant when the damping increases up to $\sigma = 1$ N · s/m, since overdamped motions make it more difficult for the NES and BNES to activate their nonlinearity and take advantage of it.

Varying the location of the vibration absorbers on the ABH beam, the performance indicator I_{ω_2} of mode 2 as a function of x_c is depicted in Fig. 8(a), for each of the three tested configurations: TMD, NES and BNES. Interestingly, a direct link between on the value of I_{ω_2} and the corresponding mode shape function is observed, whatever the absorber is mounted on the ABH beam. This point is verified by the fact that the absolute value of the mode function $|\phi_2(x)|$, when multiplied

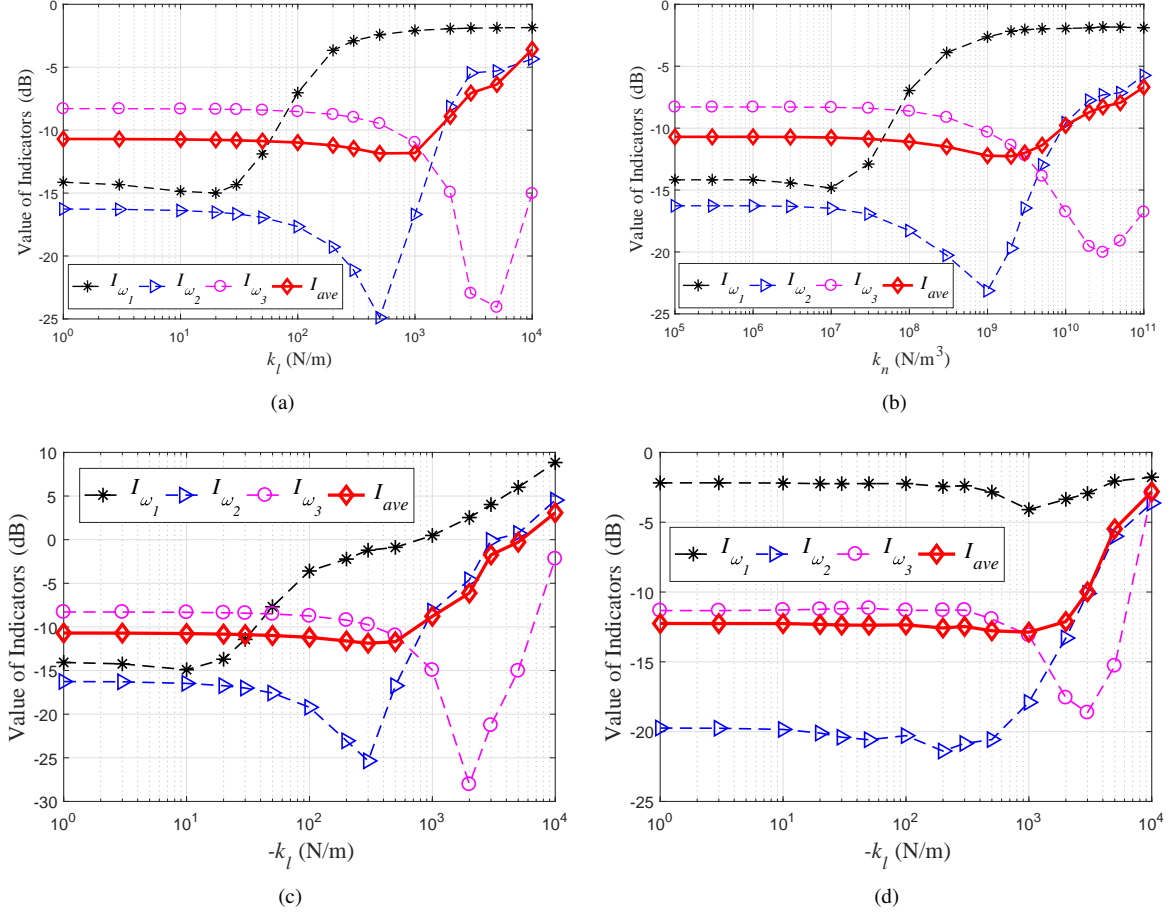

Figure 6: Variations of indicators I_{ω_1} , I_{ω_2} , I_{ω_3} , and I_{ave} as functions of the linear and nonlinear stiffnesses: (a) TMD, indicators as function of linear stiffness k_l (b) NES, indicators as function of the nonlinear stiffness k_n , (c) BNES, indicators as function of the negative stiffness $-k_l$, with nonlinear stiffness fixed as $k_n = 10^6$ N/m³, (d) BNES, indicators as function of the negative stiffness $-k_l$, with $k_n = 2 \times 10^9$ N/m³.

Figure 7: Effect of the damping coefficient σ on the indicator I_{ave} . The TMD Stiffness is $k_l = 500$ N/m, the NES Stiffness $k_n = 2 \times 10^9$ N/m³, and the BNES Stiffnesses are $k_n = 2 \times 10^9$ N/m³, $k_l = -300$ N/m. For all the absorbers, the mass ratio is $\epsilon=0.1$

by a certain coefficient, is well fitted with the variation of the indicator I_{ω_2} . Hence, as a direct conclusion, in order to obtain an optimal reduction of a given mode, the linear or nonlinear dampers should be located at a local maximum of the given mode described by the shape function.

Considering the combined effects of the low frequency modes involved below the cut-on frequency, the value of average performance indicator I_{ave} exhibits the variation depicted in Fig. 8(b). For all the absorbers, the optimal location lies clearly in the ABH termination (gray area) of the beam, where most of the vibration is localized. However, for practical considerations, one should keep in mind also that in this ABH area, the thickness of the ABH severely decrease from

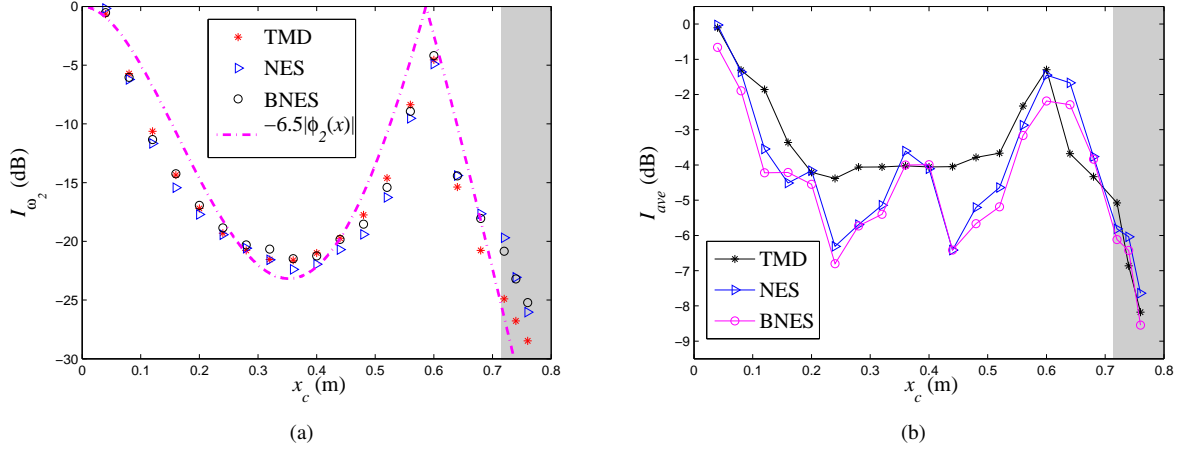

Figure 8: Effect of the position x_c of the absorbers on the values of the performance indicators. TMD stiffness is $k_l = 500\text{N/m}$, NES stiffness $k_n = 2 \times 10^9\text{N/m}^3$, and BNES stiffnesses are $k_n = 2 \times 10^9\text{N/m}^3$ and $k_l = -300\text{N/m}$, (a): value of I_{ω_2} , (d): value of I_{ave} . The damping for each vibration damper is selected as $\sigma = 0.5\text{N} \cdot \text{s/m}$ for (a) and $\sigma = 0.05\text{N} \cdot \text{s/m}$ for (b). The gray area refers to the ABH profile.

$x = 0.71\text{m}$ in the selected design. Consequently, for practical reasons it does not appear as desirable to set a damper in this region of small thickness where the beam is weaker. On the region on constant thickness, there are also two optimal positions clearly observed for the NES and BNES, at $x_c = 0.24\text{m}$ and $x_c = 0.44\text{m}$. While the TMD shows a quite flat plateau at a wider range $x \in [0.2, 0.55]\text{m}$, and is not able to produce averaged improved performance below -4dB . This important difference also shows that the nonlinear absorbers are more sensitive to the location as compared to the TMD.

Robustness to the forcing amplitude

The last parameter to be studied is the forcing amplitude. Indeed, as it is expected, the influence of this parameter is crucial for the cases of a NES and a BNES. It is well known that unlike a linear system, a nonlinear system has quite different performance at different energy levels, hence a NES or BNES that is optimally designed at one energy level might lose its effectiveness at another energy level, and vice versa. On the other hand, for a NES, an energy barrier exists for activating targeted energy transfer, making the NES generally not able for effective vibration suppression in too small vibration amplitudes, while a BNES is known to have a smaller energy barrier. Thus the effect of forcing amplitude becomes to be of special significance for evaluating the performance of these vibration absorbers.

For forcing amplitude A increases from 0.01 to 100N , the variations of I_{ω_2} and I_{ave} are shown in Fig. 9. The performances of TMD (black), NES (blue) and BNES (red) are then compared for two different values of parameters, where the solid lines refer to the case where the optimal parameters in each strategy, while the dashed lines show how they behave in a weak damping case with internal damping $\sigma = 0.05$. Indeed, it has appeared interesting to show this case since the optimal damping value is very large and probably difficult to implement in a practical situation.

Major differences could be found for the three absorbers on the effect of forcing amplitude. As it can be expected, the TMD is always independent to the amplitude: the indicator at all excitation level remains the same. On the other hand, the performances of the NES or the BNES are highly relevant to the amplitude, in Fig. 9(a), a energy barrier at 0.1N could be observed for the NES. Below this barrier, the performance of I_{ω_2} is weak and it starts to increase to meet an optimal performance around 2.5N . The performance is deteriorated at very large amplitudes. Similar conclusion is also evidenced for the average performance I_{ave} in Fig. 9(b). When adding a negative stiffness in the NES, representing a BNES, the performance at the low amplitude level that limited by the energy barrier is improved. Finally, at very high excitation level, the performance of NES and BNES are similar, and both ineffective.

In a summary all these results show that all the proposed solutions, if appropriately designed and tuned, are able to achieve a clear broadband vibration mitigation.

Conclusion

Aiming at improving the low frequency performance of a beam equipped with an ABH termination three different types of vibration absorbers (TMD, NES and BNES) have been proposed and simulated numerically. The main results confirm that all the proposed vibration absorbers, despite being linear or nonlinear, once appropriately designed, could be effective to reduce the low frequency resonance peaks in the ABH beam with a reduction at more than 10dB .

The parametric effect in each method is also discussed. The values of the stiffnesses (linear and non-linear) play the most important role for the performance of each absorber and it should be carefully designed according to different applications. On the other hand, at weak damping level, NES and BNES outperform the TMD, but for large values of the damping, they behave linearly and all the three absorbers exhibit similar performances. The investigation on the location illustrates that whatever the absorber is, its optimal performance for a single resonance modes lies in the local maximum of the targeted

Solid line: computation with the optimal parameters, dashed line: comparison in the weak damping case. dashed black: TMD with $k_l = 500\text{N/m}$ and weak damping $\sigma = 0.05\text{N} \cdot \text{s/m}$; solid black: TMD with optimized parameters $\sigma = 2\text{N} \cdot \text{s/m}$ and $k_l = 500\text{N/m}$; dashed blue: NES with $k_n = 2 \times 10^9\text{N/m}^3$ and weak damping $\sigma = 0.05\text{N} \cdot \text{s/m}$; solid blue: NES with optimized parameters $\sigma = 2\text{N} \cdot \text{s/m}$ and $k_n = 2 \times 10^9\text{N/m}^3$; dashed red: BNES with $k_n = 2 \times 10^9\text{N/m}^3$, $k_l = -300\text{N/m}$, and weak damping $\sigma = 0.05\text{N} \cdot \text{s/m}$; solid red: BNES with optimized parameters $\sigma = 2\text{N} \cdot \text{s/m}$, $k_l = -300\text{N/m}$, and $k_n = 2 \times 10^9\text{N/m}^3$;

mode function.

A Robustness study to the forcing amplitude demonstrates that while a TMD with linear behavior is always independent on the vibration level, the NES and BNES could be strongly dependent on the forcing amplitude. A NES is generally effective only at a moderate excitation level, and its performance is deteriorated at low and high amplitude levels. Hence for a robustness point of view, a TMD is better than the NES. Using a BNES improves a lot the performance at low amplitude level, but the performance at high amplitude level stays also ineffective.

Resonant Triads of Acoustic-Gravity Waves in Shallow Water

Evan Ricketts* and Usama Kadri†

*School of Engineering, Cardiff University, Cardiff, CF24 3AA, UK

†School of Mathematics, Cardiff University, Cardiff, CF24 4AG, UK

Summary. We consider the interaction of wave disturbances for shallow water of uniform depth. When we allow for compressibility effects in the linear theory, acoustic waves are assumed to be decoupled from free-surface gravity waves due to their disparity in propagation. However, it is possible to have energy exchange between acoustic and gravity wave modes given a non-linear interaction through a resonating triad. In this study, we analyse the case of a single gravity wave and two counter propagating acoustic modes which are of comparable length scales, but differing temporal scales. We derive amplitude evolution equations to describe the cyclic exchange of energy they exhibit through asymptotic methods, and implement them numerically to gain insight into the energy exchange of the triad with respect to the steepness of the waves. We find that the interaction allows a periodic exchange of energy in the triad where the steepness parameter is proportional to the a magnitude and inversely proportional to the period.

Introduction

In classical water-wave theory, the effects of compressibility are ignored, which stems from the idea that acoustic waves are essentially decoupled from free-surface waves. This assumption can be rationalised for the linear theory due to the speed of sound in water exceeding that of the maximum phase speed of surface waves, thus giving rise to differing spatial and/or temporal scales in the acoustic modes, and a somewhat decoupled system. However, when considering the non-linearity of the two types of waves, this assumption may not be as well justified. In a seminal paper by Longuet-Higgins [1], it has been shown that quadratic interactions of surface gravity waves can excite compression modes when we consider water of finite depth. It was argued that the formulation of oceanic microseisms could be due to such nonlinear coupling. Through studying quadratic interactions of two counter propagating wave trains of the same frequency, the behaviour was not in keeping with the classical theory, due to a non-decaying pressure component. Accounting for compressibility gave rise to resonance in the second order when an acoustic mode had double the frequency of the surface wave. Thus, the effects of compressibility must be considered to allow for this non-decaying component.

In this work we consider a non-linear coupling of acoustic and gravity waves in water of finite depth, and their interaction through a resonating triad. In recent years, numerical evidence has been presented that the resonant behaviour seen in Longuet-Higgins (1950) is a particular example of a resonant triad for two surface waves travelling in opposing directions and a propagating acoustic wave mode[2]. Also shown was that the amplitude of the free acoustic-gravity wave which was generated at resonance, or near-resonance conditions, was significantly larger than that of the bound acoustic-gravity wave, being generated far from resonance conditions. It was argued that the resonating triad amplitudes should be governed by a system of ordinary differential equations, and evolve in time, being governed by amplitude evolution equations of the same form as that of a standard resonant triad, see [3]. Following this, asymptotic theory was developed for resonant triad interactions concerning acoustic-gravity waves, taking waves of comparable temporal but differing spatial scales[4]. As Kadri and Stiassnie (2013)[2] suggested, it was shown that there is a resonance interaction between a given triad of two opposing gravity waves and a long-crested acoustic wave. Due to the interaction time scale being longer than that of a standard resonant triad, cubic terms were needed to display the wave self-interaction. What followed later was the derivation of evolution equations through asymptotic methods for both the acoustic wave and both gravity waves[4].

In the following we proceed with a similar approach as Kadri and Akylas, (2016)[4], but consider a triad of two counter-propagating acoustic modes, and a single gravity wave. In light of this, we consider differing temporal, but comparable spatial scales of the acoustic-gravity modes, and use multiple scale analysis to derive the evolution equations for the given amplitudes of the waves. Section 2 details the formulation of the the problem, deriving the governing equations and finding the dispersion relations through linearisation. Section 3 discusses the resonance conditions and the cyclic exchange of energy. Section 4 derivation for the evolution equations for a normal mode wave form, and Section 5 presents a numerical solution to the problem with results and conclusions on the interaction and its corresponding energy exchange.

Preliminaries

We look at the propagation of surface and acoustic wave disturbances in water of a constant depth h with a rigid bottom ($z = -h$), accounting for the effects of compressibility and gravity. In this setting we consider water as an inviscid barotropic fluid such that the density ρ of the fluid is solely a function of its pressure p , the motion of such fluid to be irrotational, and the speed of sound $c = (dp/d\rho)^{1/2}$ to be constant. An important parameter μ , defined as

$$\mu^2 = \frac{gh}{c^2}, \quad (1)$$

for g the gravitational acceleration, controls the effects of compressibility relative to gravity. Generally we can say that $\mu \ll 1$ due to the fact that the speed of sound in water, $c = 1.5 \times 10^3 \text{ m s}^{-1}$, and would surpass the maximal phase velocity of gravity waves $(gh)^{1/2}$.

The following analysis is focused on nonlinear interactions of a single gravity wave mode with two acoustic wave modes, all of similar spatial but differing temporal scales. The temporal disparity arises from the frequency of the gravity wave being much smaller than that of the acoustic waves. To interpret μ , we can take $\tau_{ac} \sim h/c \implies \tau_{gr} \sim (\lambda/g)^{1/2}$, where τ_{ac} is the acoustic time scale and τ_{gr} the gravity time scale. If we take the scales to be comparable, this implies that $\tau_{ac} \sim \mu\tau_{gr}$, where μ can be thought of as the ratio of temporal scales. Thus, to introduce non-dimensional variables, we can take the time scale and length scale as $(h/g)^{1/2}$ and h respectively.

Due to the assumption of an irrotational fluid, the problem can be formulated in terms of a velocity potential $\phi(x, z, t)$ such that we have a velocity field $\mathbf{u} = \nabla\phi$. The governing equation for $\phi(x, z, t)$ within the fluid interior is determined by combining continuity with the unsteady Bernoulli equation [1, 4], such that $\phi(x, z, t)$ satisfies

$$\frac{1}{\mu^2}(\phi_{xx} + \phi_{zz}) - \phi_{tt} - \phi_z - |\nabla\phi|_t^2 - \frac{1}{2}(\phi_x|\nabla\phi|_x^2 + \phi_z|\nabla\phi|_z^2) = 0. \quad (2)$$

The standard kinematic and dynamic conditions are applicable at the free surface $z = \eta(x, t)$, and it is sufficient to satisfy these conditions up to third order in the perturbations for the weakly nonlinear analysis that is to follow. Once the two free-surface conditions have been expanded about $z = 0$, η can be expressed in terms of ϕ at the desired order. Thus, it is possible to obtain the boundary condition for ϕ on $z = 0$ [4]

$$\begin{aligned} \phi_{tt} + \phi_z + |\nabla\phi|_t^2 - (\phi_t(\phi_{tt} + \phi_z))_z + \frac{1}{2}\mathbf{u} \cdot \nabla(|\nabla\phi|^2) - (\phi_t|\nabla\phi|_t^2)_z \\ - \frac{1}{2}\{(\phi_{tt} + \phi_z)(|\nabla\phi|^2 - \phi_t^2)\}_z = 0 \text{ for } (z = 0) \end{aligned} \quad (3)$$

At the rigid bottom, the standard no penetration condition is derived

$$\phi_z = 0 \quad (z = -1) \quad (4)$$

We now analyse the linear problem which is responsible for the disparity in temporal scales. We can drop the nonlinear terms in (2), (3) and (4) and assume ϕ as

$$\phi = f(z) \exp\left(\frac{1}{2}\mu^2 z\right) \exp(i(kx - \sigma t)) \quad (5)$$

being the normal mode form, and seek wave modes propagating along x with wave number and frequency k and σ respectively. By substituting (5) into (2), (3) and (4), the boundary-value problem for the vertical profile $f(z)$ becomes

$$\begin{aligned} \frac{d^2 \hat{f}}{dz^2} + \Omega^2 \hat{f} &= 0, \text{ for } (-1 < z < 0) \\ -\omega^2 \hat{f} + \mu^2 \frac{d\hat{f}}{dz} + \frac{1}{2}\mu^4 \hat{f} &= 0, \text{ for } (z = 0) \\ \frac{d\hat{f}}{dz} + \frac{1}{2}\mu^2 \hat{f} &= 0, \text{ for } (z = -1) \end{aligned} \quad (6)$$

where $\Omega^2 = \omega^2 - k^2 - \frac{\mu^4}{4}$ and $\omega = \mu\sigma$. As $\mu \ll 1$, we assume the solution of this system to be oscillatory, giving us the solution

$$\hat{f} = \cos \Omega(z + 1) - \frac{\mu^2}{2\Omega} \sin \Omega(z + 1). \quad (7)$$

The dispersion relation for the gravity mode can be obtained in the standard way by substitution of the solution (7) into the boundary condition, specifically at $z = 0$, such that

$$\sigma^2 = \lambda \tanh \lambda \quad (8)$$

where ignoring compressibility gives $k = \lambda$. To find a similar relation for the acoustic mode, we first notice that $\Omega^2 > 0$, implying that we can take $\Omega = \sqrt{\omega^2 - k^2} + O(\mu^4)$. Thus, by substituting our general solution back into the boundary condition at $z = 0$ as well as our expression for Ω , we have the acoustic dispersion relation

$$\omega^2 = \omega_n^2 + k^2 + \frac{\omega_n^2 - k^2}{\omega_n^2 + k^2} \mu^2 + O(\mu^4), \quad (9)$$

where $\omega_n = (n + \frac{1}{2})\pi$.

Resonance Conditions

It has been seen numerically that if we allow for the influence of compressibility, two gravity waves can interact resonantly with an acoustic-gravity wave [2, 4]. In this study, we consider if the same holds true for two counter propagating acoustic modes (k_+, ω_+) and (k_-, ω_-) , and a single gravity mode $(k, \mu\sigma)$. In order for these to form a resonant triad, they must satisfy the prescribed resonance conditions

$$(i) \quad k_+ + k_- = k \quad \text{and} \quad (ii) \quad \omega_+ - \omega_- = \mu\sigma. \quad (10)$$

as well as the appropriate dispersion relations (8), (9). Hence, we investigate said triads in the limit as $\mu \ll 1$. If we define

$$(I) \quad \omega_{\pm} = \tilde{\omega} \pm \frac{\mu\sigma}{2} \quad \text{and} \quad (II) \quad k_{\pm} = \frac{k}{2} \quad (11)$$

then by (I) and our acoustic dispersion relation (9),

$$\begin{aligned} \tilde{\omega}^2 \pm \mu\sigma\tilde{\omega} + \frac{\mu^2\sigma^2}{4} &= \omega_n^2 + k_{\pm}^2 + \frac{\omega_n^2 - k_{\pm}^2}{\omega_n^2 + k_{\pm}^2} \mu^2 + O(\mu^4) \\ \implies k_{\pm}^2 &= \tilde{\omega}^2 - \omega_n^2 \pm \mu\sigma\tilde{\omega} + O(\mu^2). \end{aligned} \quad (12)$$

Thus, if these conditions are satisfied along with the given dispersion relations, then the gravity mode can form a resonant triad with two counter-propagating acoustic waves for the given conditions. Under these conditions, we expect interactions between the resonant triad to result in a somewhat cyclic exchange of energy between the participants. As is seen in [4], due to having disparity in the temporal scales, the interaction time scale and the amplitude evolution equations will vary compared with the standard theory on resonance interactions.

Amplitude Evolution Equations

We look to derive the amplitude equations for our resonant triad. The two acoustic modes of complex amplitudes A_{\pm} with frequencies ω_{\pm} interact with a single gravity mode of amplitude S and frequency $\mu\sigma$ such that $A_+ = e^{i(k_+x - \omega_+t)}$, $A_- = e^{i(k_-x - \omega_-t)}$, and $S = e^{i(kx - \mu\sigma t)}$. Thus, under appropriate assumptions, the expanded velocity potential can be seen as

$$\begin{aligned} \varphi &= \epsilon \{ A_+(X, T) \cos \omega_n(z+1) e^{i(k_+x - \omega_+t)} + c.c. \} \\ &+ \epsilon \{ A_-(X, T) \cos \omega_n(z+1) e^{i(k_-x - \omega_-t)} + c.c. \} \\ &+ \epsilon \{ S(X, T) \cosh \lambda(z+1) e^{i(kx - \epsilon^{\frac{1}{2}}\sigma t)} + c.c. \} + \dots \end{aligned} \quad (13)$$

where $X = \epsilon x$, $\lambda^2 = k^2 - \mu^2\sigma^2$ and $c.c.$ is the complex conjugate. The amplitudes depend on the "slow" time $T = \epsilon t$, where the wave steepness $0 < \epsilon \ll 1$ is related to μ as $\mu = \epsilon^{\frac{1}{2}}$. We begin by substituting (13) into our governing equations (2) through (4), and collect terms based on those which are proportional to $e^{i(kx - \mu\sigma t)}$ and $e^{i(k_+x - \omega_+t)}$. By doing this, we are left with terms which contribute towards resonance in the form of a reduced boundary-value problem. We then formulate a solvability condition based on this, whereby the amplitude evolution equations will follow. We start with the gravity mode by collecting terms which are proportional to $e^{i(kx - \mu\sigma t)}$, and impose a correction to (13) of leading order $O(\epsilon^{\frac{5}{2}})$ of the form

$$\epsilon^{\frac{5}{2}} \{ F(X, z, T) \exp \{ i(kx - \epsilon^{\frac{1}{2}}\sigma t) \} + c.c. \}, \quad (14)$$

such that F satisfies the boundary-value problem

$$\begin{aligned} \epsilon^{\frac{5}{2}} F_{zz} - k^2 \epsilon^{\frac{5}{2}} F &= R_1 \quad \text{for } (-1 < z < 0) \\ \epsilon^{\frac{5}{2}} F_z &= R_2 \quad \text{for } (z = 0) \\ F_z &= 0 \quad \text{for } (z = -1) \end{aligned} \quad (15)$$

where

$$\begin{aligned} R_1 &= -2i\epsilon k \frac{\partial S}{\partial X} \cosh \lambda(z+1) - 2i\epsilon^{\frac{5}{2}} \sigma \frac{\partial S}{\partial T} \cosh \lambda(z+1) - \epsilon^2 \sigma^2 S \cosh \lambda(z+1) + \epsilon \lambda S \sinh \lambda(z+1) \\ &+ 2i\epsilon^{\frac{5}{2}} k_+ k_- \sigma A_+ A_- \cos^2 \omega_n(z+1) - 2i\epsilon^{\frac{5}{2}} \omega_n^2 \sigma A_+ A_- \sin^2 \omega_n(z+1) \\ R_2 &= 2i\epsilon^{\frac{5}{2}} \sigma \frac{\partial S}{\partial T} \cosh \lambda + \epsilon^2 \sigma^2 S \cosh \lambda - \epsilon \lambda S \sinh \lambda + 2i\epsilon^{\frac{5}{2}} \omega_n^2 \sigma A_+ A_- \end{aligned} \quad (16)$$

The solution to the corresponding homogeneous system is $\cosh kz$, so we must be able to employ a certain solvability condition for the in-homogeneous problem (15). Here, we multiply both sides of the field equation by $\cosh kz$ and integrate over the whole domain $-1 < z < 0$, such that

$$kR_2 + R_1 \Big|_{z=-1} \sinh k = k \int_{-1}^0 R_1 \cosh kz \, dz. \quad (17)$$

Finally, we obtain the evolution equation for the gravity mode by substituting our expressions for R_1 and R_2 into the solvability condition (17), resulting in

$$\frac{\partial S}{\partial T} - \frac{k}{\epsilon^{\frac{3}{2}}} \left(\frac{\sigma}{\lambda^2 - \sigma^2} \right) \frac{\partial S}{\partial X} = -\frac{\sigma S}{2i\epsilon^{\frac{3}{2}}} \left\{ \epsilon\sigma^2 - \frac{\lambda^2}{\lambda^2 - \sigma^2} \right\} + \frac{A_+ A_-}{\lambda \cosh \lambda - \sinh \lambda} \left\{ \Psi + (\sinh \lambda - k)\omega_n^2 - \frac{k^2}{4} \sinh \lambda \right\} \quad (18)$$

where $\Psi = \frac{k^4 + 2k^2\omega_n^2}{4k^2 + 16\omega_n^2} - \frac{2\omega_n^4}{2k^2 + 8\omega_n^2}$. Similarly, we employ a correction of

$$\epsilon^2 \{ F(X, z, T) \exp\{i(k_{\pm}x - \omega_{\pm}t)\} + c.c. \} \quad (19)$$

so that for leading order of $O(\epsilon^2)$, we are left with acoustic-gravity interaction and cubic acoustic self interaction terms. Here, the solution to the homogeneous system is $\cos \omega_n(z+1)$, and we can formulate the solvability condition in a similar way as above. After multiplication by the homogeneous solution, and integrating over the domain, we arrive at the condition

$$-\frac{\omega_n}{\omega_{\pm}^2} R_4(-1)^n = \int_{-1}^0 R_3 \cos \omega_n(z+1) dz \quad (20)$$

where

$$\begin{aligned} R_3 = & -2i\epsilon k_{\pm} \frac{\partial A_{\pm}}{\partial X} \cos \omega_n(z+1) - 2i\epsilon^2 \omega_{\pm} \frac{\partial A_{\pm}}{\partial T} \cos \omega_n(z+1) - \epsilon \omega_n A_{\pm} \sin \omega_n(z+1) \\ & + 2i\epsilon^2 k_{\mp} k \omega_{\pm} A_{\mp} S \cos \omega_n(z+1) \cosh \lambda(z+1) \\ & + 2i\epsilon^2 \omega_n \omega_{\pm} \lambda A_{\mp} S \sin \omega_n(z+1) \sinh \lambda(z+1) = 0, \\ R_4 = & \epsilon \omega_n A_{\pm} (-1)^n - 2i\epsilon^2 \omega_n \omega_{\pm} \lambda A_{\mp} S (-1)^n \sinh \lambda = 0. \end{aligned} \quad (21)$$

Again, we compute the necessary integrals and rearrange to give us the acoustic evolution equation

$$\frac{\partial A_{\pm}}{\partial T} + \frac{k_{\pm}}{\epsilon \omega_{\pm}} \frac{\partial A_{\pm}}{\partial X} = \frac{\omega_{\pm}^2 - 2\omega_n^2}{2i\epsilon \omega_{\pm}^3} A_{\pm} - 2 \sinh \lambda \Phi A_{\mp} S \quad (22)$$

where

$$\Phi = \frac{4\omega_n^4 \lambda + \omega_n^2 \lambda^3 - \omega_{\pm}^2 \omega_n^2 \lambda}{8\omega_{\pm}^2 \omega_n^2 + 2\omega_{\pm}^2 \lambda^2} - \frac{3\lambda^3 - 8\omega_n^2 \lambda}{32\omega_n^2 - 8\lambda^2}, \quad (23)$$

Simulation and Discussion

As we now have our evolution equations, we want to gain a qualitative understanding of the interaction they convey, and whether there is periodic exchange of energy. The equations derived were solved numerically in MATLAB by an explicit Runge–Kutta method. By making use of the acoustic and gravity dispersion relations, we are able to define the variables needed in the solution process. We can then run the analyses for various initial conditions and see the temporal evolution of the triad interaction. We note that all waves are assumed to be of Gaussian form.

Figures 1 and 2 show the interaction where we assume no spatial influences. It can be seen quite clearly in figure 1 how the generation of the gravity wave plays out, and the cyclic exchange of energy, where the change in amplitude is periodic. There is an overall increase and decrease in the amplitude of the acoustic modes which is sinusoidal. The gravity wave quickly grows and decays, transferring its energy back and forth between the two acoustic modes. Similarly in figure 2, when all waves begin with amplitude of 1, we can see how the energy is shared amongst the triad. When the amplitude of the gravity wave is high, the energy has been transferred, so that of the acoustic is lower, and vice versa. In both cases, the acoustic waves mirror each other and as such the temporal evolution has been given for a single acoustic mode.

The variable ϵ is pivotal to the way the interaction plays out. It represents the steepness of the waves, so taking ϵ higher will result in greater energy transfer to the gravity wave. In the case of figure 1, $\epsilon \sim 0.3$, which is why the maximum amplitude of the generated gravity wave does not grow above 0.15, whereas, when taking a larger epsilon in the case of figure 2, the maximum amplitude grows above 1.

We now want to analyse the energy exchange in terms of the value of the steepness, ϵ . We again look at the case where the gravity wave is generated, relating to the initial conditions $S(0) = 0$ and $A_{\pm}(0) = 1$. It is justifiable to take the two acoustic modes as equal for simplicity. The other parameters such as σ and ω_{\pm} are prescribed by the overall set up of the problem and are related through the acoustic and gravity dispersion relations as before. Under these initial conditions, we have the conservation law

$$\int_{-\infty}^{\infty} (|S|^2 + 2|A|^2) dX = 2 \int_{-\infty}^{\infty} |S_0|^2 dX \quad (24)$$

where the initial condition $S_0 \rightarrow 0$ as $X \rightarrow \pm\infty$. In our computation we took the initial condition $S_0 = \exp\{-X^2\}$, the Gaussian wave packet. Then we can see from (24) that

$$E(T) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} |S|^2 dX \quad (25)$$

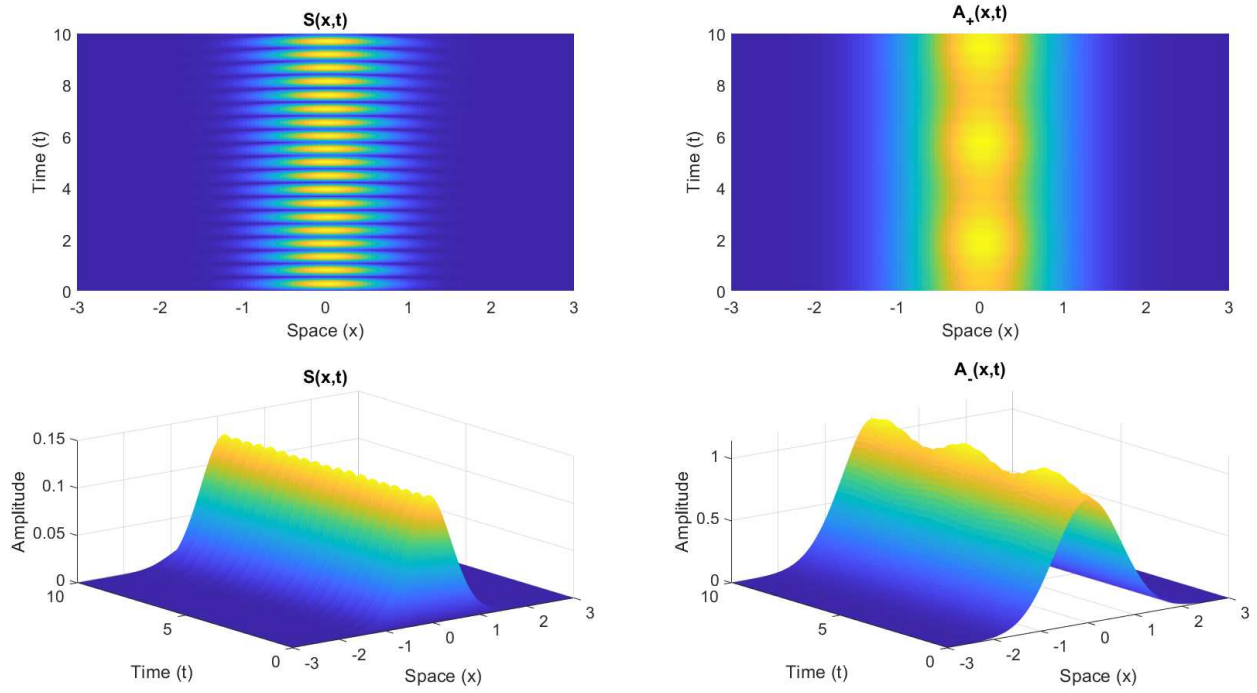

Figure 1: Generation of gravity wave with no spatial influences

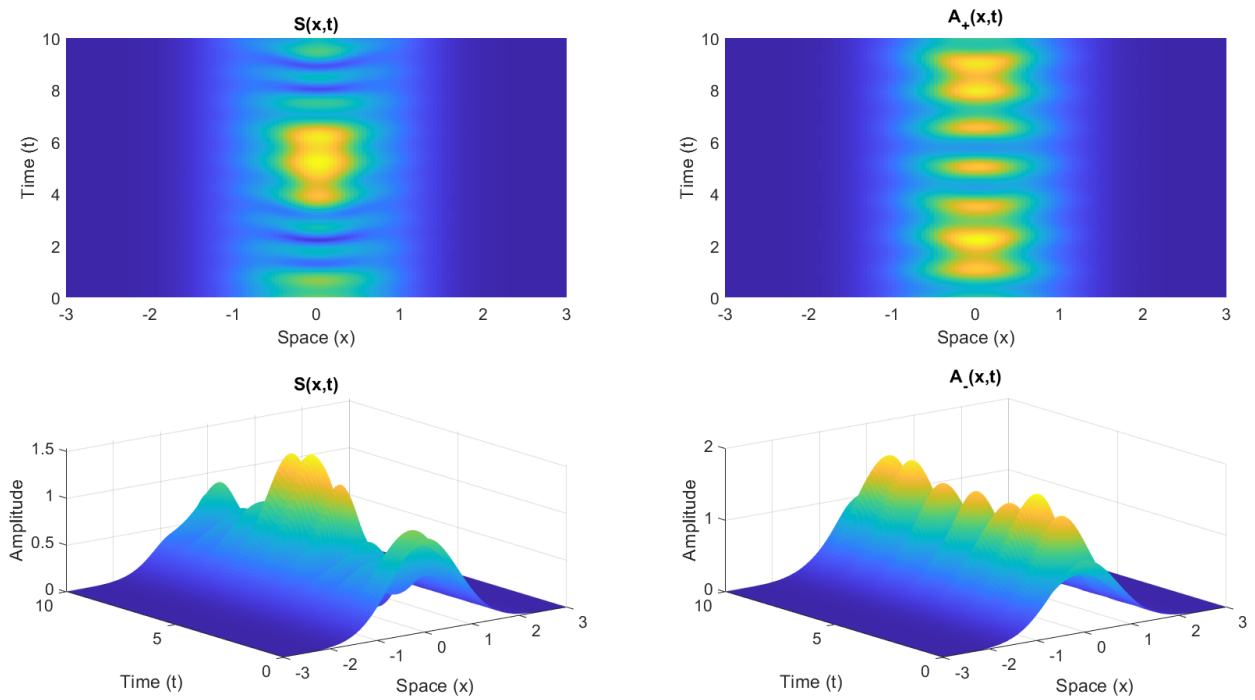

Figure 2: Interaction when all waves begin with amplitude 1 for non-spatial dependencies

 Figure 3: Transfer of energy to the gravity mode over time for varying small ϵ

 Figure 4: Transfer of energy for increasing ϵ

is the energy of the gravity wave generated. Implementing (25) numerically, we observe how increasing ϵ results in a larger amount of energy transferred to the generated gravity mode over time as shown in figure 3. Here, we used the outlined conditions above, and took small values of ϵ . As $\epsilon \rightarrow 0$, the amount of energy transferred becomes smaller, but much more frequent in its exchange, as indicated by $\epsilon = 0.1$ compared with $\epsilon = 0.5$. The periodic behaviour of curves is representative of the energy transfer between the acoustic modes and the generated gravity wave.

It is also worth analysing the rate and magnitude of energy exchange as $\epsilon \rightarrow 1$, which is shown in figure 4. As ϵ increases, we begin to have infinite periodicity occurring, where the value of the energy plateaus. This is due to our assumptions upon ϵ , mainly being that it can not be $O(1)$. So as we approach the value of 1, our resonance condition breaks down, and less energy is able to be exchanged back to the acoustic mode from the gravity wave.

Conclusion

We have derived spatial and temporal evolution equations in the case of a resonant triad of acoustic-gravity waves, and using these, have been able to analyse the energy exchange between them. Similarly to what was observed in Kadri and Akylas (2016), triad interaction of this nature differs from a standard resonant triad due to the disparity of temporal scales for the given waves. Through the presented asymptotic analysis and numerical implementation, the cyclic exchange of energy expected in a conventional resonant triad is observed, resulting from cubic self-interaction terms that were preserved when taking certain leading order. These terms directly impact the amplitude-dependent change in gravity wave frequency and the exchange of energy from surface to acoustic waves.

Similarly, the importance of the steepness parameter ϵ has been highlighted, heavily changing the interaction and effecting the cyclic exchange of energy. As the steepness increases we see larger periodicity with more energy being exchanged in each cycle. Further analysis should be conducted to investigate its effects for alternative initial conditions. Here, the generation of a single gravity wave was observed, but this choice was arbitrary. Further to this, the relationship between the interaction time and amplitudal growth would be worth investigating, as we would then have a wider picture of how

the given interaction occurs. If we were able to analyse this interaction time, and find its relationship with the amount of energy transferred, then we would have much more control over the given interaction.

Abstract

In this study, an acoustic resonator – a bass trombone – with multiple resonances coupled to an exciter – the player's lips – with one resonance is modelled by a multidimensional dynamical system, and studied using the continuation and bifurcation software AUTO [1]. Bifurcation diagrams are explored with respect to the blowing pressure, with focus on the minimal blowing pressure giving stable periodic regime.

Brass instruments can be described thanks to both linear and nonlinear mechanisms: a localised nonlinear element (the lips' valve effect) excites a passive linear acoustic multimode element (the musical instrument, usually characterised by its input impedance in the frequency domain); the latter acoustic resonator in turn exerts a retroaction on the former mechanical resonator. Such musical instruments are self-sustained oscillators: they generate an oscillating acoustic pressure (the note played) from a static overpressure in the player's mouth (the blowing pressure).

A brass instrument having N acoustic modes and M mechanical modes can be mathematically modelled as an autonomous nonlinear dynamical system of dimension $2(N+M)$ [2, 3]. On the one hand, the corresponding acoustic input impedance of the resonator is defined in the Fourier domain by the ratio between the pressure and the volume flow at the input of the instrument :

$$P(\omega) = Z(\omega)U(\omega) \quad (1)$$

with ω the angular frequency. The modulus of Z is shown figure 1 for a bass trombone. Since AUTO requires equations to be expressed in the time domain, a modal decomposition is performed on the measured input impedance of a bass trombone in order to obtain an analytical form for $Z(\omega)$, thus allowing equation (1) to be expressed in the time domain by taking its inverse Fourier transform.

On the other hand, the nonlinear behaviour of the lips can be modelled by the relation between the volume flow $u(t)$ and the acoustic pressure $p(t)$:

$$u(t) = wh(t)\Theta(h)\operatorname{sgn}(p_m - p(t))\sqrt{\frac{2|p_m - p(t)|}{\rho}} \quad (2)$$

with w and $h(t)$ the width and the height of the lips' aperture respectively, p_m the mouth pressure, and ρ the air density. The Heaviside distribution Θ accounts for the fact that lips cannot interpenetrate: as soon as the lips touch ($h = 0$), the volume flow is forced to zero. The sign function sgn accounts for the possibility of having an airflow going from the instrument into the player's mouth, in the absence of experimental evidence to the contrary.

Eventually, $h(t)$ can be linked to $p(t)$ to close the system by the following equation, which accounts for the resonance of the lips :

$$\ddot{h} + \frac{\omega_l}{Q_l}\dot{h} + \omega_l^2(h - h_0) = \frac{p_m - p}{\mu} \quad (3)$$

with ω_l and Q_l being respectively the frequency resonance and the quality factor of the lips, and μ the lips' mass per unit area.

In this study, the input impedance of the brass instrument addressed – a bass trombone – will be described by $N = 12$ acoustic modes, and the exciter – the player's lips – will be assumed to have only one mechanical mode ($M = 1$), resulting in a 26-dimensional dynamical system. It is worth noting that this minimal brass model does not account for the « brassy » sound produced by a trombone, which requires a nonlinear description of sound propagation in the instrument to be addressed.

The behaviour of the instrument can be first studied close to its static equilibrium using the Linear Stability Analysis (LSA), so as to determine if oscillatory regimes (corresponding to the instrument producing a sound) could potentially arise from destabilised equilibrium eigenvalues of the linearised system. Such an approach has already been carried out in [4], especially to characterise the ease of playing of a brass instrument. Indeed, the latter can be related as a first approximation to the linear threshold pressure (figure 2a), since the lower the threshold pressure, the lower the physical effort the player has to make to play a note.

Figure 1: Modulus of the input impedance of a bass trombone vs. frequency. 12 resonances (orange dots) can be seen, corresponding to $N = 12$ acoustic modes.

for $n > 5$, thus implying $p_{\text{thresh}}^{\text{osc}} = p_{\text{thresh}}^{\text{lin}}$ for these.

The ease of playing is then assessed in more depth through the study of the dynamic behaviour of the instrument, using the continuation and bifurcation software AUTO [1] as in [5] or using an alternative continuation method (Manlab) as in [6], thanks to which bifurcation diagrams are explored with respect to the blowing pressure for instance. The oscillation threshold pressure can then be inferred from such a diagram (figure 2b). It is worth noticing that the oscillation threshold pressure is not necessarily equal to the linear threshold pressure, as it is the case on figure 2b. It then results in an actual threshold pressure lower than the linear threshold pressure given by the LSA (figure 2c), hence the need to take into account the dynamic behaviour of the system. Also, the n^{th} regimes are all direct Hopf bifurcations

Figure 2: Linear Stability Analysis (left), bifurcation diagrams (middle), and comparison of threshold pressure values given by the LSA and AUTO (right), corresponding to the case of the input impedance of a bass trombone shown figure 1. Left: top and bottom plots represent respectively the linear threshold pressure and frequency vs. the lip frequency. The orange circles identify the value of f_l corresponding to a local minimum of the curve (easiest note to obtain), and dotted lines represent the resonance frequencies of the input impedance for comparison. Middle: Top and bottom plots represent respectively the maximum amplitude of the periodic oscillation branches and the frequency of the corresponding periodic solutions vs. the blowing pressure. Right: top and bottom plots represent respectively the threshold pressures and frequencies given by the LSA and AUTO vs. the lip frequency. As for figure 2a, the circles identify the value of f_l corresponding to a local minimum of a curve.

In the present study, the effects of the inclusion of the instrument's dynamic behaviour on the minimum threshold pressure is focused on, so as to enrich the results given by the Linear Stability Analysis.

Fast Explicit Algorithms for Hamiltonian Numerical Integration

Stefan Bilbao* and Michele Ducceschi†

*Acoustics and Audio Group, University of Edinburgh, Edinburgh UK

†Department of Industrial Engineering, University of Bologna, Bologna, Italy

Summary. Numerical integration methods for Hamiltonian systems are of importance across many disciplines, including musical acoustics, where many systems of interest are very nearly lossless. Of particular interest are methods possessing a conserved pseudoenergy. Though most such methods have an implicit character, an explicit method was proposed recently by Marazzato et al. The proposed method relies on a continuous integration which must be performed exactly in order for the conservation property to hold—as a result, it holds only approximately under numerical quadrature. Here, we show an explicit scheme for Hamiltonian integration, with a different choice of pseudoenergy, which is exactly conserved. Most importantly, a fast implementation is possible through the use of structured matrix inversion, and in particular Sherman Morrison inversion of the rank 1 perturbation of a matrix. Applications to the cases of fully nonlinear string vibration, and to the Föppl-von Kármán system describing large amplitude plate vibration are illustrated. Computation times are on par with the simplest non-conservative methods, such as Störmer integration.

Introduction

Numerical integration methods that preserve an invariant energy-like quantity (or pseudoenergy) form part of the larger family of geometric numerical integration methods [1]. In a recent article [2], an explicit method for Hamiltonian integration was presented, incorporating a conserved pseudo-energy. The method relies, however, on a continuous integration, meaning that pseudoenergy is only preserved approximately due to discretisation error.

New methods, relying on potential energy quadratisation are suitable for systems under more restrictive conditions (non-negativity of the potential energy) [3]. In this paper, it will be shown that such methods can be made fully explicit through structured matrix inversion techniques, and in particular, Sherman Morrison inversion for matrices under a rank-1 perturbation. This allows for extremely efficient numerical solution, while maintaining pseudo-energy conservation to machine accuracy. In particular, no full linear system solutions are required to advance the solution, in contrast with what has been presented for other methods based on quadratization [3]. Numerical stability is ensured, through the enforced non-negativity of the numerical energy.

Two examples, that of fully nonlinear string vibration, and the nonlinear vibration of a thin plate according to the Föppl-von Kármán system are presented, illustrating good numerical behaviour, and acceleration relative to other energy conserving designs. In a companion paper [4], the realistic case of piano string vibration will be broached in detail, as well as the very important topic of the possibility of the shift in the potential energy of the system in order to improve convergence rates.

Hamiltonian Systems and Quadratisation

Consider a Hamiltonian $H(\mathbf{p}, \mathbf{q})$ of the form:

$$H(\mathbf{p}, \mathbf{q}) = \frac{1}{2} \mathbf{p}^T \mathbf{M}^{-1} \mathbf{p} + V(\mathbf{q}) \quad (1)$$

Here, $\mathbf{p}(t)$ and $\mathbf{q}(t)$ are $N \times 1$ vectors and functions of time $t \geq 0$. $\mathbf{M} > 0$ is a constant symmetric $N \times N$ mass matrix (for simplicity constrained here to be diagonal). \mathbf{p} and \mathbf{q} have the interpretation of generalized momentum and position, respectively. Hamilton's equations [5] follow as

$$\mathbf{M} \dot{\mathbf{q}} - \mathbf{p} = \mathbf{0} \quad \dot{\mathbf{p}} + \nabla V = \mathbf{0} \quad (2)$$

Here, ∇ is the gradient with respect to \mathbf{q} , and dots indicate time differentiation. Equations (2) require initialisation through $\mathbf{p}(0) = \mathbf{p}_0$ and $\mathbf{q}(0) = \mathbf{q}_0$.

Under the constraint that $V \geq 0$, one may write, using $\psi = \sqrt{2V}$,

$$H(\mathbf{p}, \mathbf{q}) = \frac{1}{2} \mathbf{p}^T \mathbf{M}^{-1} \mathbf{p} + \frac{1}{2} \psi^2 \quad (3)$$

Now, Hamilton's equations may be written as

$$\mathbf{M} \dot{\mathbf{q}} - \mathbf{p} = \mathbf{0} \quad \dot{\mathbf{p}} + \psi \mathbf{g} = \mathbf{0} \quad \dot{\psi} = \mathbf{g}^T \dot{\mathbf{q}} \quad (4)$$

where the intermediate variable $\mathbf{g} \triangleq \nabla \psi$ has been introduced. Such a quadratisation of the potential energy has appeared recently in the context of port-Hamiltonian methods [6, 7], and in finite difference schemes modeling collisions [8] and for string vibration under nonlinear conditions [9], and in other areas such as the modeling of binary fluids [10].

Notice that the form of the Hamiltonian in (1) is not the most general available, and thus some restrictions are placed on the range of applications in this paper. First, the energy is quadratic in the momentum \mathbf{p} , and thus the resulting dynamics are linear in \mathbf{p} —a very common choice across many application areas in structural vibration. Second, the potential energy V is constrained to be non-negative—a condition also common in structural vibration, but violated in other systems, such as the N -body problem under a gravitational potential. The numerical stability property of the methods presented in this paper hinges on these two restrictions.

A Pseudo-energy Conserving Explicit Fast Algorithm

Consider now a time-interleaved scheme for the dynamical system in (4):

$$\mathbf{q}^{n+1} = \mathbf{q}^n + k\mathbf{M}^{-1}\mathbf{p}^{n+\frac{1}{2}} \quad \mathbf{p}^{n+\frac{1}{2}} = \mathbf{p}^{n-\frac{1}{2}} - \frac{k}{2} \left(\psi^{n+\frac{1}{2}} + \psi^{n-\frac{1}{2}} \right) \mathbf{g}^n \quad \psi^{n+\frac{1}{2}} = \psi^{n-\frac{1}{2}} + \frac{1}{2} (\mathbf{g}^n)^T (\mathbf{q}^{n+1} - \mathbf{q}^{n-1}) \quad (5)$$

It is defined for discrete time sequences \mathbf{q}^n , $\mathbf{p}^{n+\frac{1}{2}}$ and $\psi^{n+\frac{1}{2}}$, for integer n , representing approximations at times $t = nk$ to $\mathbf{q}(t)$ and at times $t = (n + \frac{1}{2})k$ to $\mathbf{p}(t)$ and $\psi(t)$. Here, k is the time step. \mathbf{g}^n may be calculated explicitly by evaluating the analytic gradient of ψ at \mathbf{q}^n . The scheme (5) conserves the following pseudoenergy:

$$H^{n+\frac{1}{2}} = \frac{1}{2} \left(\mathbf{p}^{n+\frac{1}{2}} \right)^T \mathbf{M}^{-1} \mathbf{p}^{n+\frac{1}{2}} + \frac{1}{2} \left(\psi^{n+\frac{1}{2}} \right)^2 = \text{constant} \quad (6)$$

and thus $H^{n+\frac{1}{2}} = H$ is a constant for all n . It is non-negative, implying unconditional stability, as well as bounds on $\mathbf{p}^{n+\frac{1}{2}}$ for all n . In particular, (6) above implies that

$$\|\mathbf{p}^{n+\frac{1}{2}}\| \leq \sqrt{\frac{2H}{\lambda_{\max}(\mathbf{M})}} \quad (7)$$

where $\lambda_{\max}(\mathbf{M})$ is the maximum eigenvalue of \mathbf{M} , and $\|\mathbf{p}^{n+\frac{1}{2}}\|$ is the L_2 norm of $\mathbf{p}^{n+\frac{1}{2}}$.

Fast Update

At first glance, the updates (5) appear to be implicit, thus requiring an iterative solver at each time step. This is not the case, however. Given \mathbf{q}^n , \mathbf{q}^{n-1} and $\psi^{n-\frac{1}{2}}$ (as well as \mathbf{g}^n , determined directly from \mathbf{q}^n), they may be consolidated into an update of the form

$$\mathbf{A}^n \mathbf{q}^{n+1} = \mathbf{b}^n \quad \mathbf{A}^n = \mathbf{M} + \frac{k^2}{4} \mathbf{g}^n (\mathbf{g}^n)^T \quad \mathbf{b}^n = 2\mathbf{M}\mathbf{q}^n - k^2 \mathbf{g}^n \psi^{n-\frac{1}{2}} - \left(\mathbf{M} - \frac{k^2}{4} \mathbf{g}^n (\mathbf{g}^n)^T \right) \mathbf{q}^{n-1} \quad (8)$$

This update, which does not require iterative solvers, can be simplified by exploiting the structure of \mathbf{A}^n , which is a rank one perturbation of a matrix with an easily computed explicit inverse (\mathbf{M}). Using the Sherman-Morrison formula [11],

$$(\mathbf{A}^n)^{-1} = \mathbf{M}^{-1} - \frac{k^2}{4} \frac{\mathbf{M}^{-1} \mathbf{g}^n (\mathbf{g}^n)^T \mathbf{M}^{-1}}{1 + \frac{k^2}{4} (\mathbf{g}^n)^T \mathbf{M}^{-1} \mathbf{g}^n} \quad (9)$$

For diagonal \mathbf{M} a linear system solution requires $O(N)$ operations (and for full \mathbf{M} , a linear system involving \mathbf{M}^{-1} must be solved, which is the same as in the case of other algorithms presented [2]).

Example: Nonlinear String Vibration

As a nontrivial example of interest in musical acoustics, consider the case of fully nonlinear string vibration including longitudinal/transverse coupling [12]. This system has been dealt with by various authors, leading to energy-conserving methods relying on nonlinear iterative solvers [13], quadratised methods requiring full linear system solution [9] as well as in the recent article by Marazzato et al. [2]. It may be written as the following (nondimensional) coupled system of PDEs:

$$\partial_t^2 u = \partial_x (\partial \mathcal{V} / \partial w_u) \quad \partial_t^2 v = \partial_x (\partial \mathcal{V} / \partial w_v) \quad w_u = \partial_x u \quad w_v = \partial_x v \quad (10)$$

Here, $u(x, t)$ and $v(x, t)$ are the longitudinal and transverse displacement of a string, defined for $x \in [0, 1]$, and $t \geq 0$. ∂_t and ∂_x represent partial differentiation with respect to x and t , respectively.

The potential energy density \mathcal{V} is defined by

$$\mathcal{V}(w_u, w_v) = \frac{1}{2} (w_u^2 + w_v^2) - \alpha \left(\sqrt{(1 + w_u)^2 + w_v^2} - 1 - w_u \right) \quad (11)$$

The complete Hamiltonian for the system is

$$H = \int_0^L \frac{1}{2} (\partial_t u)^2 + \frac{1}{2} (\partial_t v)^2 + \mathcal{V} dx \quad (12)$$

After semidiscretisation (using, e.g., basic finite difference operators to approximate spatial differentiation), a Hamiltonian ODE system of the form of (1) results. Simulation results are presented in Figure 1, under initial conditions of increasing amplitude, and illustrating pseudo-energy conservation to machine accuracy. Calculation time is comparable to that of basic explicit methods (such as, e.g., Störmer). For more details regarding the particular application to the problem of nonlinear string vibration, the reader is referred to the companion paper [4]. A key aspect not discussed here is the possibility of adding an offset, or gauge to the potential energy, which can have a significant ameliorating effect on convergence rates in the resulting numerical implementation. See [4].

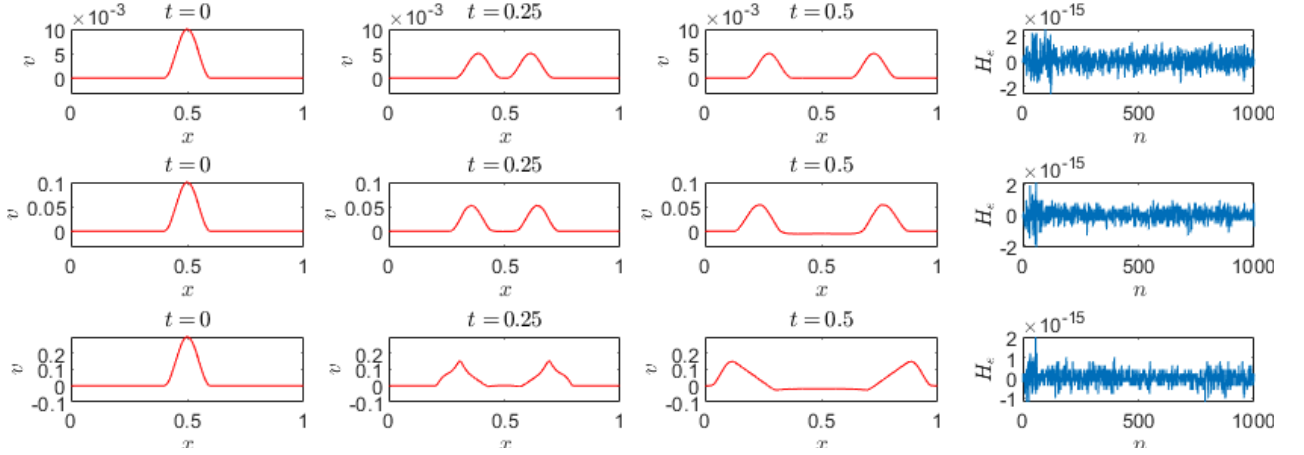

Figure 1: Wave propagation for a pseudo-energy conserving scheme for the nonlinear string system, as defined in (10), with $\alpha = 0.8$, and $k = 10^{-4}$. The string is initialised with zero initial velocity conditions, and with $u = 0$, and with v set to raised cosine distributions of increasing amplitude (top: 0.01, middle: 0.1, bottom; 0.3). At right, the relative energy variation $H_e = (H^{n+1/2} - H^{n-1/2}) / H^{1/2}$ is plotted as a function of time step n , showing energy conservation to machine accuracy (approximately 10^{-15}).

Split Forms and Numerical Methods

In some cases, it can be useful to split the potential energy $V(\mathbf{q})$ as

$$V(\mathbf{q}) = V_0(\mathbf{q}) + V'(\mathbf{q}) \quad \text{where} \quad V_0(\mathbf{q}) = \frac{1}{2} \mathbf{q}^T \mathbf{K} \mathbf{q} \quad \text{and} \quad V'(\mathbf{q}) \geq 0 \quad (13)$$

for some positive definite matrix $\mathbf{K} > 0$. While the underlying dynamics are unchanged under such a splitting, it becomes possible to apply different numerical integration techniques to different parts of the problem. In particular, V_0 , a quadratic form, may encapsulate the underlying linear dynamics of a particular system, and V' additional effects due to a nonlinear mechanism.

Under the constraint that $V' \geq 0$, one may write, using $\psi = \sqrt{2V'}$,

$$H(\mathbf{p}, \mathbf{q}) = \frac{1}{2} \mathbf{p}^T \mathbf{M}^{-1} \mathbf{p} + \frac{1}{2} \mathbf{q}^T \mathbf{K} \mathbf{q} + \frac{1}{2} \psi^2 \quad (14)$$

Hamilton's equations may be written as

$$\mathbf{M} \dot{\mathbf{q}} - \mathbf{p} = \mathbf{0} \quad \dot{\mathbf{p}} + \mathbf{K} \mathbf{q} + \psi \mathbf{g} = \mathbf{0} \quad \dot{\psi} = \mathbf{g}^T \dot{\mathbf{q}} \quad (15)$$

where $\mathbf{g} = \nabla \psi$ as before.

Numerical Scheme

Consider the following time-interleaved scheme:

$$\mathbf{q}^{n+1} = \mathbf{q}^n + k \mathbf{M}^{-1} \mathbf{p}^{n+\frac{1}{2}} \quad \mathbf{p}^{n+\frac{1}{2}} = \mathbf{p}^{n-\frac{1}{2}} - k \mathbf{K} \mathbf{q}^{n-\frac{k}{2}} \left(\psi^{n+\frac{1}{2}} + \psi^{n-\frac{1}{2}} \right) \mathbf{g}^n \quad \psi^{n+\frac{1}{2}} = \psi^{n-\frac{1}{2}} + \frac{1}{2} (\mathbf{g}^n)^T (\mathbf{q}^{n+1} - \mathbf{q}^{n-1}) \quad (16)$$

The update follows, from the extension of (8), as

$$\mathbf{A}^n \mathbf{q}^{n+1} = \mathbf{b}^n \quad \mathbf{A}^n = \mathbf{M} + \frac{k^2}{4} \mathbf{g}^n (\mathbf{g}^n)^T \quad \mathbf{b}^n = (2\mathbf{M} - k^2 \mathbf{K}) \mathbf{q}^n - k^2 \mathbf{g}^n \psi^{n-\frac{1}{2}} - \left(\mathbf{M} - \frac{k^2}{4} \mathbf{g}^n (\mathbf{g}^n)^T \right) \mathbf{q}^{n-1} \quad (17)$$

and again, a fast implementation is possible using Sherman Morrison, through the explicit inversion of \mathbf{A}^n .

This scheme now possesses the conserved numerical energy:

$$H^{n+\frac{1}{2}} = \frac{1}{2} \left(\mathbf{p}^{n+\frac{1}{2}} \right)^T \mathbf{M}^{-1} \mathbf{p}^{n+\frac{1}{2}} + \frac{1}{2} (\mathbf{q}^{n+1})^T \mathbf{K} \mathbf{q}^n + \frac{1}{2} \left(\psi^{n+\frac{1}{2}} \right)^2 = \text{constant} \quad (18)$$

This expression, though conserved, is of indefinite sign, due to the second term. However, this term may be bounded as

$$\frac{1}{2} (\mathbf{q}^{n+1})^T \mathbf{K} \mathbf{q}^n \geq -\frac{1}{8} (\mathbf{q}^{n+1} - \mathbf{q}^n)^T \mathbf{K} (\mathbf{q}^{n+1} - \mathbf{q}^n) = -\frac{k^2}{8} \left(\mathbf{p}^{n+\frac{1}{2}} \right)^T \mathbf{M}^{-1} \mathbf{K} \mathbf{M}^{-1} \mathbf{p}^{n+\frac{1}{2}} \quad (19)$$

and thus

$$H^{n+\frac{1}{2}} \geq \frac{1}{2} \left(\mathbf{p}^{n+\frac{1}{2}} \right)^T \left(\mathbf{M}^{-1} - \frac{k^2}{4} \mathbf{M}^{-1} \mathbf{K} \mathbf{M}^{-1} \right) \mathbf{p}^{n+\frac{1}{2}} + \frac{1}{2} \left(\psi^{n+\frac{1}{2}} \right)^2 \quad (20)$$

A condition for non-negativity then follows as

$$k \leq \frac{2}{\lambda_{\max} \left(\mathbf{M}^{-\frac{1}{2}} \mathbf{K} \mathbf{M}^{-\frac{1}{2}} \right)} \quad (21)$$

where $\mathbf{M}^{\frac{1}{2}}$ is the positive matrix square root of the diagonal matrix \mathbf{M} . (If \mathbf{M} is not diagonal, but still positive definite, then the condition above may be generalized to include the unique triangular factors of \mathbf{M} .) This serves as a numerical stability condition for scheme (16). Notice that the scheme is now conditionally stable, but the stability condition depends only on the linear dynamics, and is independent of the nonlinearity. This scheme is distinct from (5), which is unconditionally stable. Indeed, beyond these two choices a family of conservative conditionally stable methods is available, depending on how the splitting of the potential energy V is carried out.

Example: The Föppl-von Kármán Equations

Consider a flat, thin plate, of thickness ξ in m, and of material characterised by Young's modulus E , in Pa, density ρ , in $\text{kg} \cdot \text{m}^{-3}$, and Poisson's ratio ν . The plate is assumed defined over a region $(x, y) \in \mathcal{D} \in \mathbb{R}^2$, and has displacement $u(x, y, t)$. High amplitude vibration of the plate is described by the The Föppl-von Kármán equations:

$$\rho \xi \Delta \partial_t^2 u = -D \Delta \Delta u + \mathcal{L}(u, F) \quad \frac{2}{E \xi} \Delta \Delta F = -\mathcal{L}(u, u) \quad (22)$$

Here, $D = E \xi^3 / 12(1 - \nu^2)$ is the flexural rigidity for the plate, and $F(x, y, t)$ is the Airy stress function, Δ is the two-dimensional Laplacian operator $\Delta = \partial_x^2 + \partial_y^2$, where ∂_x and ∂_y represent partial differentiation with respect to x and y , respectively. $\Delta \Delta$ is the biharmonic operator. The special bilinear operator \mathcal{L} is defined by

$$\mathcal{L}(f, g) = \partial_x^2 f \partial_y^2 g + \partial_y^2 f \partial_x^2 g - 2 \partial_x \partial_y f \partial_x \partial_y g \quad (23)$$

Two initial conditions, $u(x, y, 0)$ and $\partial_t u|_{x,y,t=0}$ are required; in this paper, boundary conditions are chosen to be simply supported over the boundary $\partial \mathcal{D}$ of \mathcal{D} [14].

The Hamiltonian for this system is given by

$$H = \iint_{\mathcal{D}} \frac{\rho \xi}{2} (\partial_t \xi)^2 + \frac{D}{2} (\Delta u)^2 + \frac{1}{2 E \xi} (\Delta F)^2 d\sigma \quad (24)$$

(Note that this particular form of the Hamiltonian is not the most general, but holds under simply supported conditions. It must be augmented by an additional term in the case of, e.g., free edge conditions.)

Semidiscretization

Consider the simple case of a square plate defined over $(x, y) \in [0, L]^2$, for some plate side length L . Assume also that the displacement $u(x, y, t)$ is approximated over a grid with a grid function $u_{l,m}(t)$ such that

$$u_{l,m}(t) \approx u(x = lh, y = mh, t) \quad l, m = 1, \dots, M - 1 \quad (25)$$

Here, h is the grid spacing, and is chosen such that $h = L/M$, for some integer M . Simply supported conditions are assumed here, so that $u_{l,m}(t) = 0$ for $l, m = 0, M$.

There are many approaches to spatial discretization; the simplest is to make use of basic difference operators of the form:

$$\delta_{x\pm} u_{l,m} = \pm \frac{1}{h} (u_{l\pm 1,m} - u_{l,m}) \quad \delta_{y\pm} u_{l,m} = \pm \frac{1}{h} (u_{l,m\pm 1} - u_{l,m}) \quad (26)$$

which are forward and backward approximations to the spatial derivatives ∂_x and ∂_y , respectively. (Note that the time dependence of $u_{l,m}$ has been suppressed above.) Approximations to the Laplacian and biharmonic operator follow as

$$\delta_{\Delta} = \delta_{x+}\delta_{x-} + \delta_{y+}\delta_{y-} \quad \delta_{\Delta\Delta} = \delta_{\Delta}\delta_{\Delta} \quad (27)$$

A discrete approximation ℓ to the bilinear operator \mathcal{L} may be written, for two grid functions $f_{l,m}, g_{l,m}$, as

$$\begin{aligned} \ell(f, g) = & \delta_{x+}\delta_{x-} f \delta_{y+}\delta_{y-} g + \delta_{y+}\delta_{y-} f \delta_{x+}\delta_{x-} g \\ & - \frac{1}{2} \delta_{x+}\delta_{y+} f \delta_{x+}\delta_{y+} g - \frac{1}{2} \delta_{x+}\delta_{y-} f \delta_{x+}\delta_{y-} g - \frac{1}{2} \delta_{x-}\delta_{y+} f \delta_{x-}\delta_{y+} g - \frac{1}{2} \delta_{x-}\delta_{y-} f \delta_{x-}\delta_{y-} g \end{aligned} \quad (28)$$

A centered second order accurate approximation to (22) follows as

$$\rho \xi \ddot{u}_{l,m} = -D \delta_{\Delta\Delta} u_{l,m} + \ell(u, F) = 0 \quad \frac{2}{E\xi} \delta_{\Delta\Delta} F_{l,m} = -\ell(u, u) \quad (29)$$

It is useful, at this stage, to introduce consolidated vector representations $\mathbf{u}(t)$ and $\mathbf{F}(t)$ of $u_{l,m}(t)$ and $F_{l,m}(t)$; both are $(M-1)^2 \times 1$ column vectors (grid points at the plate edges have been removed here, due to the use of simply supported boundary conditions). All of the difference operators δ above may be replaced by matrix equivalents \mathbf{D} . In particular, $\mathbf{D}_{x-}, \mathbf{D}_{y-}$ are of dimensions $M(M-1) \times (M-1)^2$, $\mathbf{D}_{x+}, \mathbf{D}_{y+}$ are of dimensions $(M-1)^2 \times M(M-1)$, and \mathbf{D}_{Δ} and $\mathbf{D}_{\Delta\Delta}$ are of dimensions $(M-1)^2 \times (M-1)^2$. In this case, simply supported boundary conditions have been taken into account—all matrices are sparse, with $O(M^2)$ nonzero entries.

In this case, (29) can be rewritten as

$$\rho \xi \ddot{\mathbf{u}} = -D \mathbf{D}_{\Delta\Delta} \mathbf{u} + \ell(\mathbf{u}, \mathbf{F}) = \mathbf{0} \quad \frac{2}{E\xi} \mathbf{D}_{\Delta\Delta} \mathbf{F} = -\ell(\mathbf{u}, \mathbf{u}) \quad (30)$$

To arrive at a first order form (15) in terms of momentum $\mathbf{p} = M\dot{\mathbf{u}}$ and displacement $\mathbf{q} = \mathbf{u}$, with associated Hamiltonian (14) and energy splitting (13), one may use

$$\mathbf{M} = \rho \xi h^2 \mathbf{I}_{(M-1)^2} \quad \mathbf{K} = D h^2 \mathbf{D}_{\Delta\Delta} \quad V' = \frac{h^2}{2E\xi} |\mathbf{D}_{\Delta} \mathbf{F}|^2 \quad (31)$$

where here, $\mathbf{I}_{(M-1)^2}$ is the identity matrix of size $(M-1)^2 \times (M-1)^2$.

Fully Discrete Schemes

The most basic scheme for the Föppl-von Kármán system follows from a centered difference approximation to the semi-discrete system of ODEs (30). Introducing the discrete-time vectors \mathbf{u}^n and \mathbf{F}^n , approximating $\mathbf{u}(t)$ and $\mathbf{F}(t)$ at $t = nk$, for integer n and a time step k , the Störmer scheme results as

$$\frac{\rho \xi}{k^2} (\mathbf{u}^{n+1} - 2\mathbf{u}^n + \mathbf{u}^{n-1}) = -D \mathbf{D}_{\Delta\Delta} \mathbf{u}^n + \ell(\mathbf{u}^n, \mathbf{F}^n) = \mathbf{0} \quad \frac{2}{E\xi} \mathbf{D}_{\Delta\Delta} \mathbf{F}^n = -\ell(\mathbf{u}^n, \mathbf{u}^n) \quad (32)$$

This scheme is simple, but stability is highly dependent on both the choice of time step and on the initial conditions—in general, this scheme will become unstable as the size of the initial condition is increased. The first equation represents the update, and is fully explicit. The second requires the solution of a linear system involving the matrix $\mathbf{D}_{\Delta\Delta}$. As this is of a known form, a Cholesky factorisation may be computed prior to entering the runtime loop, greatly accelerating calculation. This scheme will be referred to as Scheme I subsequently here.

A family of energy-conserving and provably numerically stable schemes has been presented in previous work [15, 14]. Though too elaborate to present in detail here, in its most general form, the update equation is of the form

$$\mathbf{A}^n \mathbf{u}^{n+1} = \mathbf{b}^n \quad (33)$$

where, as in (32), \mathbf{u}^n is the plate displacement in vector form. Here, \mathbf{A}^n and \mathbf{b}^n are a matrix/vector pair which in general are dependent on \mathbf{u}^n and \mathbf{u}^{n-1} ; Although no iterative solvers are required, and thus existence/uniqueness are guaranteed, the linear system to be solved must be constructed anew at each time step, in contrast with (32), and thus compute times are much longer. This scheme will be referred to as Scheme II subsequently here.

Finally, one may employ the fast conservative scheme, as given in (16), and under the choices given in (31). This scheme will be referred to as Scheme III subsequently here. In this case, the scheme is stable under the condition (21) which reduces, in this case, to the following condition on the grid spacing h in terms of the time step k :

$$h \geq h_{\min} = 2\sqrt{k} (D/\rho \xi)^{\frac{1}{4}} \quad (34)$$

Table 1: Timing comparison: Schemes I, II and III for the Föppl-von Kármán System. Run times for 1 s output are given, with time steps k as indicated.

Scheme	$k = 10^{-3}$	$k = 5 \times 10^{-4}$	$k = 10^{-4}$	$k = 5 \times 10^{-5}$	$k = 10^{-5}$
I: Störmer-Verlet	0.032	0.142	0.344	6.04	25.24
II: Energy conserving	0.149	0.636	8.92	327.8	1742.8
III: Fast energy conserving	0.055	0.290	0.593	7.76	31.36

Numerical Results: Föppl-von Kármán Equations

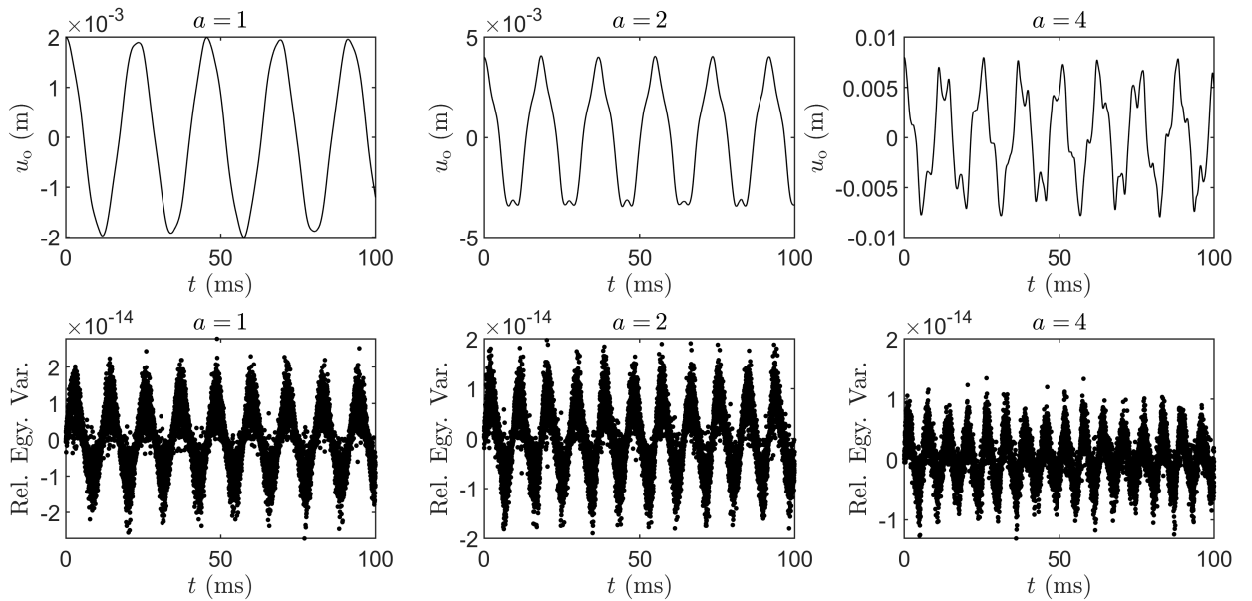

As an example, consider a square plate of side length $L = 0.5$ m, of thickness $\xi = 0.002$ m, and made of steel, with $E = 2 \times 10^{11}$ Pa, $\rho = 7850$ kg·m⁻³, and $\nu = 0.3$. Simply supported boundary conditions are assumed, and the plate is assumed initialised in the lowest linear mode shape, and with zero transverse velocity, so that

$$u(x, y, 0) = a\xi \sin(\pi x/L) \sin(\pi y/L) \quad \partial_t u|_{x,y,t=0} = 0 \quad (35)$$

for some non-dimensional amplitude a . See Figure 2, illustrating plate displacement u_o at the plate center as a function of time, as well as the relative numerical energy variation H_e , defined as

$$H_e^{n+\frac{1}{2}} = \frac{H^{n+\frac{1}{2}} - H^{\frac{1}{2}}}{H^{\frac{1}{2}}} \quad (36)$$

The time step is chosen as $k = 10^{-4}$ s. In all cases, the relative energy variation is on the order of machine accuracy in double precision floating point arithmetic. See also figure 3, illustrating convergence of computed waveforms to trusted high accuracy solutions generated using the standard Scheme I (Störmer) with a very small time step.

 Figure 2: Top row: plate displacement at the plate center, as a function of time, for different initial condition amplitudes $a = 1$, $a = 2$ and $a = 4$. Bottom row: relative numerical energy variation H_e , as defined in (36).

In Table 1 timings per second output are given, for the plate with parameters as described above, and using different time steps k as indicated. All computations were performed in Matlab on a Lenovo P50 laptop on a Xeon E3. Timings are given for the basic Störmer method (Scheme I), the stable energy conserving method as given in [15] (Scheme II) and the new stable energy conserving method presented here (Scheme III). As is clearly evident, the new method performs nearly on par with Störmer, in cases where Störmer is stable—recall that this scheme has obscure stability properties that are highly dependent on the initialisation. These results were computed with initial condition (35) with $a = 4$; at higher amplitudes, Störmer exhibits instability at larger time steps.

Concluding Remarks

A fully explicit method for Hamiltonian numerical integration has been presented here, with a pseudo-energy conservation property leading to unconditional numerical stability—it is different in character from other explicit methods presented

Figure 3: Computed waveforms at the plate center, using scheme III (in red) at different choices of time step k as indicated. Here, a high initial condition amplitude of $a = 4$ is chosen. For reference, a high accuracy solution is computed using Scheme I (Störmer) using a small time step of $k = 10^{-6}$ s, and is shown in black.

recently, in that an additional update is required for the root-potential energy, which is treated as a new independent variable. An extension to the case of split potential forms is also presented, useful in arriving at conditionally stable numerical methods.

The fully explicit character of the eventual update follows from the exploitation of matrix structure, and leads to large increases in computational speed relative to other provably stable energy conserving methods. The method on the whole is nearly as efficient as the simplest explicit schemes for Hamiltonian integration.

Summary. This work addresses the problem of the struck piano string. This system is highly nonlinear, and a sound representation of the energy balance is therefore necessary in any time stepping routine used in simulation, in order to preserve stability. Many algorithms have been developed in previous works. Among them, some present fully-implicit discretisations, which are only approachable using iterative root finders such as Newton-Raphson. Others are linearly-implicit, but not quite suited for real-time rendering. Here, a novel approach is presented, based on the idea of energy quadratisation. It will be shown that, when the nonlinearities are consolidated into a scalar auxiliary state function, the time stepping scheme presents a fast inversion formula. A C++ implementation of the proposed scheme yields indeed compute times below real-time, for typical strings.

Introduction

The dynamics of musical strings is often assumed to be linear. However, many perceptual phenomena cannot be explained by linear theory alone, and inclusion of nonlinearities results therefore necessary [1]. This is certainly true for the piano, where the appearance of “phantom partials” in the output spectra is often explained in terms of the nonlinear coupling between the transverse and the longitudinal waves. Furthermore, the intermittent hammer-string interaction cannot be modelled linearly [2]. At the simulation level, a sound representation of the energy balance of the hammer-string system is necessary to preserve stability of the underlying time stepping scheme, and this can be accomplished via fully-implicit discretisations [3, 4]. The finite element method, in particular, is preeminent here, see e.g. [5, 6], where the conservation of a non-negative numerical energy allows to derive a stability condition involving the mesh size and the time step. Since these methods are fully-implicit, they require the solution of a large nonlinear algebraic system at each time step, for which existence and uniqueness of the solution must be proven, and which are only approachable using iterative routines such as Newton-Raphson. Further complications arise in the choice of the tolerance thresholds and maximum number of iterations of the routine [7, 8].

In recent years, a new class of schemes has emerged, based on the idea of “quadratisation”: when the nonlinear potential energy is non-negative, it can be written as the square of an auxiliary function. This leads to schemes for which the update is computable as the solution of a linear system, thus sidestepping the machinery of iterative root finders. Besides the obvious computational advantage, existence and uniqueness of the computed solution are proven by inspection of the update matrix alone. These methods have appeared in various guises, including applications in Port-Hamiltonian systems [9, 10, 4, 11], nonlinear parabolic phase-field models [12, 13, 14], and others. This latter class of methods is often referred to as “Invariant Energy Quadratisation” (IEQ) method, in that the auxiliary state function is treated as an independent grid function to be solved for. This method has been applied successfully to the geometrically exact nonlinear string [15, 16]. In this work, a different kind of quadratisation is proposed, where the auxiliary state function is not treated as a distributed state variable, but as a scalar one. This idea shares some similarities with the “Scalar Auxiliary Variable” (SAV) approach [17], but it also exploits the form of the update matrix to yield an extremely efficient algorithm. The application of this method to Hamiltonian system is the subject of a companion paper [18]; here, the example of the struck string is considered in detail. First, the problem is semi-discretised in space, resulting in a system of nonlinearly coupled ordinary differential equations in time. Then, all the nonlinear components (i.e. the geometric nonlinearity of the string, and the hammer-string nonlinear potential) are consolidated into a single, scalar state function. Then, it is shown that the update matrix is in the form of a rank-1 perturbation of a diagonal matrix, and thus invertible efficiently using the Sherman-Morrison formula [19]. A computational test is then performed, showing that a sound implementation of this method in C++ yields speedups of the order of 10^2 , compared to Matlab implementations of previously available methods. In particular, compute times for typical piano strings are below real-time. The introduction of a shift constant in the nonlinear potential energy is also illustrated, aiding convergence of the quadratised numerical scheme.

A Continuous Struck String Model

Piano strings are known to vibrate in a nonlinear regime as a consequence of the large strains originating during motion [1, 20]. The striking mechanism is also nonlinear, due to the intermittent contact between the string and the hammer

[2, 21]. A suitable mathematical model incorporating these effects may be given as follows:

$$(\rho A \partial_t^2 - \mathcal{L}_u)u(x, t) = \partial_x \left(\frac{\partial \phi_s}{\partial (\partial_x u)} \right) + \delta(x - x_c) \frac{d\phi_c}{d\eta}, \quad (1a)$$

$$(\rho A \partial_t^2 - \mathcal{L}_v)v(x, t) = \partial_x \left(\frac{\partial \phi_s}{\partial (\partial_x v)} \right), \quad (1b)$$

$$M_h \frac{d^2 U(t)}{dt^2} = -\frac{d\phi_c}{d\eta}, \quad (1c)$$

$$\eta(t) = U(t) - \int_0^L \delta(x - x_c) u(x, t) dx. \quad (1d)$$

Above, constants appear as: ρ , the string's volume density; A the area of the string's cross section; M_h , the mass of the hammer. The notation ∂_s^p denotes the p -th partial derivative with respect to s . $u = u(x, t) : [0, L] \times \mathbb{R}_0^+ \rightarrow \mathbb{R}$ is the transverse displacement of the string, and $v = v(x, t) : [0, L] \times \mathbb{R}_0^+ \rightarrow \mathbb{R}$ is the longitudinal displacement, where L is the string length; $\mathcal{L}_u, \mathcal{L}_v$ are linear differential operators (to be specified shortly) including the tension, stiffness and loss components for the two displacements; $\phi_s : \phi_s(\partial_x u, \partial_x v) : \mathbb{R} \times \mathbb{R} \rightarrow \mathbb{R}_0^+$ is the nonlinear potential density due to the string's large stretching; $\phi_c : \phi_c(\eta) : \mathbb{R} \rightarrow \mathbb{R}_0^+$ is the collision potential modelling the hammer-string interaction; $U = U(t) : \mathbb{R}_0^+ \rightarrow \mathbb{R}$ is the hammer's displacement; $\eta = \eta(t) : \mathbb{R}_0^+ \rightarrow \mathbb{R}$ defines the compression of the hammer felt, expressed as the difference between the hammer and string displacements at the contact point x_c .

The linear operators $\mathcal{L}_u, \mathcal{L}_v$ are given as:

$$\mathcal{L}_u = T_0 \partial_x^2 - EI \partial_x^4 - 2\rho A(\sigma_0 - \sigma_1 \partial_x^2) \partial_t; \quad \mathcal{L}_v = T_0 \partial_x^2 - 2\rho A \sigma_l \partial_t. \quad (2)$$

\mathcal{L}_u includes tension and stiffness terms, the latter borrowed from the Euler-Bernoulli beam theory (this is largely sufficient for musical strings, see e.g. [22, 23]). T_0 is the applied tension, E is Young's modulus, I is the area moment of inertia. Losses in the transverse direction are modelled via the terms proportional to the coefficients $(\sigma_0, \sigma_1) \geq 0$, yielding a quadratic loss profile in the frequency domain. Inclusion of more refined loss profiles, such as the one proposed by Cuesta and Vallette [24], is possible, but this will be neglected here for simplicity. \mathcal{L}_v includes a tension term, and a simple loss model proportional to $\sigma_l \geq 0$.

The forms of the potentials are given here as:

$$\phi_s(\partial_x u, \partial_x v) = \frac{EA - T_0}{2} \left(\sqrt{(1 + \partial_x v)^2 + (\partial_x u)^2} - 1 \right)^2, \quad \phi_c(\eta) = \frac{B}{\alpha + 1} [\eta]_+^{\alpha+1}. \quad (3)$$

Here, B is the stiffness coefficient of the hammer felt, $\alpha \geq 1$ is an exponent: these values can be determined experimentally [25]. The notation $[\cdot]_+$ stands for "positive part", that is $[\eta]_+ \triangleq 0.5(\eta + |\eta|)$. Note that $\phi_c = 0$ whenever $\eta \leq 0$, that is, the collision model is one-sided, and note that this model is consistent only when the hammer strikes from below. Note as well that $\phi_s \geq 0$ when $EA \geq T_0$, a condition that is always verified for musical strings. In view of the numerical application shown below, it is convenient to lump the nonlinear potentials into one single scalar function ϕ , as

$$\phi(\partial_x u, \partial_x v, \eta) = \int_0^L \phi_s(\partial_x u, \partial_x v) dx + \phi_c(\eta) + \frac{p_0}{2}, \quad (4)$$

where $p_0 \geq 0$ is a constant shifting the zero-point of the potential, but not affecting the equations of motion. This constant will prove useful in the numerical scheme presented below.

Equation (1c) must be completed by two initial conditions, setting the hammer in motion. These can be given as $U_0 \triangleq U(t = 0)$ and $V_0 \triangleq dU/dt(t = 0)$. Furthermore, the string's boundary conditions are given as: $u(0, t) = u(L, t) = \partial_x^2 u(0, t) = \partial_x^2 u(L, t) = v(0, t) = v(L, t) = 0$. These define an energy conserving set of boundary conditions; in particular, the string is simply-supported transversely and fixed longitudinally. Under such conditions, system (1) is energy-passive. A proof may be obtained by taking an l_2 inner product (i.e. an integral over the domain) of (1a) with $\partial_t u$, of (1b) with $\partial_t v$, and a product of (1c) with dU/dt , and summing the three equations. After suitable integrations by parts [16], one gets the following energy balance

$$\frac{dH}{dt} = -2\rho A \left(\int_0^L (\sigma_0 (\partial_t u)^2 + \sigma_l (\partial_t v)^2 + \sigma_1 (\partial_t \partial_x u)^2) dx \right) \leq 0, \quad (5)$$

where the energy is

$$H(t) = \int_0^L \left(\frac{\rho A}{2} ((\partial_t u)^2 + (\partial_t v)^2) + \frac{T_0}{2} ((\partial_x u)^2 + (\partial_x v)^2) + \frac{EI}{2} (\partial_x^2 u)^2 \right) dx + \frac{M_h (dU/dt)^2}{2} + \phi \geq 0 \quad (6)$$

Equation (5) represents the energy balance of the hammer-string, encoding passivity (i.e. the total energy is positive, and decays over time).

Semi-discretisation

System (1) may be semi-discretised in a number of ways, yielding a system of coupled nonlinear ordinary differential equations in time. Here, a finite difference approach will be adopted, but the numerical method described below applies equally to any other suitable semi-discrete problem, obtained for instance via Galerkin-type methods (modal methods, finite elements, etc.). For the finite difference method, the continuous domain of length L is divided into segments of length h , the grid spacing. Let the total number of subintervals be M , that is, the grid is composed of $M + 1$ grid points, including the boundary points. Then, the continuous displacements $u(x, t)$, $v(x, t)$ are approximated by grid functions $\mathbf{u}(t)$, $\mathbf{v}(t)$, which may be taken as column vectors of length $M - 1$: here, the end points need not be stored or updated, since the boundary conditions are of fixed type. Difference matrices are now introduced, starting from the definition of the backward difference matrix acting on the column vector \mathbf{u} :

$$\mathbf{D}^- \mathbf{u} = \frac{1}{h} ([\mathbf{u}^\top, 0] - [0, \mathbf{u}^\top]). \quad (7)$$

Note that this is a rectangular matrix of size $M \times M - 1$. From this, one may define the forward difference matrix, the Laplace operator and the biharmonic operator, as

$$\mathbf{D}^+ = -(\mathbf{D}^-)^\top, \quad \mathbf{D}^2 = \mathbf{D}^+ \mathbf{D}^-, \quad \mathbf{D}^4 = (\mathbf{D}^2)^2, \quad (8)$$

and note that these matrices are consistent with the prescribed boundary conditions in the transverse and longitudinal directions. Note as well that the Laplace and biharmonic operators are of size $M - 1 \times M - 1$. Owing to these definitions, semi-discretisation of the linear operators \mathcal{L}_u , \mathcal{L}_v in (2) is obtained as

$$\mathbf{l}_u = T_0 \mathbf{D}^2 - E I \mathbf{D}^4 - 2\rho A(\sigma_0 - \sigma_1 \mathbf{D}^2) \frac{d}{dt}; \quad \mathbf{l}_v = T_0 \mathbf{D}^2 - 2\rho A \sigma_l \frac{d}{dt}. \quad (9)$$

The Dirac delta function is here approximated using a linear Lagrange interpolant, that is, via the column vector \mathbf{J} of length $M - 1$. This is an all-zero vector, except at the grid points $m_c \triangleq \text{floor}(x_c/h)$ and $m_c + 1$, for which

$$J_{m_c} = (1 - \alpha)/h, \quad J_{m_c+1} = \alpha/h, \quad \text{where } \alpha = x_c/h - m_c. \quad (10)$$

Using this definition, a semi-discrete version of (1d) is obtained as:

$$\eta(t) = U(t) - h \mathbf{J}^\top \mathbf{u}(t). \quad (11)$$

Note that the letter η is used here in a different fashion than in (1d) (in this section, the semi-discrete definition (11) is adopted). It is now convenient to define two interleaved grid functions, \mathbf{q} and \mathbf{r} , which are column vectors of length M defined as:

$$\mathbf{q} = \mathbf{D}^- \mathbf{u}, \quad \mathbf{r} = \mathbf{D}^- \mathbf{v}. \quad (12)$$

Owing to these, a semi-discrete version of the nonlinear potential ϕ in (4) is obtained as:

$$\Phi = h \sum_{i=1}^M \Phi_s^i(q_i, r_i) + \Phi_c(\eta) + \frac{p_0}{2}; \quad \text{where } \Phi_s^i = \frac{EA - T_0}{2} \left(\sqrt{(1 + r_i)^2 + q_i^2} - 1 \right)^2, \quad \Phi_c = \frac{B}{\alpha + 1} [\eta]_+^{\alpha+1}. \quad (13)$$

Note that here $\Phi = \Phi(\mathbf{q}, \mathbf{r}, \eta) : \mathbb{R}^M \times \mathbb{R}^M \times \mathbb{R} \rightarrow \mathbb{R}_0^+$, and it will be necessary to compute partial derivatives according to \mathbf{q} , \mathbf{r} , η . These are denoted as

$$(\nabla_{\mathbf{q}} \Phi)_i \triangleq \frac{\partial \Phi_s^i}{\partial q_i}, \quad (\nabla_{\mathbf{r}} \Phi)_i \triangleq \frac{\partial \Phi_s^i}{\partial r_i}, \quad (\nabla_{\eta} \Phi) \triangleq \frac{d\Phi_c}{d\eta}, \quad i = 1, \dots, M. \quad (14)$$

The chain rule gives

$$\frac{d\Phi}{dt} = (\nabla_{\mathbf{q}} \Phi)^\top \frac{d\mathbf{q}}{dt} + (\nabla_{\mathbf{r}} \Phi)^\top \frac{d\mathbf{r}}{dt} + (\nabla_{\eta} \Phi) \frac{d\eta}{dt} = \underbrace{[-(\mathbf{D}^+ \nabla_{\mathbf{q}} \Phi)^\top - h \nabla_{\eta} \Phi \mathbf{J}^\top, -(\mathbf{D}^+ \nabla_{\mathbf{r}} \Phi)^\top, \nabla_{\eta} \Phi]}_{\mathbf{g}_\Phi^\top} \frac{d\mathbf{w}}{dt}, \quad (15)$$

where $\mathbf{w} \triangleq [\mathbf{u}^\top, \mathbf{v}^\top, U]^\top$ is the state vector, lumping the longitudinal and transverse string grid functions, and the hammer's displacement. Note that the second equality in (15) is obtained using the transposition property of the forward and backward difference matrices in (8), and the definition of η in (11). Owing to these definitions, the semi-discrete equations can be written in compact form, as:

$$\mathbf{M} \frac{d^2 \mathbf{w}(t)}{dt^2} + \mathbf{C} \frac{d\mathbf{w}(t)}{dt} + \mathbf{K} \mathbf{w}(t) = -\mathbf{S} \mathbf{g}_\Phi, \quad (16)$$

where $\mathbf{M} \triangleq \text{diag}([\rho A \mathbf{I}, \rho A \mathbf{I}, M_h])$, $\mathbf{K} \triangleq \text{diag}([-T_0 \mathbf{D}^2 + E I \mathbf{D}^4, -T_0 \mathbf{D}^2, 0])$, $\mathbf{C} \triangleq \text{diag}([2\rho A(\sigma_0 \mathbf{I} - \sigma_1 \mathbf{D}^2), 2\rho A \sigma_l \mathbf{I}, 0])$, $\mathbf{S} \triangleq \text{diag}([\mathbf{I}/h, \mathbf{I}/h, 1])$. Here, the operator “diag” produces a block-diagonal matrix, with blocks given as components separated by commas. The matrix \mathbf{I} is here the $M - 1 \times M - 1$ identity matrix.

In (16), the left-hand side includes all the linear components (the mass, stiffness and loss matrices), and the nonlinearities are now lumped in the vector \mathbf{g}_Φ as defined in (15). From here, it is now easy to see that system (16) is energy-passive: it is sufficient to multiply both sides of the equation on the left by $(\mathbf{S}^{-1} \frac{d\mathbf{w}}{dt})^\top$. This gives

$$\frac{d\mathfrak{h}}{dt} = -\frac{d\mathbf{w}^\top}{dt} \tilde{\mathbf{C}} \frac{d\mathbf{w}}{dt} \leq 0, \text{ with } \mathfrak{h} = \frac{1}{2} \frac{d\mathbf{w}^\top}{dt} \tilde{\mathbf{M}} \frac{d\mathbf{w}}{dt} + \frac{1}{2} \mathbf{w}^\top \tilde{\mathbf{K}} \mathbf{w} + \Phi \geq 0, \quad (17)$$

where the “tilde” notation indicates the rescaled matrices $\tilde{\mathbf{M}} = \mathbf{S}^{-1} \mathbf{M}$, $\tilde{\mathbf{K}} = \mathbf{S}^{-1} \mathbf{K}$, $\tilde{\mathbf{C}} = \mathbf{S}^{-1} \mathbf{C}$ (the scaling by the factor h is needed here to restore units of Joules in the transverse and longitudinal string components). Note that the “tilde” matrices are all non-negative, hence the inequalities in (17) ensue.

Quadratisation

The expression for the semi-discrete energy \mathfrak{h} in (17) includes a linear part, given by the sum of quadratic forms corresponding to the kinetic and linear potential energy components, plus the nonlinear potential Φ . It results therefore convenient to “quadratiser” the nonlinear potential via the transformation

$$\Psi = \sqrt{2\Phi}, \quad (18)$$

for the function $\Psi = \Psi(\mathbf{q}, \mathbf{r}, \eta) : \mathbb{R}^M \times \mathbb{R}^M \times \mathbb{R} \rightarrow \mathbb{R}_0^+$. This transformation is always well-defined since Φ is non-negative. This transformation yields a semi-discrete system entirely equivalent to (16), but expressed in terms of Ψ as:

$$\mathbf{M} \frac{d^2 \mathbf{w}(t)}{dt^2} + \mathbf{C} \frac{d\mathbf{w}(t)}{dt} + \mathbf{K} \mathbf{w}(t) = -\Psi(t) \mathbf{S} \mathbf{g}_\Psi, \quad (19)$$

where

$$\mathbf{g}_\Psi = [- (\mathbf{D}^+ \nabla_{\mathbf{q}} \Psi)^\top - h \nabla_\eta \Psi \mathbf{J}^\top, - (\mathbf{D}^+ \nabla_{\mathbf{r}} \Psi)^\top, \nabla_\eta \Psi], \quad (20)$$

and note that the partial derivatives of Ψ are easily obtained from (14), since e.g. $\nabla_{\mathbf{q}} \Psi = \nabla_{\mathbf{q}} \Phi / \Psi$. Division by Ψ in the expression of the partial derivatives may be ill defined when the shift constant p_0 in (13) is set to zero, and it will therefore be necessary to shift the potential energy by a finite amount. Application of the chain rule gives

$$\frac{d\Psi}{dt} = \mathbf{g}_\Psi^\top \frac{d\mathbf{w}}{dt}. \quad (21)$$

The energy balance now reads:

$$\frac{d\mathfrak{h}}{dt} = -\frac{d\mathbf{w}^\top}{dt} \tilde{\mathbf{C}} \frac{d\mathbf{w}}{dt} \leq 0, \text{ where } \mathfrak{h} = \frac{1}{2} \frac{d\mathbf{w}^\top}{dt} \tilde{\mathbf{M}} \frac{d\mathbf{w}}{dt} + \frac{1}{2} \mathbf{w}^\top \tilde{\mathbf{K}} \mathbf{w} + \frac{\Psi^2}{2} \geq 0, \quad (22)$$

and the expression for the energy only contains quadratic terms. Note that the nonlinear energy components are now lumped in the single scalar function Ψ . The “quadratised” expression for the nonlinear energy is convenient since it can be exploited in a time-stepping integrator yielding a non-negative nonlinear numerical energy, as detailed below. Note that this type of quadratisation is fundamentally different from the one proposed in [15, 16], in that here the auxiliary state function is a scalar, and not a distributed quantity. Applications of this method to Hamiltonian systems are presented in the companion paper [18].

Time Stepping Procedure

(19) defines a system of nonlinearly coupled ordinary differential equations in time. Integration is now performed using finite differences. To that end, the continuous state vector $\mathbf{w}(t)$ is approximated at the time $t_n = kn$ by a vector time series \mathbf{w}^n , where $n \in \mathbb{N}$ is the time index, and $k = 1/f_s$ is the time step, defined as the multiplicative inverse of the sample rate f_s . The basic operators in discrete time are the identity and shift operators, defined as:

$$1\mathbf{w}^n = \mathbf{w}^n, \quad e_+ \mathbf{w}^n = \mathbf{w}^{n+1}, \quad e_- \mathbf{w}^n = \mathbf{w}^{n-1}. \quad (23)$$

From these, the time difference operators can be defined as:

$$\delta_+ = \frac{e_+ - 1}{k}, \quad \delta_- = \frac{1 - e_-}{k}, \quad \delta_c = \frac{e_+ - e_-}{2k}. \quad (24)$$

These are the forward, backward and centred operators respectively. The second-difference operator is obtained by combining the the operators above:

$$\delta_2 = \delta_+ \delta_- . \quad (25)$$

Finally, averaging operators can be written as:

$$\mu_+ = \frac{e_+ + 1}{2}, \quad \mu_- = \frac{1 + e_-}{2}, \quad \mu = \frac{e_+ + e_-}{2}. \quad (26)$$

The auxiliary state function is discretised on an interleaved time grid, so that $\Psi(t) \rightarrow \Psi^{n-1/2}$. The definitions of the difference operators are formally unchanged when applied to an interleaved time series, so that e.g. $\delta_+ \Psi^{n-1/2} = (\Psi^{n+1/2} - \Psi^{n-1/2})/k$, etc. Note that $\Psi^{n-1/2}$ will be treated here as an *independent* scalar time series, to be updated at each time step. To that end, it is necessary to discretise (19) along with the time derivative of Ψ in (21). One possible such discretisation is given here as

$$\mathbf{M} \delta_2 \mathbf{w}^n + \mathbf{C} \delta_- \mathbf{w}^n + \mathbf{K} \mathbf{w}^n = -\mu_+ \Psi^{n-1/2} \mathbf{S} \mathbf{g}_\Psi^n, \quad \delta_+ \Psi^{n-1/2} = (\mathbf{g}_\Psi^n)^\top \delta_- \mathbf{w}^n. \quad (27)$$

This defines a three-step scheme, in which the updates \mathbf{w}^{n+1} , $\Psi^{n+1/2}$ are obtained from the previous state values \mathbf{w}^n , \mathbf{w}^{n-1} , $\Psi^{n-1/2}$. Note as well that \mathbf{g}_Ψ^n is known, and computed from (20) at the time step n , using the analytic expressions for the derivatives of the continuous function Ψ .

System (27) is completed by initial conditions on \mathbf{w} and Ψ . At the initial time $n = 0$, it is assumed that the string is at rest, with the hammer moving according the initial conditions given above. The time series Ψ must be initialised accordingly, using definition (18) and the expression of Φ from (13). Thus

$$\mathbf{w}^0 = [\mathbf{0}^\top, \mathbf{0}^\top, U_0]^\top, \quad \mathbf{w}^1 = [\mathbf{0}^\top, \mathbf{0}^\top, kV_0 + U_0]^\top, \quad \Psi^{1/2} = \sqrt{p_0}. \quad (28)$$

Scheme (27) is energy-conserving. A proof is obtained by multiplying on left by $(\mathbf{S}^{-1} \delta_- \mathbf{w}^n)^\top$, and using various identities (not shown here for brevity; see e.g. [20]). One gets

$$\delta_+ \mathfrak{h}^{n-1/2} = -(\delta_- \mathbf{w}^n)^\top \tilde{\mathbf{C}} \delta_- \mathbf{w}^n \leq 0, \quad (29)$$

where

$$\mathfrak{h}^{n-1/2} = \frac{1}{2} (\delta_+ \mathbf{w}^n)^\top \left(\tilde{\mathbf{M}} - \frac{k}{2} \tilde{\mathbf{C}} \right) \delta_+ \mathbf{w}^n + \frac{1}{2} (\mathbf{w}^n)^\top \tilde{\mathbf{K}} e_- \mathbf{w}^n + \frac{(\Psi^{n-1/2})^2}{2}. \quad (30)$$

This expresses the fully-discrete energy balance. It is worth noting that the expression for the fully discrete energy (30) is not positive semi-definite in all cases (as opposed to the semi-discrete energy in (22), which is always non-negative). However, conditions on non-negativity can be obtained by inspection of the linear part alone, since the nonlinear energy is here clearly non-negative, and expressed via the square of Ψ . It is possible to show (see e.g. [20, 16]) that, when the loss coefficients are small (as is the case for all musical strings), a sufficient condition for the non-negativity of the total discrete energy is

$$h \geq \sqrt{E/\rho} k. \quad (31)$$

When this condition is enforced, the discrete energy is non-negative, and hence stability of the time stepping scheme follows. Note that (31) is the CFL condition associated with the longitudinal motion, and it is expressed as a lower bound on h : this is much larger than the natural bound for the transverse waves (which is of the order of $\sqrt{T_0/\rho A} k$ for thin strings). Thus, enforcing condition (31) has consequences in the choice of the sample rate f_s , which has to be chosen much larger than typical audio rates (such as e.g. 44.1 kHz) to get enough resolution within the audio band.

Note as well that in (27) the operator δ_- was used to approximate the time derivative of the losses. This formally produces a first-order convergent scheme in time. However, it also allows for a fast update, as detailed below. Since losses are small, and since the time step k has to be chosen in the $10^{-5} - 10^{-6}$ range, this approximation does not introduce significant errors compared to a second-order accurate discretisation of the same derivative.

Scheme Update

Scheme (27) yields an efficient update equation. To show this, first use the identity $\mu_+ = (k/2)\delta_+ + 1$ in order to express the right-hand side of the first equation in (27) in terms of $\delta_- \mathbf{w}^n$ from the second equation. Then, one rearranges the terms to get

$$\left(\frac{\mathbf{M}}{k^2} + \frac{1}{4} \mathbf{S} \mathbf{g}_\Psi^n (\mathbf{g}_\Psi^n)^\top \right) \mathbf{w}^{n+1} = \left(\frac{2\mathbf{M}}{k^2} - \frac{\mathbf{C}}{k} - \mathbf{K} \right) \mathbf{w}^n + \left(-\frac{\mathbf{M}}{k^2} + \frac{\mathbf{C}}{k} + \frac{1}{4} \mathbf{S} \mathbf{g}_\Psi^n (\mathbf{g}_\Psi^n)^\top \right) \mathbf{w}^{n-1} - \Psi^{n-1/2} \mathbf{S} \mathbf{g}_\Psi^n, \quad (32)$$

and note that the update matrix is now composed of the diagonal matrix \mathbf{M}/k^2 plus the rank-1 perturbation $\frac{1}{4} \mathbf{S} \mathbf{g}_\Psi^n (\mathbf{g}_\Psi^n)^\top$. This is invertible in $O(M)$ operations using the Sherman-Morrison formula [19, 18]. Once \mathbf{w}^{n+1} is known, one may compute $\Psi^{n+1/2}$ using the second equation in (27).

Figure 1: Snapshots of the hammer-string interaction. Here, the hammer and the string parameters are taken from [25], for the C2 string. The hammer initial velocity is 2 m/s. The sample rate used is $12 \cdot 48000$ Hz, resulting in a state size $2M - 1 = 547$ components. The times indicated are in ms.

Numerical Experiments

Scheme (27) is now tested in a number of numerical experiments. Figure 1 shows snapshots of the hammer-string dynamics, for the C2 piano string (the string and hammer parameters are taken from [25]). As expected, the hammer strikes the string intermittently. Here, the string's largest displacement is of the order of 4 mm, large enough to entail nonlinear effects.

The energetic behaviour of scheme (27) is checked in Figure 2, where the same C2 string is simulated in the absence of losses (that is, the matrix \mathbf{C} is the zero matrix here). The discrete energy (30) is indeed conserved, with the error in the range of 10^{-14} . Note that here the kinetic energy includes that of the string and the hammer; the linear potential energy includes the string's alone, and the nonlinear energy includes the contributions of both the string's large displacement and the hammer-string collision. Note that the shift constant p_0 was set to a finite amount, to avoid division by zero in the computation of the derivatives of Ψ .

Figure 2: (a) Energy components and (b) energy error for the same case as Figure 1. In (a), E_k is the kinetic energy (comprising the string and the hammer), E_p is the linear potential energy of the string, E_n is the nonlinear potential energy including the string's nonlinear energy and the hammer-string collision potential, H is the total energy. In (b), ΔH is defined as $1 - \mathfrak{h}^{n-1/2}/\mathfrak{h}^{1/2}$, where the expression for the discrete energy \mathfrak{h} is as per (30). In this simulation, the shift constant p_0 is set to 10^{-15} .

A quick convergence test is presented in Figure 3. Here, the time domain solutions at one output point are plotted, for a number of sample rate values. As mentioned above, significant oversampling factors are needed, compared to audio rate, since the number of grid points is now set according to bound (31), yielding a large grid spacing compared to typical wavelengths in the transverse direction. For high enough sample rates ($\text{OF} \gtrsim 12$), the computed solutions are very close, but discrepancies are evident for low-sampled waveforms. Various tests were run (not shown here), indicating that an oversampling factor of at least 12 is usually required for good resolution within the audio band. Some audio files are available on the companion webpage¹.

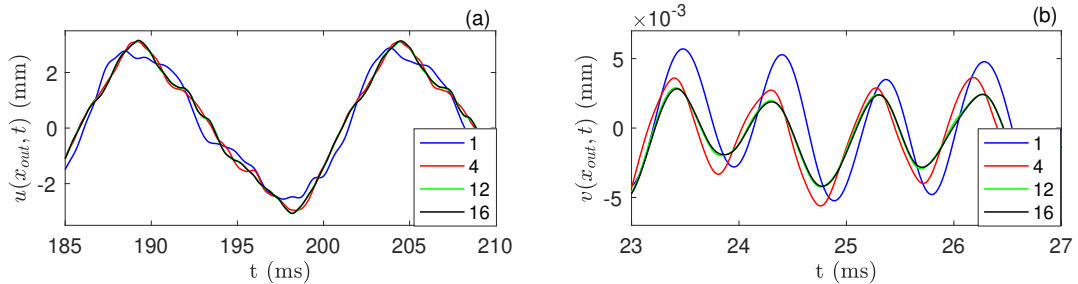

Figure 3: Convergence test under various oversampling factors for a base sample rate $f_{s0} = 48$ kHz, indicated in the legend. (a): transverse displacement. (b): longitudinal displacement. Here $x_{out} = 0.32L$, and the string's parameters are the same as in Figure 1.

Figure 4 presents the output spectra of the longitudinal displacement under three different hammer initial velocities. Note the change in brightness as the velocity increases, as well as the appearance of phantom partials.

Figure 4: Output spectra for the D2 string, with initial hammer velocities as indicated. Output is extracted at $x_{out} = 0.32L$

Table 1 presents a computational testing comparing various schemes, and implementations. Two schemes, called ICA_IT and ICA_NIT, are taken from [15]. ICA_IT is a finite difference iterative scheme, obtained via a fully-implicit conservative discretisation of the gradient in a fashion similar to that used in many works, see e.g. [3, 4, 5, 26]; ICA_NIT is a non-iterative finite difference scheme obtained via quadratisation, in a fashion similar to the scheme presented here, but where the nonlinear auxiliary variable Ψ is approximated via a *grid function*, and not as a single scalar variable as here (that is, it is not possible to update ICA_NIT using the fast Sherman-Morrison formula, though the scheme’s update is in a form of a linear system). LU_NIT, presented in [16], is also a non-iterative scheme, where the transverse waves are simulated using finite differences, and the longitudinal waves are approximated using a modal approach. The system is again in “quadratised” form, and a block LUD decomposition is adopted to compute the update. All these schemes were coded in Matlab. Finally, SM_MTL and SM_C++ present the compute times for the fast Sherman-Morrison formula

OF	M	M_{long}	ICA_IT	ICA_NIT	LU_NIT	SM_MTL	SM_C++
1	10	2	14.6	8.73	7.59	14.1	0.008
2	21	4	24.7	19.8	16.1	16.4	0.029
4	42	7	53.4	41.4	22.5	19.1	0.108
8	85	14	145	102	87.0	26.6	0.362
12	128	21	267	191	173	37.8	0.756
16	170	28	453	324	279	58.3	1.15

Table 1: Compute time / real time ratios, using various schemes and implementations, for the D3 piano string from [25]. Here, ICA_IT and ICA_NIT are, respectively, the finite difference iterative and non-iterative schemes presented in [15]; LU_NIT is the non-iterative mixed finite difference-modal method described in [16] (where the transverse displacement is approximated using finite differences, and the longitudinal displacement using a modal approach); SM_MTL is the Sherman-Morrison implementation presented here, using Matlab; SM_C++ is the same scheme implemented in C++. In the table, OF indicates the oversampling factor for a base sample rate $f_{s0} = 48$ kHz. M is the number of grid points; M_{long} is the number of longitudinal modes used in LU_NIT. In this test, for simplicity, the hammer was not considered, and the string was initialised in its first mode of vibration in the transverse direction, i.e. $u_0(x) = 0.01 \sin(\pi x/L)$. The size of the state vector, for all schemes, is then $2M - 2$, with the exception of LU_NIT for which the size is $M - 1 + M_{long}$. Below-real-time simulations are highlighted. All simulations were run on a 2016 Macbook Pro, equipped with a 2.9 GHz Intel i7 processor. Matlab simulations were run in MatlabR2020.

given here, using both Matlab and C++ implementations. A few aspects are worth commenting. First, note that the rate of growth of the compute times for the two SM schemes is much lower than for the other schemes, since, as remarked previously, the Sherman-Morrison formula is solvable in $O(M)$ operations. Second, note how the C++ implementation yields considerable speedups compared to Matlab. Here, all the matrix operations were “unrolled”, avoiding the need for sparse matrix libraries. Update (32) is remarkably fast, yielding under-real-time compute times for systems with over 250 nonlinearly coupled degrees-of-freedom. Compared to typical fully-implicit discretisations, such as ICA_IT coded in Matlab, SM_C++ is about 350 times faster at OF = 12.

Concluding Remarks

The piano string was modelled using a nonlinear, geometrically exact model, and including the hammer-string interaction. The model was first discretised in space using the finite difference method, and then “quadratised” via a scalar auxiliary state function. The resulting system was then integrated in time. It was shown that the update matrix lends itself to a fast inversion via the Sherman-Morrison formula. A C++ implementation of the proposed scheme was given, yielding speedups of a few orders of magnitude compared to Matlab realisations of previously available schemes. In particular, real-time simulations of typical piano strings are now available. The proposed schemes are part of a larger class of schemes of recent development, based on the idea of quadratisation.

Summary: In this paper, the special class of on-board rotor undergoing rotor-stator contact is under investigation. In particular, a well-known and harmful contact instability, the dry-whip phenomenon, is addressed. The aim of the paper is to present original experiments evidencing this instability being triggered by a multi-axial shock translation from the rigid rotor base. Moreover, the influence of the base motion parameters, such as the shock amplitudes, directions and time instants, on the onset of dry-whip is investigated both numerically and experimentally.

Introduction

On-board rotors represent a very special class of rotors, which are subject to motions of their base that may induce high vibration levels. In practice, they can be encountered in a large variety of industrial fields such as energy, transports, defense, etc. In this context, these systems have recently raised a particular interest as highlighted by the literature [1-2]. Due to the base motions, contact is likely to occur between rotating and non-rotating parts. In some cases, these contacts can lead to harmful dynamic instabilities, such as the dry-whip phenomenon, threatening the structural integrity of the mechanical systems. The latter is characterized by a sudden change in the whirl that leads to backward whirl owing to the tangential friction contact forces, which causes high displacement amplitudes and frequencies. It can be triggered by a mass unbalance only or in combination with an external disturbance [3] such as a hammer impact or a base motion. The evidencing of the dry-whip phenomenon as caused by base motion is relatively recent [4]. The aim of this paper is to emphasize the experimental and numerical outcomes of [4]. Moreover, the conditions of onset of the instability depending on the base motion parameters are investigated in more details.

Experimental and numerical investigations

The on-board rotor test rig (two disks mounted on a slender shaft) used in this context is modelled with Timoshenko beam elements and its mesh is sketched in Figure 1. It is equipped with two short fluid film bearings at Nodes 6 and 23 and with multiple contact rings. The ring at Node 15 is intended to be the first one to experience rotor-stator contacts and to be responsible for the dry-whip occurrence while the others are stator bores used rather for safety requirements.

Figure 1: FE mesh of the on-board rotor-bearing system mounted on finite-length journal bearings and equipped with multiple contact rings

In a first study case, the rotor rotates at a fixed speed of rotation of 1700 rpm and two mass unbalances of $2.37 \cdot 10^{-3}$ kg with a $57.0 \cdot 10^{-3}$ m gyration radius are screwed on each disk at 0° and 20° . After reaching the steady-state response, a multi-axial base motion composed of two synchronous transverse shocks (pre- and post- 10 ms pulse of 15 m/s^2) is imposed suddenly and briefly in order to trigger the dry-whip. The measured response in terms of the full spectrogram of the Node 16 transverse displacements is shown in Figure 2. The whirl transition from forward at $\sim 28 \text{ Hz}$ (1700 rpm) to backward at $\sim 170 \text{ Hz}$ is clearly identified when the shock is performed near $t = 2.55 \text{ s}$. Meanwhile, critical vibration levels are also highlighted, until $t \sim 6 \text{ s}$ where the instability suddenly vanished because of the motor-shaft coupling failure and the damping effects.

Figure 2: Full spectrogram of the measured Node 16 orbit of the test rig subject to mass unbalance and to pre- and –post pulse from the base

Then, the instant of the shock is varied numerically in order to impact the contact ring at different rotation angles and to assess if this may favor or inhibit the dry-whip triggering. To this aim, ten values of time instants, equally distributed between 0° and 360° (0° and 360° corresponding to $t=2.55$ s and $t=2.55$ s + T , respectively, with T the mass unbalance period), are performed. The results are presented in Figure 3. It is noticed that for all instants, the dry-whip is triggered, however, it is more delayed and many rebounds are found for instants near 216° . This result can be assigned to the variation of the angle of contact and to the radial velocity of impact that change with the shock instant.

Figure 3: Numerical eccentricities of Node 16 of the test rig subject to mass unbalance and to a base transverse shock translation at $t=0.95$ s with different time instants equivalent to (a) $[0^\circ-144^\circ]$ and to (b) $[180^\circ-324^\circ]$

Investigation of bifurcations in a nonlinear rotor system using numerical continuation

Mehmet S Akay*, Alexander D Shaw*, Michael I Friswell*

*College of Engineering, Swansea University, Swansea, United Kingdom

Summary. Nonlinearities in rotating systems have been seen to cause a wide variety of rich phenomena, however the understanding of these phenomena has been limited because numerical approaches typically rely on ‘brute force’ time simulation, which are inefficient due to issues of step size and settling time, cannot locate unstable solution families and may miss key responses if the correct initial conditions are not used. This work uses numerical continuation to explore the responses of such systems in a more systematic way. A simple isotropic rotor system with a smooth nonlinearity is studied, and the rotating frame is used to obtain periodic solutions. Asynchronous responses with oscillating amplitude are seen to initiate at certain drive speeds due to internal resonance, in a manner similar to that observed for non-smooth rotor stator contact systems in previous literature. These responses are isolated, in the sense that they will only meet the more trivial synchronous responses in the limit of zero damping and out of balance forcing. In addition to increasing our understanding of the responses of these systems, the work establishes the potential of numerical continuation as a tool to systematically explore the responses of nonlinear rotor systems.

Introduction

Nonlinear dynamic system’s response can show bifurcations with small changes in its parameters. Therefore, systematically locating these bifurcation points is vital. Rotating machinery makes this more challenging with gyroscopic coupling that ties the whirl frequencies to the rotor speed. As a result, the internal resonance phenomenon can occur in a large range of operating rotor speeds, resulting in the bouncing orbits involving rotor-stator contact. The contacting interaction can be defined in various ways in the literature, ranging from rigid impact [1] to soft penalty contact [2]. For the solution of nonlinear problems within rotordynamics field, time simulations [3] and analytical and semi-analytical approaches based on harmonic balance method [4] have been used, aside from experimental investigations. However, this work uses the numerical continuation method applied directly to the systems of ODE, as a contrast to Refs. [5], due to its advantages over time simulations in computational cost and over algebraic methods in setup simplicity. The analysed system is a 2-dof overhung rotor with isotropic cubic nonlinearity, shown in Figure 1 in the dimensional form. The equation of motion is nondimensionalised and transformed into the autonomous rotating coordinate frame equations given in Eq. (1).

$$U'' + (-\hat{\Omega}J(\hat{I}_p - 2) + 2\zeta)U' + (\hat{\Omega}^2(\hat{I}_p - 1) + 1 + 2\zeta\hat{\Omega}J)U + \gamma\hat{r}^2U = \hat{m}\hat{e}\hat{\Omega}^2\begin{Bmatrix} 1 \\ 0 \end{Bmatrix}, \quad J = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix} \quad (1)$$

where hat indicates the nondimensional form, $U = [\hat{u}, \hat{v}]$ is the rotating coordinate vector with coordinates \hat{u} and \hat{v} , $\hat{\Omega}$ is the rotor speed, \hat{I}_p is polar moment of inertia, ζ is damping ratio, J is a skew symmetric matrix, γ is the cubic stiffness, \hat{r} is the distance of disk geometric centre to the stationary equilibrium, \hat{m} is the disk mass, \hat{e} is the eccentricity of the disk, $(\cdot)'$ is the derivative with respect to time, all in nondimensional forms.

The main focus of this work is on asynchronous periodic orbits that are caused by internal resonance, and we address similarities and differences to the case of contacting nonlinearity. The solutions found are validated with time simulation. AUTO open-source ODE numerical continuation software and MATLAB ode45 explicit integrator were used in the study.

Figure 1: The 2-dof overhung rotor system with isotropic cubic stiffness.

Results

The bifurcation diagram resulting from the numerical continuation procedure is plotted in Figure 1(a). In this plot, the responses of the system with different damping levels are given together to see the effect of damping. The solution includes the synchronous response, which is skewed highly towards right due to stiffening, and asynchronous response that has two distinct sets of solution families, named here as double- and single-loop solution families after their apparent shapes in Figures 1(b) and 1(c). These orbits are periodic due to being viewed in the rotating frame (otherwise quasi-periodic in the stationary frame). Figures 1(d) and 1(e) show close-ups of asynchronous response to the synchronous solution. The double-loop and single-loop solutions were linked to the internal resonance conditions 3:1 and 2:1 in the rotating coordinates, respectively, by comparing them to the Campbell diagram with signed frequencies. These clearly show the closeness of the periodic responses to the stationary ones in the case of very low damping, $\zeta=1e-5$. The periodic solutions were shown to be present only below a certain damping value that is peculiar to the solution family. This limit

was found to be 0.0116 for double-loop solutions and 0.082 for single-loop solutions, as illustrated in Figure 2.

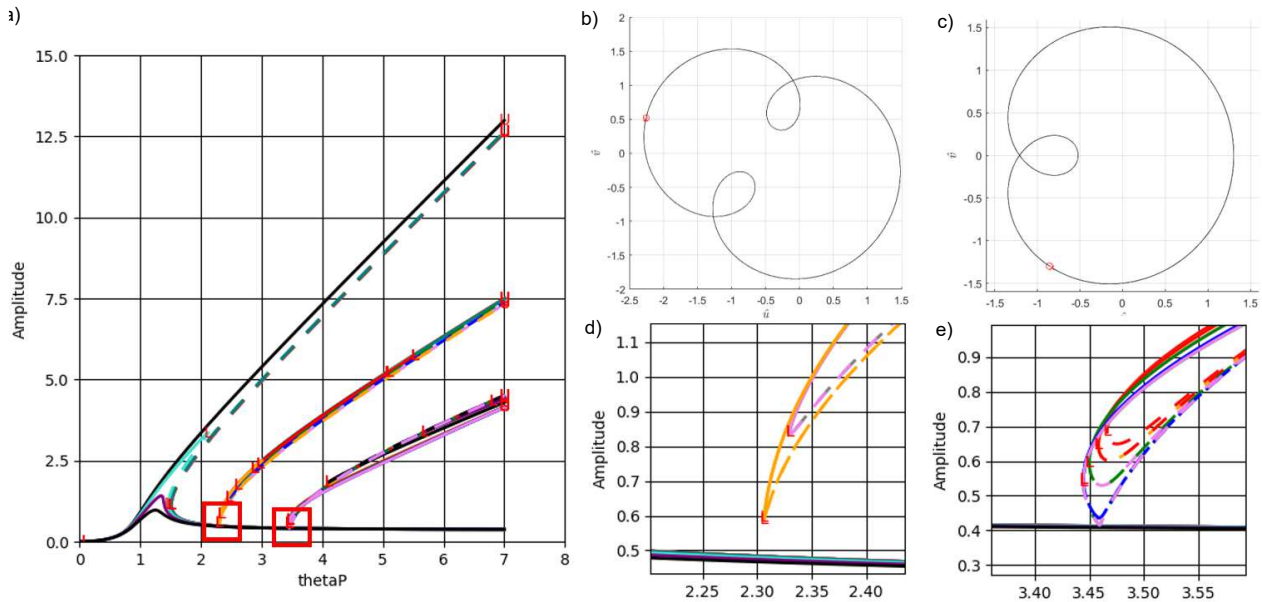

Figure 1: a) Continuation results as bifurcation diagram, b-c) double- and single-loop periodic orbits in rotating frame, d-e) and their low damping tips' close-up. Red “L” signs locate the folds of the solution families. Dashed lines show unstable solutions.

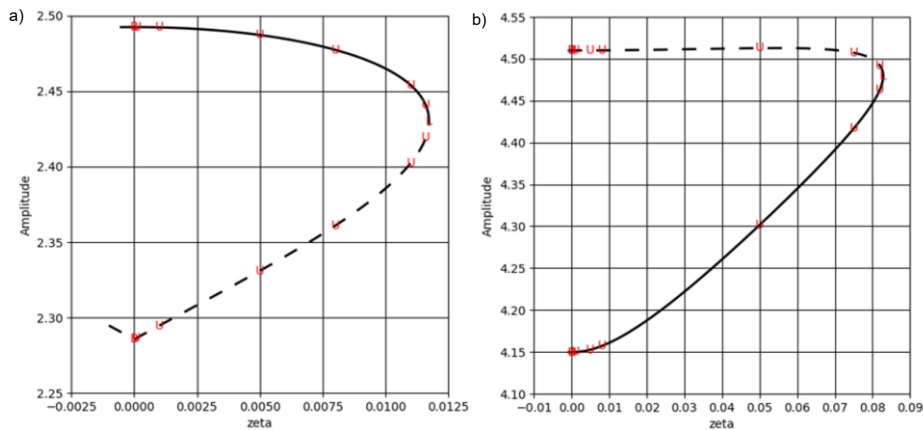

Figure 2: Damping limits for a) double- and b) single loop solution families were 0.0116 and 0.082, respectively. The “U” signs locate the orbits corresponding to the sampled damping values. Dashed lines show unstable solutions.

Conclusions

The softer extreme of rotor-stator contact interaction was investigated by replacing the contact with a cubic stiffness nonlinearity. Direct application of continuation on the equations of motion was easy to setup and the solution procedure can be validated with time simulations easily. The following conclusions were drawn. The previously reported intermittent contact patterns for the models of hard impact and compliant snubber rings can also be observed in the case of the geometric nonlinearity of cubic stiffness. The level of damping changes the region where periodic motions was expected. Higher damping can cause the periodic solutions to disappear from the bifurcation diagrams. However, for low damping there is a limit to the growth of the periodic orbit region towards the lower rotor speeds; for very low values of damping (e.g. $\zeta=1e-4$ and $1e-5$) the periodic solution family approaches the synchronous solutions. It might be inferred that the gap closes asymptotically as ζ and the oscillation amplitude approach zero. This indicates that this region requires very little disturbance for synchronous solutions to jump to the periodic orbits.

Investigation of energy dissipation based on shock and friction to suppress critical self-excited vibrations in drilling systems

Vincent Kulke*, Georg-Peter Ostermeyer* and Andreas Hohl**

* Institute of Dynamics and Vibrations, Department of Mechanical Engineering, TU Braunschweig

** Baker Hughes, Celle, Germany

Summary. In this article, a passive damper based on energy dissipation through shocks and dry friction (shock-friction damper) is investigated with regard to its effectiveness for damping self-excited torsional vibrations similar to those occurring in deep drilling. A minimal model based on a modally reduced complex finite element model of a drill string and a lumped mass representing the inertia of the forcedly connected damper is introduced for an effective and precise investigation of the dynamic motion and damping effect. Particular focus is on the energy flow within the dynamic system and on the change of the dissipation process in the friction contact. The resulting damping effect is compared with the self-excitation due to the bit-rock interaction in the drilling system. Parameters of the considered mode as well as parameters of the damper are examined regarding the damping effect. The shock-friction damper is compared to conventional friction dampers.

Introduction

In downhole drilling systems, various types of vibration occur that can reduce drilling performance and result in premature failure of components [1]. Especially in hard and dense formations, high-frequency torsional oscillations (HFTO) occur in the range of 50 to 500 Hz. These oscillations are self-excited torsional vibrations of higher-order modes that can lead to critical torsional loads. Downhole measurement data show that the self-excitation can be described by a torque characteristic at the bit that decreases with the rotary speed. In [2], an analytical criterion based on a modal transformation is introduced to determine modes that are prone to self-excitation by linearizing the torque characteristic at the mean rotary speed of the drillstring. Increasing the damping of a system is a well-known approach to reduce self-excited vibration amplitudes. Tondl investigated the effect of tuned mass dampers and dry friction [3] on self-excited vibrations. Different types of friction contacts and friction dampers for various fields of engineering were investigated and classified [4]. For example, a friction damper is analyzed in [5] designed for railway wheels consisting of an inertia mass and a friction contact. In drilling systems, the effectiveness of inertia-based dampers is limited due to the small design space in the bottom-hole assembly (BHA) that is naturally limited by the drilled borehole size [6]. This reality necessitates investigation and optimization of the nonlinear forces characteristics between the inertia-mass to dampen the structure effectively. Similar efforts and analysis for nonlinear attachments show a significant effect on the energy output of a dynamic system [7].

Modeling of a passive shock-friction damper

To investigate drillstring vibrations, a finite element model of an entire drillstring using the angular deviations \mathbf{x} from the operating point (constant angular speed and twist) with $\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{f}$ is used. Herein, \mathbf{M} , \mathbf{C} and \mathbf{K} are the mass, damping and stiffness matrices and \mathbf{f} an external force vector. The critical torsional modes are determined by a modal analysis and stability considerations. Following the modal transformation, the physical degrees of freedom \mathbf{x} are expressed by $\mathbf{x} = \mathbf{\Phi}\mathbf{q}$ with the mass-normalized modal matrix $\mathbf{\Phi}$ and the modal degrees of freedom \mathbf{q} .

To perform an efficient and accurate investigation of the damping effect and dynamic behavior of the nonlinear shock-friction damper regarding critical self-excited drill string vibrations, the complex drilling system is reduced. Downhole measurement data show that mostly one critical mode dominates the dynamic motion of the entire drillstring when HFTO occurs. Resulting in a modal single-degree-of-freedom system $\ddot{q} + 2D_i\omega_{0,i}\dot{q} + \omega_{0,i}^2q = \sum_{j=1}^n \varphi_{i,j}M_j$ where $\omega_{0,i}$ and D_i are the natural frequency and modal damping of the i -th mode ($D_i < 0$ for the self-excited HFTO-mode), M_j is an external torque that acts at the j -th node and $\varphi_{i,j}$ is the mass-normalized modal amplitude of the i -th mode at the j -th node. This minimal model can be extended to any damping force characteristic to determine its influence on the critical mode. The equation of motion

$$\begin{pmatrix} 1 & 0 \\ 0 & J \end{pmatrix} \begin{pmatrix} \ddot{q} \\ \ddot{x} \end{pmatrix} + \begin{pmatrix} 2D_i\omega_{0,i} & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} \dot{q} \\ \dot{x} \end{pmatrix} + \begin{pmatrix} \omega_{0,i}^2 & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} q \\ x \end{pmatrix} = \begin{pmatrix} -\varphi_{i,j}M(\varphi_{i,j}\dot{q} - \dot{x}) \\ M(\varphi_{i,j}\dot{q} - \dot{x}) \end{pmatrix} \quad (1)$$

describes a critical mode connected by a torque to an inertia mass.

The torque between the inertia mass and the structure (Equation 2) consists of a friction contact with a normal force F_N , a coefficient of friction μ , a friction radius r and an elastic backlash with a stiffness c and a width S .

$$M(\varphi_{i,j}\dot{q} - \dot{x}) = \begin{cases} F_N\mu r \operatorname{sgn}(\varphi_{i,j}\dot{q} - \dot{x}), & |\varphi_{i,j}q - x| < S \\ F_N\mu r \operatorname{sgn}(\varphi_{i,j}\dot{q} - \dot{x}) + c(|\varphi_{i,j}q - x| - S) \operatorname{sgn}(\varphi_{i,j}q - x), & |\varphi_{i,j}q - x| \geq S \end{cases} \quad (2)$$

The relative angular speed $v_{\text{rel}} = \varphi_{i,j}\dot{q} - \dot{x}$ and the relative angular displacement $x_{\text{rel}} = \varphi_{i,j}q - x$ between the damper and the structure are composed of the modal and physical degree of freedom.

Investigation of vibration response and energy flow

To investigate the influence of the nonlinear shock-friction damper on the structure and the energy flow within the system time domain, simulations are used. Figure 2 (left) shows the motion of the structure and the damper. For small amplitudes, sticking occurs in the friction contact. No relative movement between the structure and the damper takes place. Due to the self-excitation ($D_i < 0$), energy periodically flows into the system (Figure 2, right), resulting in an increase of the amplitude in the sticking phase. At a certain amplitude, the inertial torque of the damper is greater than the friction torque $J\ddot{x} > F_N\mu r$, resulting in sliding regimes and energy dissipation in the friction contact. When the dissipated energy in the friction contact is not sufficient to stabilize the system, the amplitude increases further, resulting in an increased relative displacement and thus in shocks between the damper and the structure.

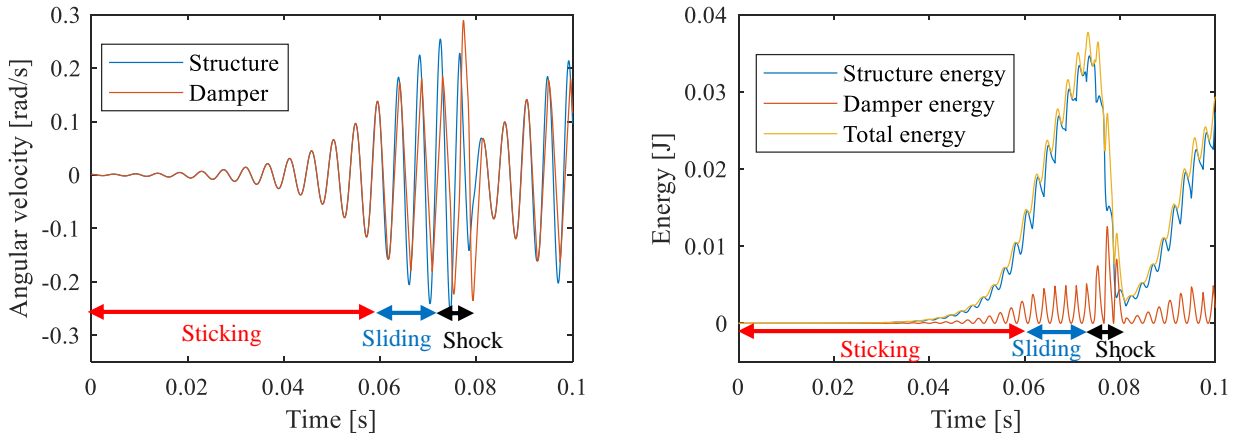

Figure 2: (left) Time response of the damper and the structure, (right) Energy flow within the system

These shocks, which do not occur in a conventional friction damper, lead to an energy transfer between the damper and the structure. Figure 2 (right) shows that while a shock occurs the energy is dissipated in the self-excited structure while the total energy remains almost constant and the energy of the damper increases. This leads to two positive effects on the stability and energy output of the system. The energy transfer reduces the energy of the structure, resulting in a reduced amplitude and thus lower energy input due to self-excitation. Secondly, the energy transfer to the damper increases the relative speed between the damper and the structure, dissipating the energy in the friction contact. Analyses with several modes show similar effects regarding the energy distribution, leading to an improved effectiveness in adjusted parameter ranges.

Parameter influences

Analyzing various parameters show that an increase of the inertia of the damper or the mass normalized modal amplitude at the position of the friction contact results in an increased damping. This is similar to the conventional friction damper without backlash, for which an analytical solution $D_{\max} = \frac{2}{\pi^2} \varphi_{i,j}^2 J$ is found by harmonic linearization [6]. In contrast to the conventional friction damper, the provided damping depends on the backlash width, the friction torque and the natural frequency. A reference for the influence of these parameters is given by the amplitude at which relative displacement occurs $\hat{q} = \frac{F_N \mu r}{\varphi_{i,j} J \omega_{0,j}^2}$. If this amplitude is significantly smaller compared to the backlash width, the damper acts like a conventional friction damper. If the amplitude is much higher, the damping effect is reduced due to limited movement.

Conclusions

This paper examines a combined friction and shock damper for its suitability to reduce self-excited torsional vibrations in downhole drilling systems. The combination of friction and backlash results in passive shocks, causing energy transfer between the self-excited structure and the damper that positively influences the energy output. Compared to a conventional friction damper without backlash, an increase in the damping effect is achieved by adjusting the normal force and backlash width with regard to the vibration frequency.

Summary. The direct parametrisation of invariant manifold is used for model order reduction of large amplitude vibrations of clamped-clamped and rotating cantilever beams. A particular emphasis is set on the computation of the backbone curve in case of internal resonance. For the clamped beam, the 1:5 resonance between first and third mode occurring at large amplitude, is reproduced with the model. For the rotating cantilever, a Campbell diagram is first used to detect the appearance of a 1:5 resonance, which is then computed with the reduction method.

Introduction

The study of slender structures is becoming a prominent issue in several industries as the mass gain becomes crucial. For instance, in the aeronautic industry, the development of more efficient engines by the use of ever larger fan is targeted. This leads to the design of large fan blades, i.e. more than 1 meter long. In order to compensate the dimension of the blade, lighter and softer materials are used, such as composite materials. The combination of the slenderness of the blade with the softness of the material may induce large displacements of the structure when it is submitted to a dynamical loading. It is then important to predict such behaviours, which can lead to specific phenomena like mode coupling and internal resonances, and to the premature failure of the structure.

Model order reduction methods are often used to compute more easily the nonlinear dynamics of such structures [6]. For application to finite element (FE) problems, important steps have been made recently with the possibility of computing directly nonlinear mappings to go from the physical space to the reduced subspace where the dynamics is governed by a very small number of master modes. The Direct Normal Form (DNF) has been proposed in [4], elaborated on a third-order development based on previous works in modal space [5]. An arbitrary order expansion, fully relying on the parametrisation method of invariant manifolds [3], has also been proposed in [7].

In this contribution, the direct parametrisation of invariant manifold is applied to two different test cases featuring internal resonances. In the case of the clamped beam, it is known that a 1:5 internal resonance exists between the 1st and 3rd flexural modes [8]. Concerning the rotating cantilever beam, the internal resonance condition may appear with the rotation and the stiffening of the structure. We will thus show the appearance of a 1:5 internal resonance between the 2nd and the 4th flexural modes, and compute its backbone with the reduction method.

Reduction method with the direct parametrisation

The Direct Parametrisation of Invariant Manifold (DPIM) is very briefly recalled here, relying on the developments shown in [7], and adapted in order to handle the effect brought by centrifugal force for a rotating system. The general equations of motion writes, using standard notations:

$$\mathbf{M}\ddot{\mathbf{x}} + [\mathbf{K} + \mathbf{N}]\mathbf{x} + \mathbf{g}(\mathbf{x}, \mathbf{x}) + \mathbf{h}(\mathbf{x}, \mathbf{x}, \mathbf{x}) = \mathbf{f}_\Omega, \quad (1)$$

with \mathbf{N} the spin softening matrix, \mathbf{f}_Ω the centrifugal effects, and where the Coriolis forces have not been taken into account [2], in contrary to geometric nonlinear terms expressed via \mathbf{g} and \mathbf{h} . These equations can be rewritten around the static equilibrium position \mathbf{x}_0 , depending on the rotation speed, by introducing $\mathbf{x} = \mathbf{x}_0 + \mathbf{u}$, leading to:

$$\mathbf{M}\ddot{\mathbf{u}} + \mathbf{K}_t\mathbf{u} + \mathbf{g}(\mathbf{u}, \mathbf{u}) + 3\mathbf{h}(\mathbf{x}_0, \mathbf{u}, \mathbf{u}) + \mathbf{h}(\mathbf{u}, \mathbf{u}, \mathbf{u}) = \mathbf{0} \quad (2)$$

with $\mathbf{K}_t = \mathbf{K} + \mathbf{N} + 2\mathbf{g}(\mathbf{x}_0, \mathbf{I}) + 3\mathbf{h}(\mathbf{x}_0, \mathbf{x}_0, \mathbf{I})$ the tangent stiffness matrix.

The direct parametrisation method introduces a nonlinear mapping between the original coordinates (displacement \mathbf{u} and velocity \mathbf{v}), and a new, *normal coordinate* \mathbf{z} , which describes the motion on invariant manifold associated to the selected linear master modes, as $\mathbf{u} = \mathbf{\Psi}(\mathbf{z})$ and $\mathbf{v} = \mathbf{\Upsilon}(\mathbf{z})$, where $\mathbf{\Psi}$ and $\mathbf{\Upsilon}$ are unknowns to be determined. The reduced dynamics is also searched under the form $\dot{\mathbf{z}} = \mathbf{f}(\mathbf{z})$. All unknowns are expanded via polynomial expressions at arbitrary order, and solved for, by plugging the expansions in the invariance equation [7]. At each order p , the homological equation gathers the unknowns, which depends only on previous orders, while the first-order term leads to the known modal problem.

Importantly, different styles of solutions exist. Finally, the reduced dynamics, which contains very few equations, can be solved with numerical continuation. The results shown in the next section used MATCONT [1] for this step.

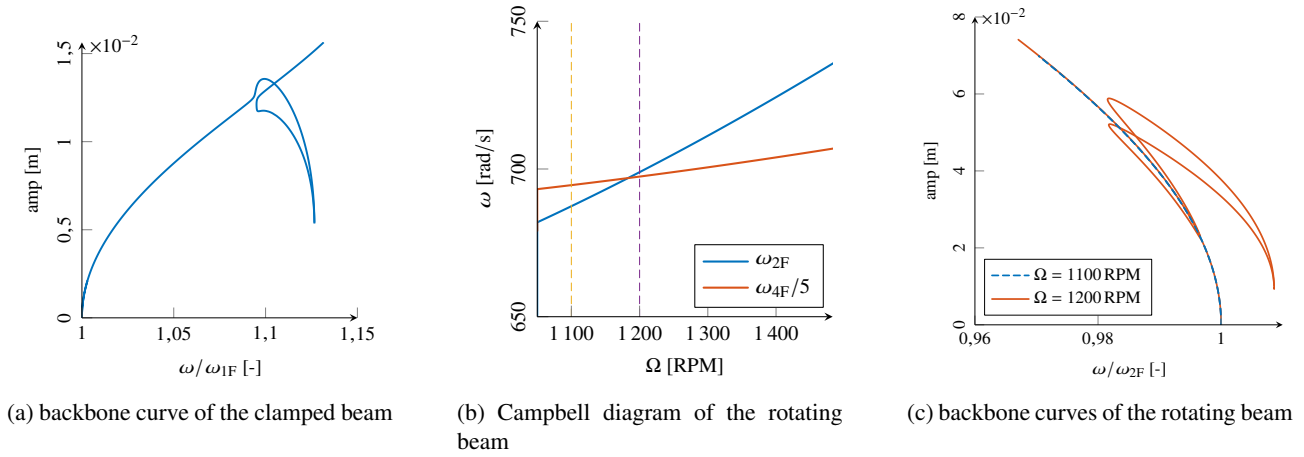

Figure 1: Internal resonances of the beam with 2 boundary conditions : clamped and rotating cantilever

Application case : nonlinear beam

The DPIM is applied here on a beam with dimensions 1 m-2 cm-3 cm. The space is discretised with 27-nodes hexaedral elements with 50 elements in the length and 2×2 in the cross-section.

The first configuration considered is the clamped one. The backbone curve of the first mode is searched for, since it is known that at relatively large amplitudes, it meets a nonlinear internal resonance relationship with the 3rd flexural mode (their linear frequency ratio being $\omega_{3F} = 5.36 \omega_{1F}$). Since a 1:5 resonance is at hand, the parametrisation is developed up to order five, using a complex normal form style. The backbone curve is shown in figure 1a, and is found to very well reproduce the tongue of internal resonance (see e.g. [8] for a reference, full-order solution).

The other configuration is the rotating cantilever beam. For this, we consider the 2nd and the 4th flexural modes. In this case, the internal resonance does not appear without rotation, even though the relation is $\omega_{4F} = 5.45 \omega_{2F}$. As it is visible on the Campbell diagram on figure 1b, the 2 modes cross at a rotation speed around 1180 RPM. In fig. 1c two backbone curves are shown, computed with the reduced order model method. Before the crossing, for a rotational speed of 1100 RPM, the backbone shows a classical softening behaviour without internal resonance (blue dashed curve in fig. 1c). On the other hand, for $\Omega = 1200$ RPM, the backbone shows a clear tongue of internal resonance (orange curve in fig. 1c), highlighting that the 1:5 internal resonance is excited and revealed by the model.

Conclusion

The DPIM [7] has been applied to compute the reduced order model solution of a beam where 2 modes interact in an internal resonance with 2 different boundary conditions. The interesting case is the rotating beam where a condition for the internal resonance to occur has been found on the rotation speed. The method allows to predict those specific behaviors with a very small computation time. Those results need full order model resolution to be compared with, which will be achieved in the near future.

Summary. In this work, the mutual influence of the nonlocal behavior superimposed to the size effects on the dynamics of electrically actuated single walled carbon nanotube based resonator are examined. In this regards, two nonlinear models to capture the nano-structure nonlocal size effects are considered: the strain and the velocity gradients theories. A reduced-order model based on the Differential-Quadrature Method (DQM) to discretize the governing nonlinear equation of motion and acquire a discretized-parameter nonlinear model of the system is investigated. Both model results show that non-local as well size effects should not be neglected since they somehow improve the prediction of corresponding dynamic amplitudes and most importantly the critical resonant frequencies of such nano-resonators.

Introduction

Thanks to their amazing electro-mechanical features, carbon nanotubes (CNTs) and their respective compounds have shown potential applications in numerous electronic devices, energy storage, smart materials and composites, sensors and actuators and etc... Consequently, a lot of researchers and scientists worldwide [1-5] have been attracted to investigate their interesting physio-mechanical properties by introducing non-classical models. Several non-classical continuum theories have been presented and developed to pave the way for precisely extracting the size-dependent behavior of CNTs for future applications. To cite few, nonlocal theories [1] and strain gradient elasticity theory [2] are very useful to account for the nanoscale characteristics of nanostructures. In nonlocal theories, it is assumed that the stress at a specific point is a function of the strains of that point and its neighborhood as well [3]. It is demonstrated that the nonlocal theories only consider the inter-atomic long-range force [4] and the gradient elasticity theory exclusively takes into account the higher-order microstructure deformation mechanism [5]. From another point of view, the gradient elasticity theory captures the hardening behavior of nanoscale structure and, on the contrary, can only model the softening behavior of nanostructures like CNTs [4]. Therefore, in order to predict two different behaviors simultaneously and combine both possible features in nanoscale structures, it is convenient to merge two theories to bring into account two distinct properties at the same time. The key motivation behind this research work is to conduct a comprehensive study to account for the nonlocality of the stress in nanostructures incorporating the complete gradient elastic analysis of structures, that is to say, the strain and velocity gradients are included in the generalized governing equations.

Problem formulation

The investigated CNT-based resonator, Fig.1, is triggered by its lower substrate with an assumed initial gap width d . The CNT will be assumed as a cylindrical beam shape of radius \bar{R} , and length L . The area moment of inertia of $I = \pi \bar{R}^4 / 4$ and a resultant cross-sectional area $A = \pi \bar{R}^2$. It also has a Young's modulus $E = 1 \text{ TPa}$ and a density $\rho = 1.35 \text{ g/cm}^3$ [6].

Figure 1: 3D drawing of an electrostatically actuated SWCNT based resonator.

Through considering the nonlocal effects of higher-order strain gradients $\varepsilon_{ij,k}$, in which the index k after the comma denotes the differentiation with respect to x_k , the extended Eringen's model gets the following expression for the internal potential energy as [7,8]:

$$U_0(\varepsilon_{ij}, \varepsilon'_{ij}, \alpha_0; \varepsilon_{ij,m}, \varepsilon'_{ij,m}, \alpha_1) = \frac{1}{2} \varepsilon_{ij} C_{ijkl} \int_V \alpha_0(|x-x'|, e_0 a) \varepsilon'_{kl} dV + \frac{l_s^2}{2} \varepsilon_{ij,m} C_{ijkl} \int_V \alpha_1(|x-x'|, e_1 a) \varepsilon'_{kl,m} dV = \frac{1}{2} \int_V (\sigma_{ij} \varepsilon_{ij} + \sigma_{ijm}^{(1)} \varepsilon_{ij,m}) dV \quad (1)$$

where $e_0 a$ and $e_1 a$ represent the influence of the inter atomic long range force and l_s stands for the strain gradient length parameter. In the framework of an Euler-Bernoulli beam theory and taking into consideration the so-called von-Karman nonlinearity, the relation for the strain-displacement of the beam (to the first order) can be written as $\varepsilon_{xx} = u_{,x} + w_{,x}^2 / 2 - z w_{,xx}$. Employing the Hamilton's principle, the following normalized nonlinear governing equations of a fixed-fixed CNT resonator based on the nonlocal strain and velocity gradient theories [4]:

$$\left(1 - \mu_1 \frac{\partial^2}{\partial x^2}\right) \frac{\partial^4 w}{\partial x^4} + \left(1 - \mu_0 \frac{\partial^2}{\partial x^2}\right) \left(\frac{\partial^2 w}{\partial t^2} + \alpha_d \frac{\partial w}{\partial t} - \alpha_r \frac{\partial^4 w}{\partial x^2 \partial t^2} - \alpha_r \left(\int_0^1 \left(\frac{\partial w}{\partial x} \right)^2 dx \right) \frac{\partial^2 w}{\partial x^2} \right) = \alpha_r \Gamma(w) + \mu_k \left(2 \frac{\partial^4 w}{\partial x^2 \partial t^2} - \alpha_r \frac{\partial^6 w}{\partial x^4 \partial t^2} \right); \quad (2)$$

where μ_k is the velocity gradient kinetic internal length scale and:

$$\alpha_i = \frac{Ad^2}{2I}, \alpha_r = \frac{\pi \varepsilon_0 L^4}{EI d^2}, \alpha_s = \frac{I}{AL^2}, \alpha_v = \tilde{c} \frac{L^4}{EI}, \mu_0 = \left(\frac{ea}{L} \right)^2, \mu_i = \left(\frac{l_i}{L} \right)^2, \mu_s = \left(\frac{l_s}{L} \right)^2, \text{ and } R = \frac{\tilde{R}}{d}, \quad (3)$$

Spatial Discretization using the Differential Quadrature Method

In order to numerically solve the nonlinear governing equation (14), we suggest to implement the Differential Quadrature Method (DQM) superimposed to the Finite-Difference Method (FDM). For the accuracy of the numerical results, the subsequent lattice distribution is assumed as $x_i = 1/2[1 - \cos((i-1)\pi/(n-1))]$, $i = 1, 2, \dots, n$ [9]. Therefore, for a normalized space variable x in the interval (0,1) and defining n discretization points in the space domain, the p^{th} -sequence derivative of w at point $x = x_i$ is written as $\partial^p w / \partial x^p \big|_{x=x_i} = \sum_{j=1}^n D_{ij}^{(p)} w_j$. The weighting coefficient matrix of the first sequence

derivative is defined as $D_{ij}^{(p=1)} = \prod_{k=1, k \neq i}^n (x_i - x_k) / (x_i - x_j) \prod_{k=1, k \neq j}^n (x_j - x_k)$, $i, j = 1, 2, \dots, n$, $i \neq j$

Nonlinear Dynamic Analysis: Results and Discussion

As a case study, the parameters of the studied SWCNT are considered as: $d=100$ nm, $L=3000$ nm and $\tilde{R}=30$ nm. In this work 19 discretization points is used in the DQM to get the converged results. The variation of the steady-state maximum deflection W_{\max} versus the forcing AC frequency Ω is outlined in Fig. 2 for different values of the nonlocal parameter μ_0 . As can be seen, when $V_{DC}=1$ volt, an increase of the nonlocal parameter resulted in decreasing the maximum dynamic amplitude of the CNT. Furthermore, when considering the nonlocality effect, a softening-like behavior of the CNT has been replaced by a hardening type behavior. Figure 3 displays the frequency response of CNT for different values of the strain gradient parameter μ_s . It is evident that the maximum amplitude of the system is increased by increasing the value of DC voltage and the bandwidth expansion is increased as the DC excitation voltage increases. Figure 4 shows the frequency-response curves for three different values of velocity gradient parameter μ_k . As can be observed, the maximum dynamic deflection of the structure is considerably amplified by increasing the velocity gradient parameter and consequently the bandwidth expansion increases as the velocity gradient parameter increases.

Figure 2: Dynamic response for three different nonlocal parameters for $V_{DC}=1$ Volt, $V_{AC}=1$ Volt.

Figure 3: Dynamic response for three different values of the DC voltage for $\mu_s = 0.1^2$.

Figure 4: Dynamic response for three different velocity gradient parameters (a) $V_{DC}=1$ Volt, $V_{AC}=1$ Volt.

Conclusion

In this numerical investigation, the nonlinear dynamics of an electrically actuated doubly-clamped single-walled carbon nanotube resonator is carried out. A nonlinear Euler-Bernoulli beam model incorporating both the nonlocal and strain/velocity gradient theories is implemented. The derived nonlinear governing equation is discretized through a Differential Quadrature Method (DQM). The acquired results in this work demonstrated the fact that neglecting the nonlocal as well as the size effects imposed considerable errors in the estimation of the dynamic response of SWCNT and consequently in determining accurately its dynamical parameters such as: its resonant deflection (approx. 10-20% error) its fundamental resonant frequency (approx. 15-20% error).

Modelling and dynamics of smart composite box beam with nonlinear constitutive behaviour of active elements

Jarosław Latański*, Jerzy Warmański*

**Department of Applied Mechanics, Faculty of Mechanical Engineering,
Lublin University of Technology, Lublin, Poland*

Summary. The presented research discusses the mathematical modelling of composite thin-walled beams with embedded active elements made of piezoceramic materials. The analysis the nonlinear relations in piezoceramics with respect to electric field (electrostrictive effect) is considered to properly capture the behaviour of the transducer in near-resonant conditions. Moreover, the importance of disregarding/accounting for the magnetic effects is highlighted. In the adopted model of the piezoceramic actuation the bending load to the hosting composite beam is achieved by means of d_{31} piezoelectric effect. The governing equations of the system are derived using Hamilton's principle for a beam undergoing complex deformation involving transverse and in-plane shearable bending, torsion and axial deformations. The obtained system of partial differential equations is transformed into a set of ordinary ones by the Galerkin discretization method. The results of performed numerical studies show the importance of non-linear terms for accurate prediction of systems dynamic properties; in particular one can observe the softening phenomenon near the resonance zone due to the nonlinear characteristics of the PZT layers and electrostrictive effect.

Over recent 10-20 years smart composite elements have received a considerable attention due to their potential for designing adaptive structures that are both light in weight and possess adaptive capabilities. Due to their unique properties like e.g. high strength-to-weight ratio and high structural damping the composite based smart structures are very competitive for many designs. In particular active transducers based on piezoelectric/piezoceramic materials have found numerous applications ranging from astronautics and aerospace technology to the automotive industry and civil engineering. Typical examples might be spacecraft antennas, helicopter rotor blades, wind turbines, multi-stable morphing shells, bridge elements etc.

Modelling of smart composite structures

The physics involved in piezoelectric theory can be regarded as a coupling between Maxwell's equations of electromagnetism and elastic stress equations of motion. The coupling takes place through the piezoelectric constitutive equations providing the relationships between the tensors of stress and strain and the vectors of electric field and electric flux density.

The system of Maxwell's equations in vector form is written as

$$\begin{aligned}\nabla \cdot \mathbf{D} &= \rho_e \\ \nabla \cdot \mathbf{B} &= 0 \\ \nabla \times \mathbf{E} &= -\dot{\mathbf{B}} \\ \frac{1}{\mu}(\nabla \times \mathbf{B}) &= i_b + \dot{\mathbf{D}}\end{aligned}\tag{1}$$

where \mathbf{D} is the electric flux density vector, also known as the electric displacement vector, ρ_e is the charge density, \mathbf{B} is the magnetic induction, \mathbf{E} is the electric field intensity vector and μ is the magnetic permeability constant. The over dots represent differentiation with time t .

In the literature there are mainly three approaches to deal with electromagnetic effects when modelling the behaviour of piezoelectric domain [1]:

- electrostatic approach when all magnetic effects are completely ignored. This involves $\mathbf{B} = \dot{\mathbf{D}} = \rho_e = i_b = 0$. Therefore the system of Maxwell's equations is reduced to $\nabla \cdot \mathbf{D} = 0$ and $\nabla \times \mathbf{E} = 0 \Rightarrow \mathbf{E} = -\nabla\phi$. This approach is the simplest one and simultaneously the most common one even when studying dynamics of smart structures. This is due to the fact that the electric potential ϕ is directly available,
- quasi-static approach that rules out some but not all the magnetic effects. Typically $\rho_e = i_b = 0$ but D and B are time-dependent. Thus, the (1)₂ implies that there exists a magnetic potential vector \mathbf{A} such that $B = \nabla \times \mathbf{A}$. Therefore, the electric potential is related to electric field and changes in magnetic potential: $\mathbf{E} = -\nabla\phi - \dot{\mathbf{A}}$,
- fully dynamic when \mathbf{A} and $\dot{\mathbf{A}}$ are left in the analysis. Depending on the type of material, body charge density ρ_e and body current density i_b can also be non-zero.

The well known physically linear relationships between the tensors of stress and strain and the vectors of electric field and electric displacement for piezoelectric materials are applicable to a particular case where nonlinear effects are negligible [2, 3]. However, numerous theoretical and experimental studies suggest the piezoceramics can exhibit nonlinear constitutive properties resulting from high electric fields, near resonant operation regimes or stress-strain hysteresis [4, 5, 6, 7, 8].

To properly capture these phenomena authors postulate to enhance the classical piezoelectric constitutive formulation by adopting the higher-order relations with respect to electric field [9]

$$\begin{aligned}\sigma &= \mathbf{C}\varepsilon - \mathbf{e}\mathbf{E} - \hat{\mathbf{b}} \operatorname{sgn}(E_3)\mathbf{E}^2 \\ \mathbf{D} &= \mathbf{e}\varepsilon + \boldsymbol{\xi}\mathbf{E} + \chi \operatorname{sgn}(E_3)\mathbf{E}^2\end{aligned}\quad (2)$$

In the above relations \mathbf{C} stands for the second order piezoceramic elasticity tensor at constant electric field, \mathbf{e} is the tensor of piezoelectric coefficients, $\boldsymbol{\xi}$ is second order permittivity tensor, $\hat{\mathbf{b}}$ is effective electrostrictive constants tensor, χ is third order electric susceptibility tensor. Moreover, the variables σ and ε stand for stress and strain tensors, respectively.

The submitted research is a continuation of former author's studies on dynamics of smart composite thin-walled beams [10, 11]. In the former one an electromechanical coupled theory is used to develop the equations of motion of a rotating thin-walled beam with surface bonded/embedded piezoelectric transducers. In the mathematical model of the hybrid structure, the non-classical effects like material anisotropy, rotary inertia and transverse shear deformation as well as an arbitrary beam pitch angle and hub mass moment of inertia are incorporated. It has been shown this approach results in an additional equation of motion for the hub sub-system and significantly enhances the generality of the formulation. Comparing to the purely mechanical model with simplified approach, the proposed electromechanical one introduces additional stiffness-type couplings between individual degrees of freedom of the system. In the following paper [11] the dynamics of layered composite piezo-beam with lamination scheme exhibiting the circumferentially uniform stiffness properties of the cross section has been presented. Moreover, the two-way coupling interaction involving the spatial distribution of electric field in the piezoceramic domain has been discussed.

Summary. This paper extends the linear concept of phase resonance, which occurs when the damping forces counterbalance exactly the external forces, to oscillators with polynomial stiffness. To this end, a first-order averaging technique is applied to a one degree-of-freedom oscillator with arbitrary polynomial stiffness. We show that phase resonance exists in the vicinity of amplitude resonance and is associated with a phase resonance of $\pi/2$.

Introduction

Modal analysis has been, and continues to be, the dominant dynamical method used in structural design. The goal of modal analysis is to find the vibration modes, resonance frequencies and damping ratios of the considered system [1]. One key assumption of modal analysis is linearity.

In linear theory, the resonant behavior of dynamical systems can be characterized either the amplitude or phase resonance. Amplitude resonance corresponds to a relative maximum in the frequency response function whereas phase resonance is associated with quadrature between the displacement and the external forcing. At phase resonance, the external forcing cancels exactly the damping force with the result that the resonance frequency coincides with the natural frequency of the linear system. The difference between the two resonances remains small for weakly damped systems.

However, real-world structures are intrinsically nonlinear because they may feature advanced materials, friction and contact [2]. In this context, the present study proposes to extend the concept of phase resonance to oscillators with arbitrary polynomial stiffness. To do so, a first-order averaging technique is applied to a one degree-of-freedom oscillator and we show that phase resonance exists in the vicinity of amplitude resonance for a phase lag of $\pi/2$.

Oscillator with polynomial stiffness

The governing equation of motion of a harmonically-forced oscillator with arbitrary polynomial stiffness is

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) + \sum_{d=2}^n k_d x^d(t) = f \sin \omega t \quad (1)$$

where m , c , k and k_d represent the mass, damping, linear and nonlinear stiffness coefficients, respectively. f is the forcing amplitude whereas ω is the excitation frequency of period T . The natural frequency of the undamped, linearized system is $\omega_0 = \sqrt{\frac{k}{m}}$. Through mass normalization, Equation (1) can be recast into:

$$\ddot{x}(t) + 2\bar{\zeta}\omega_0 \dot{x}(t) + \omega_0^2 x(t) + \sum_{d=2}^{\infty} \alpha_d x^d(t) = \bar{\gamma} \sin \omega t \quad (2)$$

where $\bar{\zeta} = \frac{c}{2\sqrt{km}}$, $\alpha_d = k_d/m$ and $\bar{\gamma} = f/m$.

An averaging technique

We consider a weakly nonlinear oscillator of the form:

$$\ddot{x}(t) + \omega_0^2 x(t) = \varepsilon f(x(t), \dot{x}(t)) \quad (3)$$

When $\varepsilon = 0$, the periodic solution of (3) is written as:

$$x(t) = u \cos \omega_0 t - v \sin \omega_0 t \quad (4)$$

where u and v are constants. When $\varepsilon \neq 0$, we seek a solution of frequency ω such that $\omega^2 - \omega_0^2 = \varepsilon \Omega$. The solution is expressed as in Equation (4) but with time-dependent u and v :

$$x(t) = u(t) \cos \omega t - v(t) \sin \omega t \quad (5)$$

We impose that the velocity should have the same form as in the case $\varepsilon = 0$, i.e.,

$$\dot{x}(t) = -u(t) \omega \sin \omega t - v(t) \omega \cos \omega t \quad (6)$$

Equation (6) holds if:

$$\dot{u}(t) \cos \omega t - \dot{v}(t) \sin \omega t = 0 \quad (7)$$

Differentiating Equation (6) and replacing $\ddot{x}(t)$ and $x(t)$ in Equation (3) yields:

$$\dot{u}(t) \omega \sin \omega t + \dot{v}(t) \omega \cos \omega t = -\varepsilon [f(x(t), \dot{x}(t)) + \Omega x(t)] \quad (8)$$

Finally, taking into account Equations (7) and (8) and solving for \dot{u} and \dot{v} , a system of first-order equations is obtained:

$$\begin{cases} \dot{u} = -\frac{\varepsilon}{\omega} [f(x(t), \dot{x}(t)) + \Omega x(t)] \sin \omega t \\ \dot{v} = -\frac{\varepsilon}{\omega} [f(x(t), \dot{x}(t)) + \Omega x(t)] \cos \omega t \end{cases} \quad (9)$$

This system has a suitable form to apply first-order averaging, which is performed herein using the Krylov-Bogolyubov technique [3, 4], which consists in integrating these equations over one period of time T , during which u and v are considered to be constants:

$$\begin{cases} \dot{u} = -\frac{\varepsilon}{\omega} \frac{1}{T} \int_0^T [f(x(t), \dot{x}(t)) + \Omega x(t)] \sin \omega t dt \\ \dot{v} = -\frac{\varepsilon}{\omega} \frac{1}{T} \int_0^T [f(x(t), \dot{x}(t)) + \Omega x(t)] \cos \omega t dt \end{cases} \quad (10)$$

Or alternatively, if we consider $\omega t = \theta$:

$$\begin{cases} \dot{u} = -\frac{\varepsilon}{\omega} \frac{1}{2\pi} \int_0^{2\pi} [f(x(\theta), \dot{x}(\theta)) + \Omega x(\theta)] \sin \theta d\theta \\ \dot{v} = -\frac{\varepsilon}{\omega} \frac{1}{2\pi} \int_0^{2\pi} [f(x(\theta), \dot{x}(\theta)) + \Omega x(\theta)] \cos \theta d\theta \end{cases} \quad (11)$$

Finally, $x(t)$ is often represented using the polar coordinates r and ϕ such that $x(t) = r(t) \sin(\omega t - \phi(t))$ with $r = \sqrt{u^2 + v^2}$ and $\phi = \text{atan2}(-u, -v)$, where $u = -r \sin \phi$ and $v = -r \cos \phi$. Furthermore, we can express the time derivatives of r and ϕ as:

$$\begin{cases} \dot{r} = \frac{\partial r}{\partial u} \dot{u} + \frac{\partial r}{\partial v} \dot{v} = \frac{u}{r} \dot{u} + \frac{v}{r} \dot{v} \\ \dot{\phi} = \frac{\partial \phi}{\partial u} \dot{u} + \frac{\partial \phi}{\partial v} \dot{v} = \frac{v}{r^2} \dot{u} - \frac{u}{r^2} \dot{v} \end{cases} \quad (12)$$

For conciseness, the time dependence for u , v , r and ϕ is dropped in the remainder of this chapter.

First-order averaging of an oscillator with polynomial stiffness

Scaling of the equation of motion

Considering Equation (2), we scale the system such that $\bar{\zeta} = \varepsilon \zeta$, $\bar{\alpha}_d = \varepsilon \alpha_d$ and $\bar{\gamma} = \varepsilon \gamma$, with ζ , α , $\gamma = \mathcal{O}(1)$, we obtain a weakly nonlinear oscillator:

$$\ddot{x}(t) + \omega_0^2 x(t) = \varepsilon \left(\gamma \sin \omega t - 2\zeta \omega_0 \dot{x}(t) - \sum_{d=2}^{\infty} \alpha_d x^d(t) \right) \quad (13)$$

Assuming a forcing frequency in the vicinity of the natural frequency of the linear system, i.e., $\omega^2 - \omega_0^2 = \varepsilon \Omega$, we can apply an averaging technique and the displacement as explained in Section . This consists in solving:

$$\begin{cases} \dot{u} = -\frac{\varepsilon}{\omega} \frac{1}{2\pi} \int_0^{2\pi} [(\gamma \sin \theta - 2\zeta \omega_0 \dot{x}(\theta) - \sum_{d=2}^{\infty} \alpha_d x^d(\theta)) + \Omega x(\theta)] \sin \theta d\theta \\ \dot{v} = -\frac{\varepsilon}{\omega} \frac{1}{2\pi} \int_0^{2\pi} [(\gamma \sin \theta - 2\zeta \omega_0 \dot{x}(\theta) - \sum_{d=2}^{\infty} \alpha_d x^d(\theta)) + \Omega x(\theta)] \cos \theta d\theta \end{cases} \quad (14)$$

For clarity, the different terms are analysed separately, i.e., the forcing, damping, frequency and stiffness terms.

Furthermore, to solve these integrals, we make use of the fact that:

$$\int_0^{2\pi} \cos^a \theta \sin^b \theta d\theta = \frac{1}{2} [(-1)^a + 1] [(-1)^b + 1] \frac{\Gamma(\frac{a}{2} + \frac{1}{2}) \Gamma(\frac{b}{2} + \frac{1}{2})}{\Gamma(\frac{a}{2} + \frac{b}{2} + \frac{1}{2})} \quad (15)$$

which is always equal to 0 if either a or b is odd. Therefore, we can write:

$$\frac{1}{2\pi} \int_0^{2\pi} \cos^{2n} \theta \sin^{2m} \theta d\theta = \frac{1}{\pi} \frac{\Gamma(n + \frac{1}{2}) \Gamma(m + \frac{1}{2})}{\Gamma(n + m + \frac{1}{2})} \quad (16)$$

where Γ is the *Gamma* function.

Forcing term

For \dot{u} and \dot{v} , we have respectively:

$$\frac{1}{2\pi} \int_0^{2\pi} \gamma \sin^2 \theta d\theta = \frac{\gamma}{2} \quad (17)$$

and

$$\frac{1}{2\pi} \int_0^{2\pi} \gamma \cos \theta \sin \theta d\theta = 0 \quad (18)$$

Damping term

For \dot{u} and \dot{v} , we have respectively:

$$-\frac{1}{2\pi} \int_0^{2\pi} 2\zeta \omega_0 (-u \omega \sin^2 \theta - v \omega \cos \theta \sin \theta) d\theta = \zeta \omega_0 \omega u \quad (19)$$

and

$$-\frac{1}{2\pi} \int_0^{2\pi} 2\zeta \omega_0 (-u \omega \cos \theta \sin \theta - v \omega \cos^2 \theta) d\theta = \zeta \omega_0 \omega v \quad (20)$$

Frequency term

For \dot{u} and \dot{v} , we have respectively:

$$\frac{1}{2\pi} \int_0^{2\pi} \Omega (u \cos \theta \sin \theta - v \sin^2 \theta) d\theta = -\frac{\Omega v}{2} \quad (21)$$

and

$$\frac{1}{2\pi} \int_0^{2\pi} \Omega (u \cos^2 \theta - v \cos \theta \sin \theta) d\theta = \frac{\Omega u}{2} \quad (22)$$

Polynomial stiffness terms

For \dot{u} and \dot{v} , we need to solve respectively:

$$-\sum_{d=2}^{\infty} \frac{1}{2\pi} \int_0^{2\pi} \alpha_d (u \cos \theta - v \sin \theta)^d \sin \theta d\theta \quad (23)$$

and

$$-\sum_{d=2}^{\infty} \frac{1}{2\pi} \int_0^{2\pi} \alpha_d (u \cos \theta - v \sin \theta)^d \cos \theta d\theta \quad (24)$$

To do so, we need to expand the polynomial term using the binomial expansion:

$$(u \cos \theta - v \sin \theta)^d = \sum_{p=0}^d \binom{d}{p} (u \cos \theta)^{d-p} (-v \sin \theta)^p \quad (25)$$

which thus gives for \dot{u} and \dot{v} , respectively:

$$-\sum_{d=2}^{\infty} \alpha_d \sum_{p=0}^d \binom{d}{p} u^{d-p} (-v)^p \frac{1}{2\pi} \int_0^{2\pi} \cos^{d-p} \theta \sin^{p+1} \theta d\theta \quad (26)$$

and

$$-\sum_{d=2}^{\infty} \alpha_d \sum_{p=0}^d \binom{d}{p} u^{d-p} (-v)^p \frac{1}{2\pi} \int_0^{2\pi} \cos^{d-p+1} \theta \sin^p \theta d\theta \quad (27)$$

The result of the integrals depends on the parity of the exponents of the sine and cosine terms and the different possibilities are studied hereafter.

Case 1: d and p are odd.

In this case, we set $d = 2i + 1$ and $p = 2j + 1$. For \dot{u} we have:

$$\sum_{i=1}^{\infty} \alpha_{2i+1} \sum_{j=0}^i \binom{2i+1}{2j+1} u^{2(i-j)} v^{2j+1} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i-j)} \theta \sin^{2(j+1)} \theta d\theta \neq 0 \quad (28)$$

for which the result depends on the values of i and j . For \dot{v} , we have:

$$\sum_{i=1}^{\infty} \alpha_{2i+1} \sum_{j=0}^i \binom{2i+1}{2j+1} u^{2(i-j)} v^{2j+1} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i-j)+1} \theta \sin^{2j+1} \theta d\theta = 0 \quad (29)$$

since both exponents are odd.

Case 2: d is odd and p is even.

In this case, we set $d = 2i + 1$ and $p = 2j$. For \dot{u} we have:

$$-\sum_{i=1}^{\infty} \alpha_{2i+1} \sum_{j=0}^i \binom{2i+1}{2j} u^{2(i-j)} v^{2j} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i-j)+1} \theta \sin^{2j+1} \theta d\theta = 0 \quad (30)$$

since both exponents are odd. For \dot{v} , we have:

$$-\sum_{i=1}^{\infty} \alpha_{2i+1} \sum_{j=0}^i \binom{2i+1}{2j} u^{2(i-j)+1} v^{2j} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i-j+1)} \theta \sin^{2j} \theta d\theta \neq 0 \quad (31)$$

for which the result depends on the values of i and j .

Case 3: d and p are even.

In this case, we set $d = 2i$ and $p = 2j$. For \dot{u} we have:

$$-\sum_{i=0}^{\infty} \alpha_{2i} \sum_{j=0}^i \binom{2i}{2j} u^{2(i-j)} v^{2j} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i-j)} \theta \sin^{2j+1} \theta d\theta = 0 \quad (32)$$

since one of the exponents is odd. For \dot{v} , we have:

$$-\sum_{i=0}^{\infty} \alpha_{2i} \sum_{j=0}^i \binom{2i}{2j+1} u^{2(i-j)} v^{2j} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i-j)+1} \theta \sin^{2j} \theta d\theta = 0 \quad (33)$$

since one of the exponents is odd.

Case 4: d is even and p is odd.

In this case, we set $d = 2i$ and $p = 2j + 1$. For \dot{u} we have:

$$\sum_{i=0}^{\infty} \alpha_{2i} \sum_{j=0}^i \binom{2i}{2j+1} u^{2(i-j)-1} v^{2j+1} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i-j)-1} \theta \sin^{2(j+1)} \theta d\theta = 0 \quad (34)$$

since one of the exponents is odd. For \dot{v} , we have:

$$\sum_{i=0}^{\infty} \alpha_{2i} \sum_{j=0}^i \binom{2i}{2j+1} u^{2(i-j)-1} v^{2j+1} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i-j)} \theta \sin^{2j+1} \theta d\theta = 0 \quad (35)$$

since one of the exponents is odd.

Summary:

Therefore, we end up with:

$$\sum_{i=1}^{\infty} \alpha_{2i+1} \sum_{j=0}^i \binom{2i+1}{2j+1} u^{2(i-j)} v^{2j+1} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i-j)} \theta \sin^{2(j+1)} \theta d\theta \quad (36)$$

and

$$-\sum_{i=1}^{\infty} \alpha_{2i+1} \sum_{j=0}^i \binom{2i+1}{2j} u^{2(i-j)+1} v^{2j} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i-j+1)} \theta \sin^{2j} \theta d\theta \quad (37)$$

for \dot{u} and \dot{v} , respectively. We thus observe that the stiffness of even orders do not participate in the motion around the primary resonance at first order.

Averaged solution around the primary resonance

The average solution for \dot{u} is therefore:

$$\dot{u} = -\frac{\varepsilon}{\omega} \left(\frac{\gamma}{2} + \zeta \omega_0 \omega u - \frac{\Omega v}{2} + \sum_{i=1}^{\infty} \alpha_{2i+1} \sum_{j=0}^i \binom{2i+1}{2j+1} u^{2(i-j)} v^{2j+1} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i-j)} \theta \sin^{2(j+1)} \theta d\theta \right) \quad (38)$$

and for \dot{v} :

$$\dot{v} = -\frac{\varepsilon}{\omega} \left(\zeta \omega_0 \omega v + \frac{\Omega u}{2} - \sum_{i=1}^{\infty} \alpha_{2i+1} \sum_{j=0}^i \binom{2i+1}{2j} u^{2(i-j)+1} v^{2j} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i-j+1)} \theta \sin^{2j} \theta d\theta \right) \quad (39)$$

Those equations can be gathered in order to get \dot{r} and $\dot{\phi}$ using the relations from Equation 12. However, this leads to complex expressions and it is interesting to see if the effect of the polynomial stiffness can be simplified.

Solution for \dot{r}

First, for \dot{r} , it is possible to show that when we use the relation: $u\dot{u} + v\dot{v}$, then we have for the polynomial stiffness terms:

$$\begin{aligned} & \sum_{i=1}^{\infty} \alpha_{2i+1} \sum_{j=0}^i \binom{2i+1}{2j+1} u^{2(i-j)+1} v^{2j+1} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i-j)} \theta \sin^{2(j+1)} \theta d\theta \\ & - \sum_{i=1}^{\infty} \alpha_{2i+1} \sum_{j=0}^i \binom{2i+1}{2j} u^{2(i-j)+1} v^{2j+1} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i-j+1)} \theta \sin^{2j} \theta d\theta = 0 \end{aligned} \quad (40)$$

Taking out the constant terms, we end up with:

$$\sum_{j=0}^i \frac{u^{2(i-j)+1} v^{2j+1}}{2\pi} \left(\binom{2i+1}{2j+1} \int_0^{2\pi} \cos^{2(i-j)} \theta \sin^{2(j+1)} \theta d\theta - \binom{2i+1}{2j} \int_0^{2\pi} \cos^{2(i-j+1)} \theta \sin^{2j} \theta d\theta \right) = 0 \quad (41)$$

and therefore, we need to prove that

$$\binom{2i+1}{2j+1} \int_0^{2\pi} \cos^{2(i-j)} \theta \sin^{2(j+1)} \theta d\theta - \binom{2i+1}{2j} \int_0^{2\pi} \cos^{2(i-j+1)} \theta \sin^{2j} \theta d\theta = 0 \quad (42)$$

in order to show that Equation (40) is valid.

The first step is to use the results of the integrals from Equation (16) and rewrite Equation (42) as:

$$\frac{2}{\Gamma(i+2)} \left(\binom{2i+1}{2j+1} \Gamma(i-j+\frac{1}{2}) \Gamma(j+1+\frac{1}{2}) - \binom{2i+1}{2j} \Gamma(i+1-j+\frac{1}{2}) \Gamma(j+\frac{1}{2}) \right) \quad (43)$$

After that, we can make use of the following property of the *Gamma* function:

$$\Gamma(n+\frac{1}{2}) = \binom{n-\frac{1}{2}}{n} n! \sqrt{\pi} \quad (44)$$

for non-negative integer values of n , as well as the following binomial coefficient property:

$$\binom{n}{k} = \frac{n-k+1}{k} \binom{n}{k-1} \quad (45)$$

to rewrite Equation (43) as

$$\frac{2\pi}{\Gamma(i+2)} (i-j)! j! \binom{i-j-\frac{1}{2}}{i-j} \binom{j-\frac{1}{2}}{j} \binom{2i+1}{2j} \left(\frac{2i-2j+1}{2j+1} (j+\frac{1}{2}) - (i-j+\frac{1}{2}) \right) = 0 \quad (46)$$

which proves the relation from Equation (40).

Finally, we can write for \dot{r} :

$$\dot{r} = -\frac{\varepsilon}{\omega r} \left(\zeta \omega_0 \omega r^2 - \frac{\gamma}{2} r \sin \phi \right) \quad (47)$$

Solution for $\dot{\phi}$

In the case of $\dot{\phi}$, we need to use the relation $v\dot{u} - u\dot{v}$ and therefore, the terms related to the polynomial stiffness can be written as:

$$\begin{aligned} & \sum_{i=1}^{\infty} \alpha_{2i+1} \sum_{j=0}^i \binom{2i+1}{2j+1} u^{2(i-j)+1} v^{2(j+1)} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i-j)} \theta \sin^{2(j+1)} \theta d\theta \\ & + \sum_{i=1}^{\infty} \alpha_{2i+1} \sum_{j=0}^i \binom{2i+1}{2j} u^{2(i-j)+1} v^{2j+1} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i-j+1)} \theta \sin^{2j} \theta d\theta \end{aligned} \quad (48)$$

which can be simplified and written under the form:

$$\sum_{i=1}^{\infty} \alpha_{2i+1} C \sum_{j=0}^{i+1} \binom{i+1}{j} u^{2(i+1-j)} v^{2j} = \sum_{i=1}^{\infty} \alpha_{2i+1} C (u^2 + v^2)^{i+1} = \sum_{i=1}^{\infty} \alpha_{2i+1} C r^{2(i+1)} \quad (49)$$

where C is a constant to be determined. To demonstrate this, we need to show that:

$$\begin{aligned} & \sum_{j=0}^i \frac{1}{2\pi} \left(\binom{2i+1}{2j+1} u^{2(i-j)} v^{2(j+1)} \int_0^{2\pi} \cos^{2(i-j)} \theta \sin^{2(j+1)} \theta d\theta + \binom{2i+1}{2j} u^{2(i-j+1)} v^{2j} \int_0^{2\pi} \cos^{2(i-j+1)} \theta \sin^{2j} \theta d\theta \right) \\ & = C \sum_{j=0}^{i+1} \binom{i+1}{j} u^{2(i+1-j)} v^{2j} \end{aligned} \quad (50)$$

First, we rearrange the left hand side of Equation (51) such that:

$$\begin{aligned}
 & \binom{2i+1}{0} u^{2(i+1)} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i+1)} \theta \, d\theta \\
 & + \binom{2i+1}{1} u^{2i} v^2 \frac{1}{2\pi} \int_0^{2\pi} \cos^{2i} \theta \sin^2 \theta \, d\theta + \binom{2i+1}{2} u^{2i} v^2 \frac{1}{2\pi} \int_0^{2\pi} \cos^{2i} \theta \sin^2 \theta \, d\theta \\
 & + \dots \\
 & + \binom{2i+1}{2k-1} u^{2(i+1-k)} v^{2k} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i+1-k)} \theta \sin^{2k} \theta \, d\theta + \binom{2i+1}{2j} u^{2(i+1-k)} v^{2k} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i+1-k)} \theta \sin^{2k} \theta \, d\theta \\
 & + \dots \\
 & \binom{2i+1}{2i+1} v^{2(i+1)} \frac{1}{2\pi} \int_0^{2\pi} \sin^{2(i+1)} \theta \, d\theta
 \end{aligned} \tag{51}$$

Or simply:

$$\begin{aligned}
 & \binom{2i+1}{0} u^{2(i+1)} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i+1)} \theta \, d\theta \\
 & + \sum_{j=1}^i \left(\binom{2i+1}{2j-1} + \binom{2i+1}{2j} \right) u^{2(i+1-j)} v^{2j} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i+1-j)} \theta \sin^{2j} \theta \, d\theta \\
 & \binom{2i+1}{2i+1} v^{2(i+1)} \frac{1}{2\pi} \int_0^{2\pi} \sin^{2(i+1)} \theta \, d\theta
 \end{aligned} \tag{52}$$

Which can be further simplified by making use of the fact that first:

$$\binom{2i+1}{2j-1} + \binom{2i+1}{2j} = \binom{2(i+1)}{2j} \tag{53}$$

and second:

$$\binom{2i+1}{0} = \binom{2i+1}{2i+1} = 1 = \binom{2(i+1)}{0} = \binom{2(i+1)}{2(i+1)} \tag{54}$$

which leads to

$$\sum_{j=0}^{i+1} \binom{2(i+1)}{2j} u^{2(i+1-j)} v^{2j} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i+1-j)} \theta \sin^{2j} \theta \, d\theta \tag{55}$$

The final step consists in showing that:

$$\binom{2(i+1)}{2j} \frac{1}{2\pi} \int_0^{2\pi} \cos^{2(i+1-j)} \theta \sin^{2j} \theta \, d\theta = C \binom{i+1}{j} \tag{56}$$

To do so, we make use of the fact that a binomial coefficient can be written using the *Gamma* function:

$$\binom{n}{k} = \frac{\Gamma(n+1)}{\Gamma(k+1)\Gamma(n-k+1)} \tag{57}$$

Furthermore, using the results from Equation (16), we can write the left hand side of Equation (56) as:

$$\frac{1}{\pi} \frac{\Gamma(2z_1)}{\Gamma(2z_3)\Gamma(2z_2)} \frac{\Gamma(z_2)\Gamma(z_3)}{\Gamma(z_1 + \frac{1}{2})} \tag{58}$$

where $z_1 = i + 1 + \frac{1}{2}$, $z_2 = i + 1 - j + \frac{1}{2}$ and $z_3 = k + \frac{1}{2}$. Using the Legendre duplication formula:

$$\Gamma(z)\Gamma(z + \frac{1}{2}) = 2^{1-2z} \sqrt{\pi} \Gamma(2z) \tag{59}$$

it is possible to rewrite Equation (58) as:

$$\frac{\Gamma(2i+3)}{2^{2(i+1)}\Gamma^2(i+2)} \binom{i+1}{j} = C_i \binom{i+1}{j} \tag{60}$$

where $C_i = \frac{\Gamma(2i+3)}{2^{2(i+1)}\Gamma^2(i+2)}$ is a constant that only depends on i . Therefore, we can indeed rewrite Equation (48) as Equation (49). Finally, we can write for $\dot{\phi}$:

$$\dot{\phi} = -\frac{\varepsilon}{\omega r^2} \left(\sum_{i=1}^{\infty} \alpha_{2i+1} C_i r^{2(i+1)} - \frac{\Omega}{2} r^2 - \frac{\gamma}{2} r \cos \phi \right) \tag{61}$$

Solution at steady-state

Since we are interested in solutions at steady-state, we have $\dot{r} = \dot{\phi} = 0$ and therefore

$$\begin{cases} r = \frac{\gamma}{2\zeta\omega_0\omega} \sin \phi \\ \sum_{i=1}^{\infty} \alpha_{2i+1} C_i r^{2i+1} - \frac{\Omega}{2} r = \frac{\gamma}{2} \cos \phi \end{cases} \quad (62)$$

where the first relation shows that the amplitude r does not directly depend on the nonlinear stiffness coefficients α_d . This relation also confirms that even order stiffness do not participate in the motion around the primary resonance.

Amplitude and phase resonances

Amplitude resonance occurs when both $\frac{\partial r}{\partial \omega}$ and $\frac{\partial r}{\partial \phi}$ are equal to 0. From Equation (62), we obtain:

$$\begin{cases} \frac{\partial r}{\partial \phi} = \frac{\gamma}{2\zeta\omega_0\omega} \left(\cos \phi - \frac{\sin \phi}{\omega} \frac{\partial \omega}{\partial \phi} \right) = 0 \\ \frac{\partial r}{\partial \omega} = \frac{\gamma}{2\zeta\omega_0\omega} \left(\cos \phi \frac{\partial \phi}{\partial \omega} - \frac{\sin \phi}{\omega} \right) = 0 \end{cases} \quad (63)$$

where

$$\frac{\partial \phi}{\partial \omega} = -\frac{2}{\gamma \sin \phi} \left(\sum_{i=1}^{\infty} \alpha_{2i+1} C_i (2i+1) r^{2i} \frac{\partial r}{\partial \omega} - \frac{1}{2} \left(\frac{2\omega}{\varepsilon} r + \frac{\omega^2 - \omega_0^2}{\varepsilon} \frac{\partial r}{\partial \omega} \right) \right) \quad (64)$$

Eventually, we have

$$\frac{\partial r}{\partial \omega} = \frac{\gamma^2 \sin^2 \phi (\omega - \varepsilon \zeta \omega_0 \tan \phi)}{\left(2(\omega_0^2 - \omega^2) \zeta \omega_0 \omega + \varepsilon \left(2\gamma^2 \zeta^2 \omega_0^2 \omega^2 \cos \phi + \sum_{i=1}^{\infty} \alpha_{2i+1} C_i (2i+1) \frac{(\gamma \sin \phi)^{2i+1}}{(2\zeta \omega_0 \omega)^{2i-1}} \right) \right)} = 0 \quad (65)$$

This relation is verified when:

$$\tan \phi_a = \frac{\omega_a}{\varepsilon \zeta \omega_0} \quad (66)$$

Since we consider a small damping ratio $\bar{\zeta} = \varepsilon \zeta$, the phase lag ϕ_a at amplitude resonance is very close to $\frac{\pi}{2}$.

On the other hand, phase resonance for linear and nonlinear systems occurs when the external forcing counterbalances exactly the damping forces [5]. From the first equation in Equation (62), we see that this happens when the phase lag is $\pi/2$. Phase resonance thus occurs in the immediate vicinity of amplitude resonance.

Numerical validation on a Helmholtz-Duffing oscillator

The previous results are applied to a Helmholtz-Duffing oscillator governed by the following equation:

$$\ddot{x}(t) + 2\bar{\zeta}\omega_0 \dot{x}(t) + \omega_0^2 x(t) + \bar{\beta}x^2(t) + \bar{\alpha}x^3(t) = \bar{\gamma} \sin \omega t \quad (67)$$

According to Equation 62, first-order averaging around the primary resonance gives

$$\begin{cases} r = \frac{\gamma}{2\zeta\omega_0\omega} \sin \phi \\ \frac{3\alpha}{8} r^3 - \frac{\Omega}{2} r = \frac{\gamma}{2} \cos \phi \end{cases} \quad (68)$$

Setting $\bar{\beta} = 0.05 \text{ N/(kg m}^2\text{)}$, $\bar{\alpha} = 0.05 \text{ N/(kg m}^3\text{)}$ and $\bar{\zeta} = 0.005$, the numerical solution using a harmonic balance continuation procedures with 8 harmonics is compared to the analytical solution from Equation (68) in Figure 1. The two methods give very similar results around the primary resonance. In addition to that, the phase resonance points, which correspond to a phase lag of $\frac{\pi}{2}$ for the first harmonic component of the solution, is also plotted and both techniques show that it is indeed in the vicinity of the amplitude resonance.

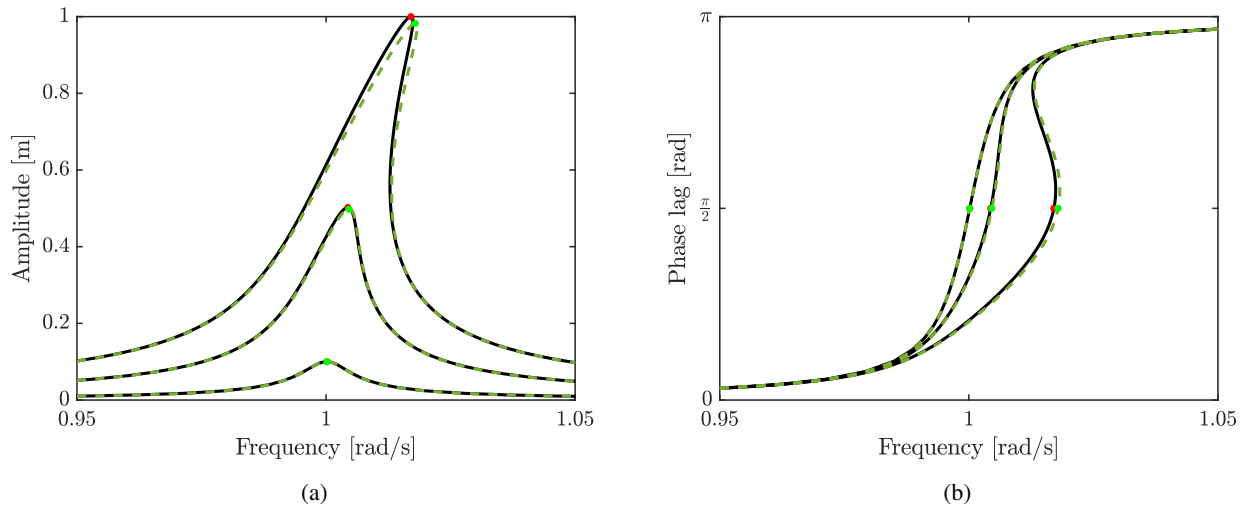

Figure 1: Nonlinear frequency responses (Numerical: black, analytical: green) around the primary resonance of the Helmholtz-Duffing oscillator for forcing amplitudes $\bar{\gamma}$ of 0.001N, 0.005N and 0.01N: (a) amplitude and (b) phase lag. The red (numerical) and green (analytical) dots correspond to a phase lag of $\frac{\pi}{2}$.

Conclusion

A first-order averaging technique was applied around the primary resonance of an oscillator with arbitrary polynomial stiffness. The results show that phase resonance associated with a phase lag of $\frac{\pi}{2}$ exists in the immediate neighborhood of amplitude resonance in the case of weak damping. These results are in agreement with those of Peeters et al. [5] and Haller et al. [6].

Parallel Harmonic Balance Method: towards very large scale systems

Loïc Salles*, Jiri Blahos*, Alessandra Vizzacarro* and Fadi El Haddad*

* *Department of Mechanical Engineering, Imperial College, London, UK*

Summary. This paper presents a parallel implementation of harmonic balance method coupled with continuation method. The different elements for a parallel implementation are introduced. The obtained software permits to accurately solve problem that has never been studied in this manner before. The results obtained with the proposed approach gives hints for creating accurate reduced order modelling.

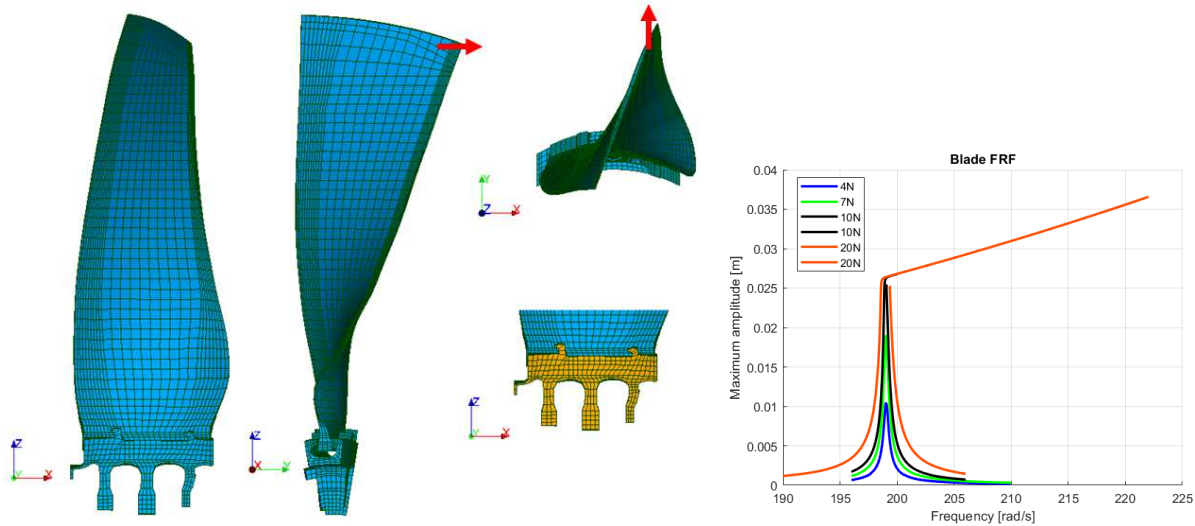

Figure 1: Fan blade with nonlinear frequency response

High-cycle fatigue caused by large resonance stresses remains one of the most common causes of turbine blade failures. Nonlinear vibration can have an important effect on the high cycle fatigue of components. Harmonic Balance Method is an efficient technique to model the nonlinear vibration of turbomachinery components. Efficient software have been developed for the last two decades but are still limited to reduced size system [5, 4, ?].

We propose in this work to present the element to develop continuation method based on harmonic balance method for large scale system. We will explore in the paper two types of common nonlinearities: localized (contact with friction) and non-localized (large deformation). The equation of motion and its transformation to nonlinear algebraic system will be introduced. We proposed an original implementation [6] that allows to easily treat any type of problem: frequency response, nonlinear modal analysis or limite cycle oscillation. We will then show how any type of localized nonlinearities can be treated using harmonic balance method and alternating frequency time procedure [3]. We will present how the computation of nonlinear forces can be parallelised using both OPENMP and MPI programming language.

In a second part the paper focus on the non-localized nonlinearities and their implementation in the Finite Element framework. A C++ code has been developed and solves the nonlinear HBM problem in parallel, using MPI. A 3rd party software package is used to load and distribute a mesh. Standard finite element scheme is then used to assemble the sparse system matrices (mass, stiffness, damping) in parallel using CSR format. Nonlinearities are added using the alternating frequency time (AFT) procedure. Frequency domain dofs are organised in a way that keeps them on the same MPI rank as their corresponding mesh nodes to minimise necessary communication. To solve the nonlinear HBM problem the Newton-Raphson iterative algorithm is used. For the underlying linear problem, we used a 3rd party software package based on parallel sparse implementation of the LU decomposition [1]. The code results have been verified against previous results presented in the scientific literature. The code has been tested on multi-million degree of freedom problems. A decent speed-up was obtained for number of MPIs up to approx. 100 MPI ranks.

Several numerical results on academic problems (cantilever beam and clamped-clamped beam) will illustrate the proposed method and gives hint for creating reduced order model. It will be shown that care has to be taken when creating reduced order model for structure in large deformation.

The paper will finish with recommendation about future work needed to develop more scalable continuation methods for nonlinear vibration analysis.

Tracking basin boundaries with Clustered Simple Cell Mapping method

Gergely Gyebrószki[†] and Gábor Csernák[†]

[†]*MTA-BME Research Group on Dynamics of Machines and Vehicles,
H-1111, Budapest, Műegyetem rkp 3.*

Summary. The Simple Cell Mapping (SCM) method [3] is a simple and effective algorithm to analyse the (discretized) state space of dynamical systems. A state space region is divided into cells and an image cell (where the dynamics lead to) is determined for each cell. SCM is able to find chaotic attractors and – depending on the cell resolution – repellers, and their basin of attraction. Chaotic structures are usually represented by a periodic cell group with high period, while basins of attraction are composed of transient cell sequences leading to periodic groups.

Previously, we have improved the SCM method with the ability to extend its underlying state space region and join the new state space region to the previous SCM solution. This method is called Clustered Simple Cell Mapping (CSCM) [2]. We show that CSCM can be a valuable tool for automatically exploring the state space or tracking certain features – for example the basin of attraction of an attractor or the closure of a chaotic repeller, especially in the case, where the underlying system can exhibit crisis bifurcations. An example is shown using the well-known Ikeda-map [4].

Clustered Simple Cell Mapping

Simple Cell Mapping (SCM) is a great tool to quickly analyse the state space of dynamical systems. An initial state space region is discretized into cells, for each cell a single image cell is determined, usually by following a trajectory from the center point of each cell for a given time step, or by applying the map corresponding to discrete systems. The SCM method then classifies cells as either periodic cells (belonging to a periodic group) or transient cells (leading to one of the periodic groups within the state space, or the region outside – the sink cell). Chaotic attractors or repellers are usually represented by a periodic cell group with high periodicity.

There are several extensions for the SCM method, some of them exploits certain properties of a class of dynamical systems: eg. discontinuous systems [5], or Filippov systems [1]. In [2] we have introduced the Clustered Simple Cell Mapping (CSCM) method, another extension aiming to adaptively extend the analysed state space region in a computationally effective manner. Clustered SCM is able to join an additional state space region to the so called *cluster* of SCMs, and update the solution by re-using the existing cell classification in the initial SCM region.

The concept is illustrated in Fig. 1: the left region is the initial SCM solution containing a periodic group (denoted by dark grey ■) and a set of transient cells leading to it (gray colour ■). The right state space region is added to the cluster of SCMs: this allows the discovery of transient cells leading to a previously classified periodic group (green ■), a new periodic group (at the boundary of the two regions) and non-trivial transients in the initial SCM's region (denoted by orange ■).

Clustered Simple Cell Mapping allows the continuation of SCM solutions towards state space structures (e.g. basins of attraction) that get clipped by the initial choice of state space region.

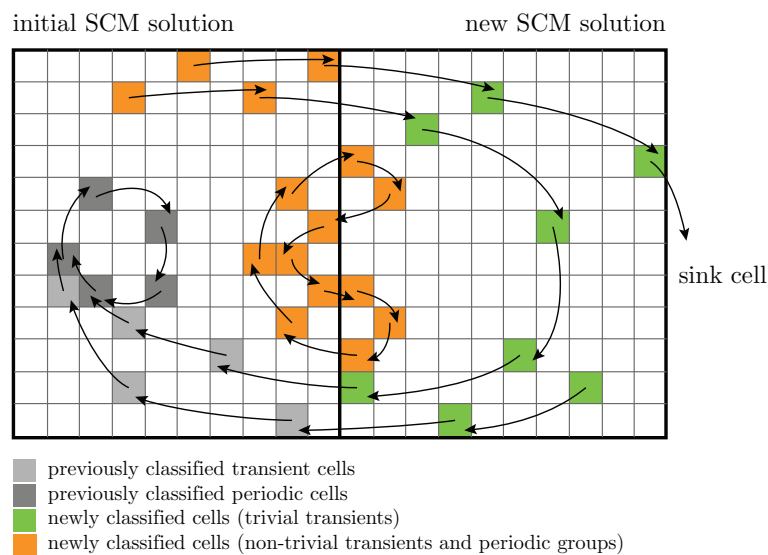

Figure 1: The concept of the Clustered Simple Cell Mapping (CSCM) method.

The Ikeda-map

The Ikeda-map [4] is originated from a model of light going around across a nonlinear optical resonator. Depending on its parameters it can have fixed points, chaotic attractors or a repeller in its state space and can exhibit crisis bifurcations.

$$\begin{aligned}x_{n+1} &= 1 + u(x_n \cos(t_n) - y_n \sin(t_n)) \\ y_{n+1} &= u(x_n \sin(t_n) + y_n \cos(t_n)),\end{aligned}\quad (1)$$

where u is a parameter and:

$$t_n = 0.4 - \frac{6}{1 + x_n^2 + y_n^2}. \quad (2)$$

An application example

We show an example of state-space exploration by using the CSCM method in the case of the Ikeda-map defined by Eq. (1). The starting region (denoted by 1 in Fig. 2) is a 6×6 square at $(0, 0)$ in the (x, y) plane, where a chaotic repeller resides. Note, that the repeller can only be found by SCM if the cell resolution is sufficiently coarse, to artificially *stabilize* it. The adaptive state-space extension algorithm adds another 8 square-shaped state space region to the cluster, by following the basin of attraction along the four main directions. This is shown on Fig. 2, where the successive state-space regions are numbered. After the initial exploration procedure, the cluster is made convex by adding regions 10 to 12. As the last state space region is included – where a fixed point resides – the SCM algorithm is able to classify its basin of attraction as well (denoted by shades from green to blue based on step numbers needed to reach the fixed point).

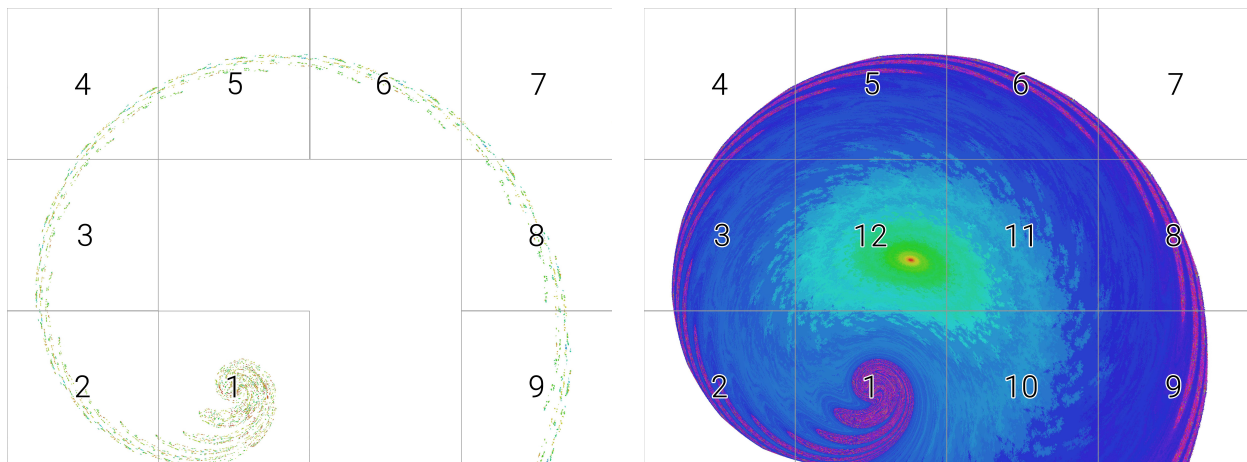

Figure 2: A CSCM cluster consisting of 9 SCM solutions (*left*) and 12 SCM solutions (*right*) of the Ikeda-map with $u = 0.96$. The state space region consists of squares with side lengths of 6.0. The first region's center is at $(0, 0)$. The whole cluster spans from $(x_0, y_0) = (-9, -3)$ to $(x_1, y_1) = (15, 15)$.

Conclusions

Clustered Simple Cell Mapping is a method allowing the successive expansion of the state space region corresponding to an SCM solution of a dynamical system. This allows quick and computationally effective exploration of the state space in case of crisis bifurcations (where certain state space features *explode*), or tracking basins of attraction as shown in Fig. 2. Since existing SCM solutions are re-used when the cluster is expanded, CSCM allows interactive or real-time applications.

Asymptotic-preserving and hybrid finite-volume/Monte-Carlo methods for kinetic equations in the plasma edge of a fusion reactor

Summary. Nuclear fusion reactor design crucially depends on numerical simulation. The plasma can usually be modeled using fluid equations (for mass, momentum and energy). However, the reactor also contains neutral (non-charged) particles (which are important in its operation), of which both the position and velocity distribution is important. This leads to a Boltzmann-type transport equation that needs to be discretised with a Monte Carlo method. In high-collisional regimes, the Monte Carlo simulation describing the evolution of neutral particles becomes prohibitively expensive, because each individual collision needs to be tracked. In this talk, we look into several strategies to overcome this computational bottleneck.

Introduction

Numerical simulations of the plasma edge play a key role in the divertor design of nuclear fusion reactors [1]. The divertor needs to handle large power loads and is essential for the power and particle exhaust in a reactor. Two types of particles are modeled in plasma edge models: the plasma, consisting of charged particles (ions and electrons), and the neutral particles. The plasma can usually be described with a Navier-Stokes-like fluid model, discretized in space with a finite volume (FV) method. For the neutrals, however, a more microscopic, kinetic description is necessary, in which the particle distribution is modeled in a position-velocity phase space. Due to the additional dimensions in velocity space, FV simulation of the kinetic equations is computationally prohibitive. Therefore, one turns to Monte Carlo (MC) simulation.

Plasma and neutral particles interact through collisions, which can be charge exchange (an ion and neutral particle collide and exchange charge) or ionization (a neutral particle becomes a plasma particle). Due to these interactions, the plasma and neutral models need to be coupled, leading, for instance, to the B2-EIRENE code [2]. During charge-exchange collisions, momentum and energy are transferred between plasma and neutrals. During ionization, also mass is exchanged. Additionally, neutrals arise from the plasma due to surface and volumetric recombination of ions and electrons. Because of the different nature of the two types of discretizations (MC and FV), the two codes cannot be solved simultaneously, and an iterative procedure is needed. One thus simulates the neutral particles against a fixed plasma “background” and estimates the source terms (mass, momentum and energy) for the plasma equations. One then solves the plasma equations with these estimated sources. This procedure is repeated until no more corrections are required.

Although B2-EIRENE is used worldwide for the analysis of experimental tokamaks and for the design of ITER, computation time is a serious bottleneck. One reason is the number of collisions neutral particles undergo in a realistic setting. Large reactors suitable for electricity generation typically operate in a so-called detached regime. In this regime, one aims at an increased interaction of the neutrals with the ions, especially by means of charge-exchange collisions. The goal is to create a kind of neutral “cushion” that prevents the ions to flow immediately to the divertor targets. While this regime is advantageous to avoid a direct interaction between the plasma and the divertor (and thus lengthens the lifetime of the reactor), this has a detrimental effect on the computational cost of the MC simulation, since each individual collision needs to be tracked.

In this presentation, we overview a number of approaches that can alleviate the computational burden associated with the high-collisional regime.

Kinetic-diffusion Monte Carlo methods

One option is to avoid simulating each individual collision. In the limit of infinite collision rate, the law of large numbers dictates the approach of an advection-diffusion like particle behaviour, in which the accumulated effect of an infinite amount of collisions is aggregated in a Brownian motion (diffusion). To maintain accuracy and remove exploding simulation costs in high-collisional regimes, one can define hybridized particles that exhibit both kinetic behaviour and diffusive behaviour depending on the local collisionality [3]. Features of the method are maintaining an asymptotically correct distribution and a correct mean, variance, and correlation for all values of the collisionality.

Multilevel Monte Carlo methods

An alternative approach is to reduce the number of Monte Carlo particles that needs to be simulated via an appropriate variance reduction technique. One very appealing option is the multilevel Monte Carlo method[5]. Asymptotic-preserving schemes as defined above result in an additional time discretization error, possibly resulting in an unacceptably large bias for larger time steps. To remove this bias, we can define a multilevel Monte Carlo scheme that reduces this bias by combining estimates using a hierarchy of different time step sizes. The multilevel Monte Carlo method relies heavily on the construction of correlated trajectories on two subsequent levels. We demonstrate how to correlate trajectories using different time steps. We also present a strategy for selecting the levels in the multilevel scheme. This approach signifi-

cantly reduces the computation required to perform accurate simulations of the considered kinetic equations, compared to classical Monte Carlo approaches.

Hybrid finite-volume Monte Carlo methods

Finally, one can also reduce the variance of the simulation by using an approximate fluid model for the neutral particles, discretized with a finite volume methods. This deterministic simulation can be used as a control variate, allowing the Monte Carlo simulation to focus on solely the deviation of the kinetic model with respect to the approximate fluid model.

Summary. The hybrid position feedback controller, proposed previously by the authors, is a control technique for bistable systems and it is based on the well-known positive-position-feedback controller. This controller is an unstable-then-stable position feedback controller, which is a second-order single-degree-of-freedom system in nature. The hybrid controller takes advantage of the resonant mode of a bistable system about one equilibrium position, destabilizes the system, and dynamically induces snap-through between the two equilibria. In this paper, a new multi degree of freedom metamaterial concept that utilizes the hybrid position feedback controller is introduced. An arbitrary number of bistable “segments” or “material elements” are attached to each other in a serial (or parallel) manner to generate a “distributed” bistable structure – also referred to as a metamaterial. Due to the simplicity of the hybrid controller, the physical implementation of proposed approach can be realized using simple circuit elements distributed in the material domain. This new metamaterial inherits the multiple bistable positions that its building blocks have; hence, the metamaterial becomes multi-stable. It can hold multiple positions without consuming power and has the capability of achieving many shapes. The proposed metamaterial concept can be used in various applications: locomotion in bioinspired systems, undulatory motion, morphing aerodynamic surfaces, wave guiding, and vibration attenuation. The concept can also be used in energy harvesting to enable maximum power extraction for a given vibratory input.

Introduction

Bistable structures are useful in many applications such as morphing aerodynamic surfaces, vibration energy harvesters, robotic actuators and mechanisms, and for locomotion of bioinspired systems where energy may be severely limited. A bistable system has two stable configurations and one unstable equilibrium.

The dynamics of bistable structures have been studied by various researchers [1-9]. The control of bistable structures using piezoelectric actuators has received significant attention in the last two decades. Shultz et al. [10] demonstrated one directional snap-through of a bistable plate using a piezoelectric actuator with static excitation. Arrieta et al. [11-13] studied the dynamic properties of bistable structures and achieved only one-directional snap-through. Later, Arrieta et al. [14] and Bilgen et al. [15] introduced resonant control with a surface bonded piezoelectric device. Zarepoor et al. [16] demonstrated the energy characteristic of a Duffing-Holmes (D-H) type bistable structure under dynamic forcing. Simsek et al. [17, 18] demonstrated an automated method for bidirectional state transfer on a wing-like cross-ply bistable plate using the hybrid control strategy and a piezocomposite actuator. Simsek et al. [19] demonstrated the prevention of chaotic behavior for Duffing-Holmes oscillator by applying the Hybrid Position Feedback (HPF) controller, which consists of the Negative Position Feedback (NPF) and Positive Position Feedback (PPF) controllers. Simsek et al. [20] analyzed the stability and response types of Duffing-Holmes oscillator with the HPF controller. Simsek et al. [21] demonstrated a piezoelectric-material induced monotonic snap-through without possibility of triggering cross-well oscillations or chaotic response. Crosswell oscillations are undesirable, as only one state is desirable (and nominal) for various applications. To this end, a hybrid position feedback (HPF) controller shows superior performance in terms of control, stability, and performance both theoretically and experimentally. In that work, the application of the HPF controller to a bistable unsymmetric cross-ply composite plate with surface-bonded piezoelectric actuators was presented.

Metamaterials or metastructures have engineered functionality that conventional materials or structures do not exhibit naturally. They have a broad range of applications from electromagnetics, acoustics, energy harvesting to vibration control. The assembly of HPF controlled bistable elements can be used to create a metamaterial or a metastructure. A system consisting of individual bistable units can form a desired configuration. Each individual element can be either at one state or the other which eventually forms a multi-stable metastructure. The proposed design can be implemented either using mechanical components such as mass-, damper- and spring-like elements, or it can be realized using circuit elements such as inductor-, resistor-, and capacitor-like elements.

The paper is organized as follows. First, the HPF control scheme is discussed. Next, the metamaterial concept is introduced. Then, the preliminary numerical simulation results are presented.

Hybrid Position Feedback Control

The hybrid position feedback controller was previously proposed by the authors to enable stable and monotonic cross-well transition of bistable (or multi-stable) structures [17, 18]. The controller is designed based on the dynamics of the stable equilibrium positions of a bistable structure around which it exhibits linear behavior for small perturbations. The control method first achieves system destabilization to make the structure move away from its current stable equilibrium position, and subsequently stabilize the system to the other (target) stable equilibrium position. The proposed hybrid control scheme employs the well-known PPF controller, and its modified version, the NPF controller. The PPF controller is a second order damped system (filter) that creates approximately 180° phase difference between input and output of the system in a certain gain range [22], which enables the system to dissipate energy through the controller. The NPF controller is a modified version of a PPF controller, here used to create a destabilizer by exploiting the phase

characteristics. As a destabilizer, the NPF controller, is expected to provide kinetic energy to the system until it reaches the desired threshold position (i.e. the unstable equilibrium.) Ref. [23] proposed and compared different switching methods for the HPF controller, and presented an analysis of the control effort and settling time.

The control diagram of the HPF controller is represented in Figure 1. In this diagram, the parameters of the NPF and PPF controllers are the same given by the block G. The reference signal $r(s)$ is considered as zero since system is in stabilizer and destabilizer mode. The authors have also investigated the system where the NPF and PPF controller parameters are individually selected and tuned.

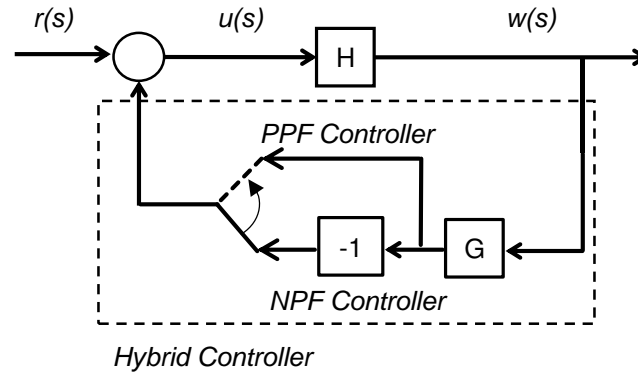

Figure 1: The block diagram for the hybrid position feedback controller.

First, the so-called NPF mode is used to start the cross-well transfer by making the PPF controller intentionally unstable. When the feedback gain is -1 , the system is destabilized, and the apparent dynamic stiffness of the system becomes negative. The controller induces an oscillatory response with increasing amplitude. When the system position reaches a threshold value at the unstable equilibrium, the feedback gain is changed to $+1$. This leads to a stable controlled (i.e. decaying) system response with decreasing amplitude. Figure 3 illustrates the cross-well motion of an example bistable system with the hybrid controller. In the figure, the stable states of the bistable structure are labeled as S1 and S2. The current position and the unstable equilibrium position are represented by w and w_{u0} respectively.

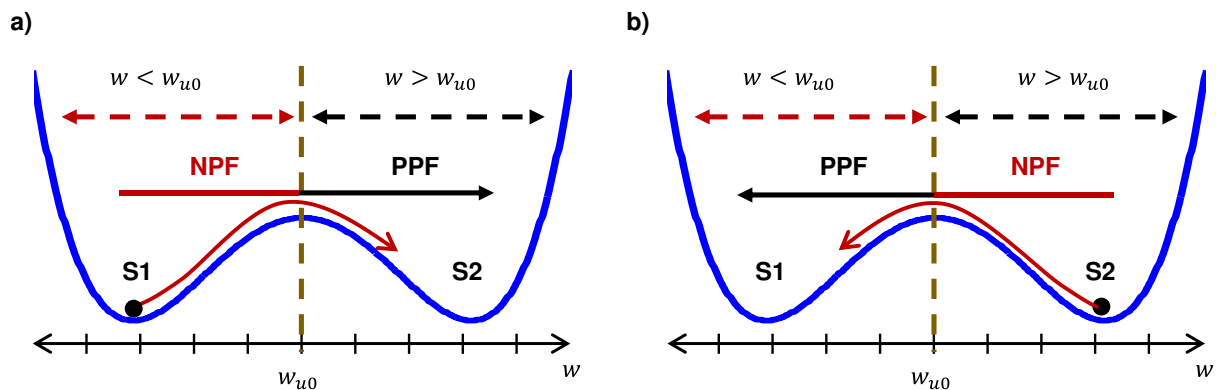

Figure 2: Illustration of state transfer a) from state 1 to state 2, and b) from state 2 to state 1.

For the state transfer from state 1 to 2, the structure is destabilized around equilibrium position S1 by using the NPF mode of the HPF controller. Due to the destabilization, the structure starts an increasing amplitude oscillation around the first equilibrium position. Once the amplitude reaches the unstable equilibrium, the structure snaps towards the second stable equilibrium position S2. The crossover is detected by an internal logic and the controller mode is switched to the PPF mode to attenuate the response around the target state of 2.

Figure 3 depicts the mechanical representation of the D-H system and HPF controller. In the system k_1 , c and k_{nl1} are linear stiffness, damping constant and cubic stiffness of system, respectively. k_c and c_c are the stiffness and damping parameter of HPF controller.

Figure 3: Mechanical model of the bistable Duffing-Holmes system with the hybrid position feedback controller.

The coupled system equations become:

$$\ddot{w} + 2\zeta\omega_n \dot{w} - \omega_n^2 w + \frac{k_{nl}}{m} w^3 = g_n \omega_n^2 u \quad (1)$$

$$\ddot{u} + 2\zeta_f \omega_f \dot{u} + \omega_f^2 u = g_f \omega_f^2 w \quad (2)$$

where ω_n and ζ represent natural frequency and damping ratio of the underlying linear system respectively, and g_n is the structure input gain. Here, it is noted that the actual value of input gain $g_n \omega_n^2$ is not constant in a physical implementation as the voltage/strain level changes [24, 25]. In this paper an effective g_n value previously determined from experiments is utilized [26]. The controller parameters ζ_f and ω_f correspond to damping ratio and natural frequency of the controller, respectively. The control gain is denoted as g_f and it is simply a proportional amplification of the feedback signal.

The complete system response depends on controller frequency, damping and gain, and depends on the system damping constant and other system parameters. The coupled system can yield three response types, namely, “intra-well,” “single cross-well,” and “multiple cross-well” types of responses. The “intra-well” response corresponds a response that will not reach to the threshold limit, while “single cross-well” response crosses the threshold limit once, and “multiple cross-well” response crosses twice or more.

The Metamaterial Concept and Mathematical Representations

In this paper, two different mechanical representations are considered. They are series and parallel configurations. The series configuration represents a cantilevered beam, and the parallel configuration represents an elastic foundation. Both of these configurations have different utilities in actual implementation.

Series Configuration

The so-called series configuration is presented in Figure 4. In this approach, the metamaterial concept is realized by connecting one bistable unit to next one with linear and cubic stiffnesses, and a viscous damper. A dedicated HPF controller is attached to each DOF. The series configuration represents a beam-like structure; however, with a multi-stable characteristic as opposed a “natural” monostable characteristic.

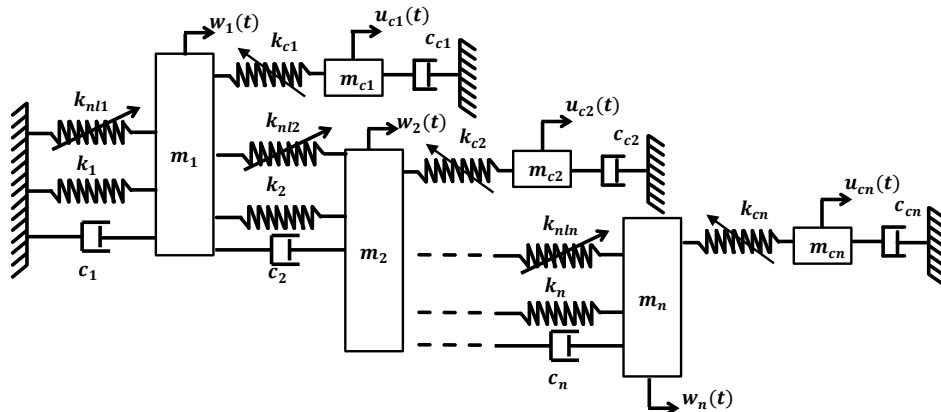

Figure 4: Mechanical model of the MDOF cascade bistable Duffing-Holmes system with the hybrid controller in series configuration.

The nonlinear coupling between the masses produces complex dynamics and a capability for the system to adopt various static or dynamic shapes. The proposed metamaterial concept is realized by adding multiple bistable oscillators in series. Figure 5 shows a representative model of cantilever beam with bistable elements connected in series.

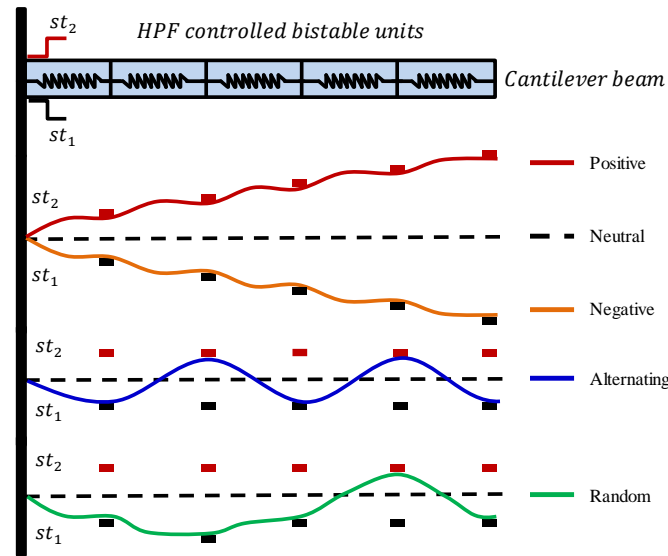

Figure 5: An illustration of a beam like metastructure with multiple bistable elements connected in series.

Parallel Configuration

Figure 5 shows an alternative, so-called parallel, configuration in which each DOFs is connected to the ground with a linear and cubic stiffness, and a viscous damper. In addition, a linear stiffness is used to connect the DOFs to each other. A dedicated HPF controller is attached to each DOF.

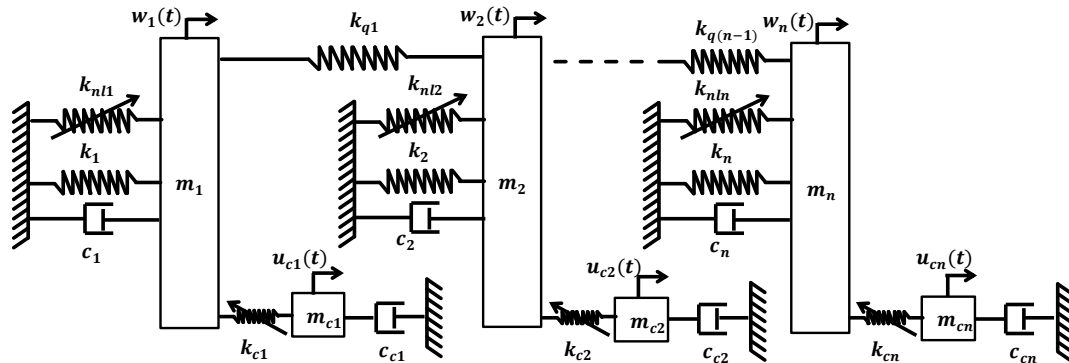

Figure 6: Mechanical model of the MDOF cascade bistable Duffing-Holmes system with the hybrid controller in parallel configuration.

This configuration reduces the coupling effect between the DOFs which minimizes the effort required to snap from one stable equilibrium while maintaining the connection between the DOFs. The proposed metamaterial concept is realized by adding multiple bistable oscillators in parallel. Figure 7 shows a representative model of a plate with bistable elastic foundation.

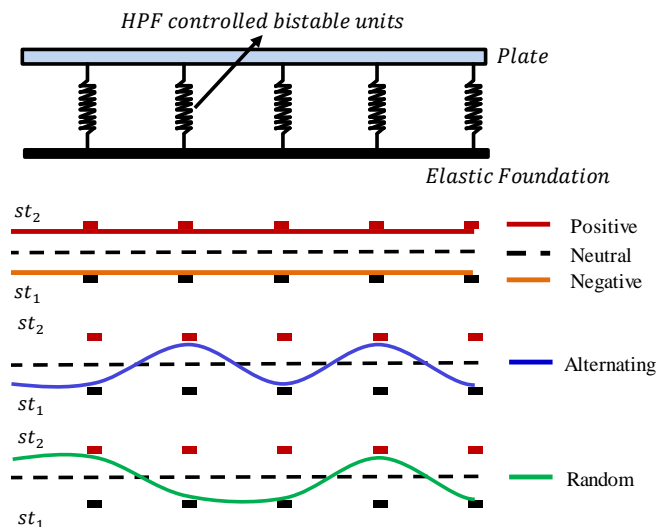

Figure 7: An illustration of a plate like metastructure with multiple bistable elements connected in parallel.

Simulation Results and Feasibility Analysis

Both the series and parallel configurations are examined through numerical integration. The dynamic response of the system is obtained using Dormand-Prince numerical integration method.

Series Configuration

The dynamic response of the series configuration is studied. Figure 8 presents the mechanical model of the 2DOF cascade bistable Duffing-Holmes system with the hybrid controller.

Figure 8: Mechanical model of the 2DOF cascade bistable Duffing-Holmes system with the hybrid controller in series configuration.

The governing equation for the series configuration is written as follows assuming unit mass for each DOF,

$$\ddot{w}_1 + 2\zeta_{s1}\omega_{s1}\dot{w}_1 - \omega_{s1}^2 w_1 + k_{nl1}w_1^3 - k_{nl2}(w_2 - w_1)^3 - k_2 w_2 - c_2 \dot{w}_2 = \omega_{s1}^2 u_{c1} \quad (3)$$

$$\ddot{u}_{c1} + 2\zeta_{c1}\omega_{c1}\dot{u}_{c1} + \omega_{c1}^2 u_{c1} = g_{f1}\omega_{c1}^2 w_1 \quad (4)$$

$$\ddot{w}_2 + 2\zeta_{s2}\omega_{s2}\dot{w}_2 - \omega_{s2}^2 w_2 + k_{nl2}(w_2 - w_1)^3 - k_2 w_1 - c_2 \dot{w}_1 = \omega_{s2}^2 u_{c2} \quad (5)$$

$$\ddot{u}_{c2} + 2\zeta_{c2}\omega_{c2}\dot{u}_{c2} + \omega_{c2}^2 u_{c2} = g_{f2}\omega_{c2}^2 w_2 \quad (6)$$

where $\omega_{s1}, \omega_{c1}, \omega_{s2}, \omega_{c2}$ and $\zeta_{s1}, \zeta_{c1}, \zeta_{s2}, \zeta_{c2}$ represent frequencies and damping ratios of the system and controllers, g_{f1} and g_{f2} is the controller gains for each DOF. k_{nl1} and k_{nl2} are cubic stiffness terms for the first and second DOFs, respectively. k_2 and c_2 are stiffness and damping terms representing linear coupling between the masses.

The dynamic response of the series configuration is presented in Figure 9. The HPF authority for two different scenarios is tested for weakly coupled 2DOF system. In the first scenario, HPF switches the first and second DOFs forward. In the second scenario, the HPF moves both DOFs backward from one state to another.

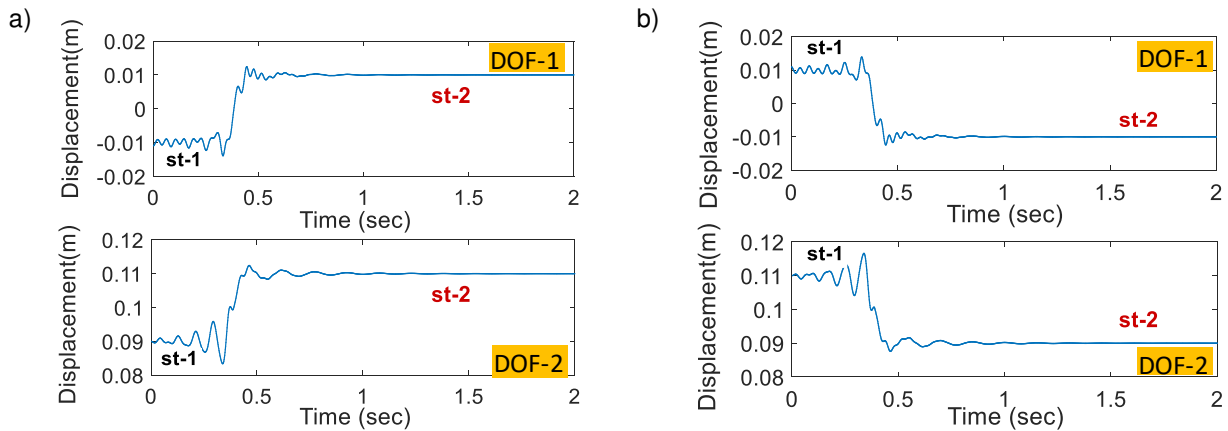

Figure 9: Example time response for the series 2DOF cascade bistable Duffing-Holmes system with the hybrid controller: a) DOF-1 st1->st2 and DOF-2 st1->st2, b) DOF-1 st2->st1 and DOF-2 st2->st1.

A parametric analysis is carried out to determine the controller parameters that satisfy the desired switch properties for different cases. The proposed schematic for series configuration can be realized when two DOFs achieve forward, backward, converse state transfer. In the analysis, two controller parameters ζ_{npf} and g_{npf} are chosen since they have the major effect on switching behavior. In the analyses, the ζ_{npf} and g_{npf} are equal for the two DOFs – they are swept

through a range to determine the optimum values that satisfy the desired switching behaviors. Figure 10 presents a parametric analysis for the series configuration.

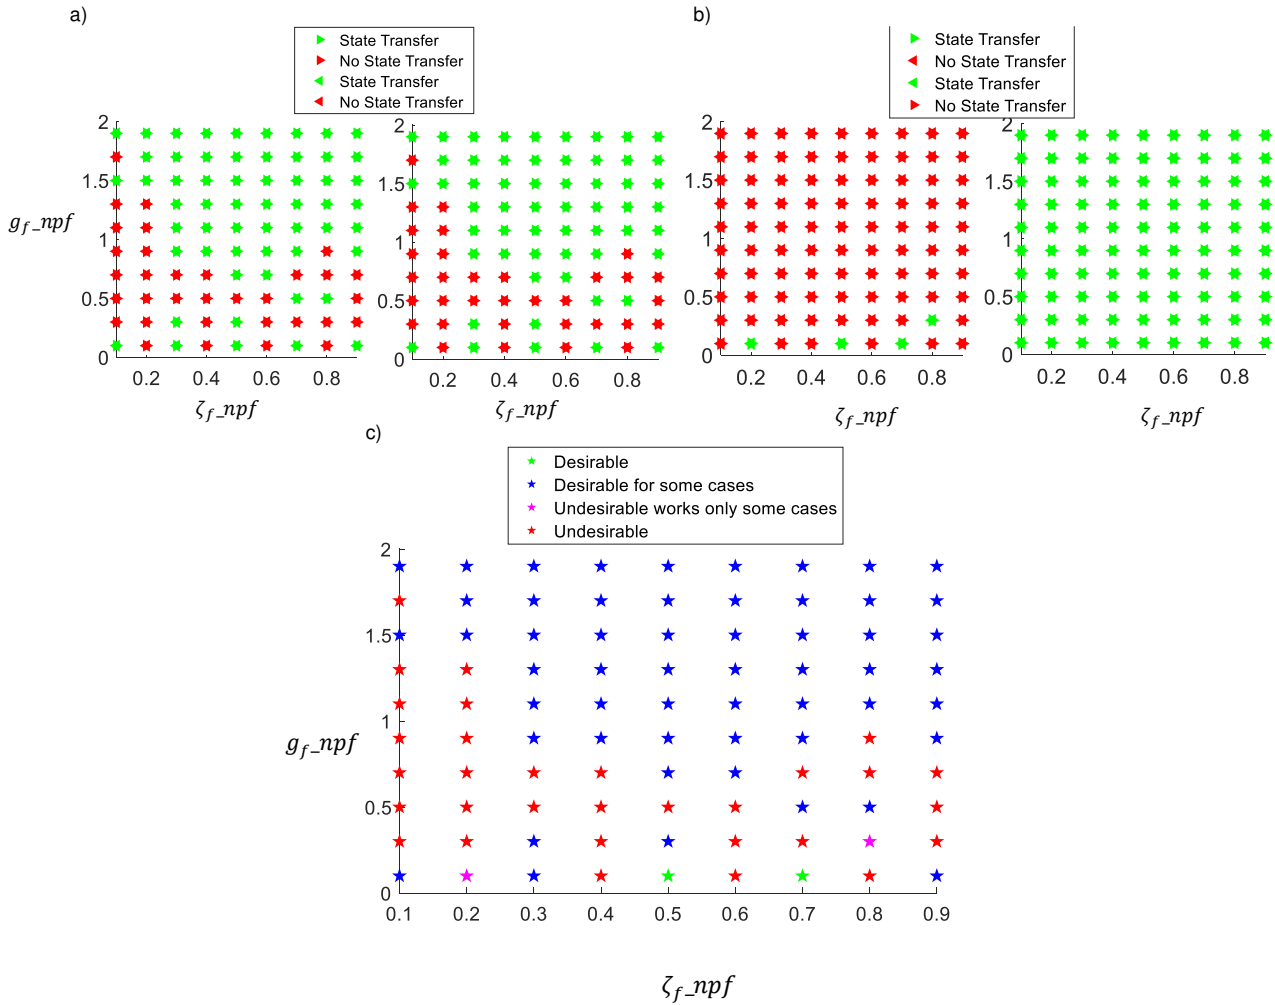

Figure 10: Parametric analysis for the series 2DOF cascade bistable Duffing-Holmes system with the hybrid controller a) Forward (DOF-1 and DOF-2: st1->st2) and Backward (DOF-1 and DOF-2: st2->st1) state transfer case, b) Converse State transfer case (DOF-1: st1->st2 and DOF-2: st2->st1, vice versa), c) all cases together.

Figure 10a presents a forward and backward state transfer behavior with respect to the controller parameters. The triangle pointing left or right shows the configuration of controller. The green and red colors indicate that initial configuration is desirable (i.e., intended state transfer) and undesirable (i.e., no state transfer), respectively. Figure 10b demonstrates the analysis carried out for converse state transfer where DOF-1 is set to achieve state transfer from state 1 to state 2 while DOF-2 is set to achieve state transfer from state 2 to state 1. Also, vice-versa case simulation is presented in this figure. Figure 10c demonstrates the behavior of controller for all cases mentioned above. The green color indicates the controller parameters that achieve successful state transfer for all scenarios. Figure 11 shows the time responses for desired configuration.

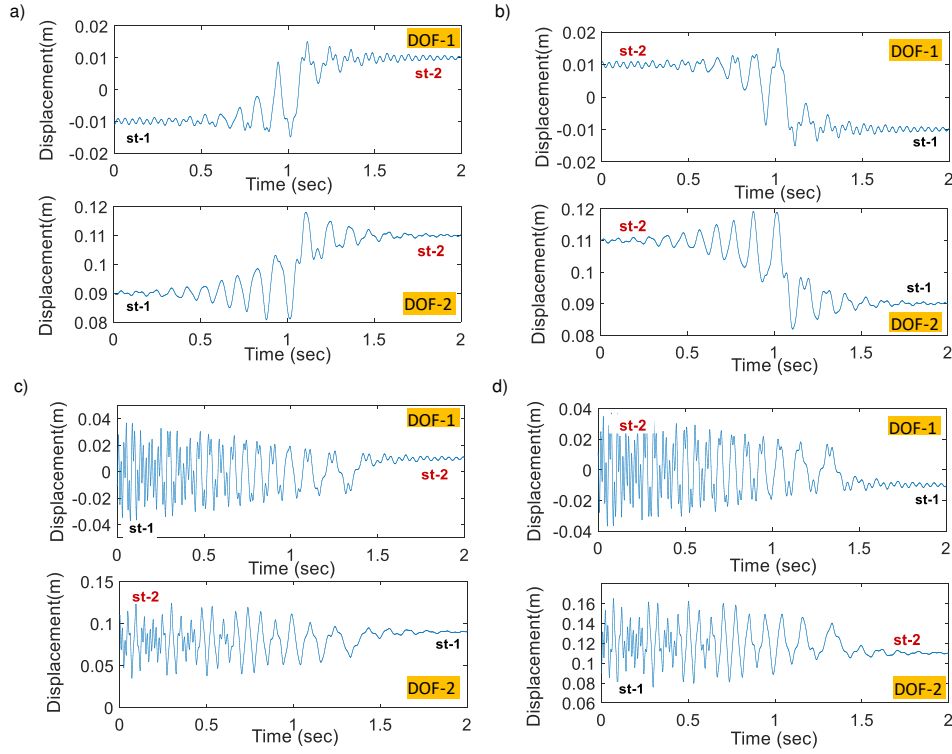

Figure 11: Time response for the parameters $\zeta_{f_{npf}} = 0.5$ and $g_{f_{npf}} = 0.1$ that achieves all scenarios of series configuration.

Parallel Configuration

The dynamic response of the parallel configuration is studied. Figure 12 presents the mechanical model of the 2DOF cascade bistable Duffing-Holmes system with the hybrid controller.

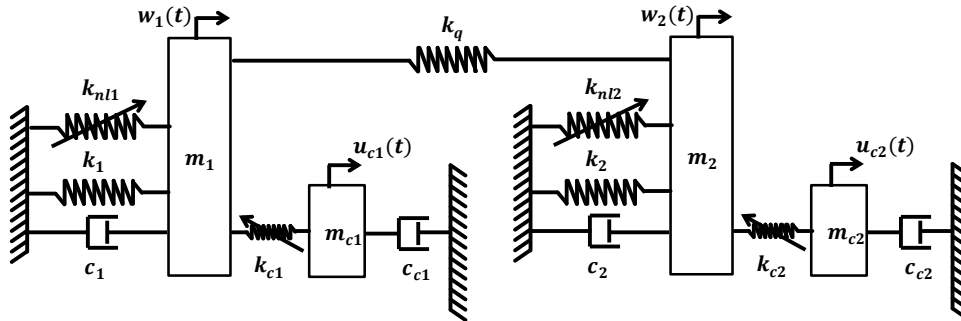

Figure 12: Mechanical model of the 2DOF cascade bistable Duffing-Holmes system with the hybrid controller in parallel configuration.

The governing equation for parallel configuration is written as follows assuming unit mass for each DOF,

$$\ddot{w}_1 + 2\zeta_{s1}\omega_{s1}\dot{w}_1 - \omega_{s1}^2 w_1 + k_{nl1}w_1^3 - k_q(w_2 - w_1) = \omega_{s1}^2 u_{c1} \quad (7)$$

$$\ddot{u}_{c1} + 2\zeta_{c1}\omega_{c1}\dot{u}_{c1} + \omega_{c1}^2 u_{c1} = g_{f1}\omega_{c1}^2 w_1 \quad (8)$$

$$\ddot{w}_2 + 2\zeta_{s2}\omega_{s2}\dot{w}_2 - \omega_{s2}^2 w_2 + k_{nl2}w_2^3 + k_q(w_2 - w_1) = \omega_{s2}^2 u_{c2} \quad (9)$$

$$\ddot{u}_{c2} + 2\zeta_{c2}\omega_{c2}\dot{u}_{c2} + \omega_{c2}^2 u_{c2} = g_{f2}\omega_{c2}^2 w_2 \quad (10)$$

where $\omega_{s1}, \omega_{c1}, \omega_{s2}, \omega_{c2}$ and $\zeta_{s1}, \zeta_{c1}, \zeta_{s2}, \zeta_{c2}$ represent frequencies and damping ratios of the system and controllers, g_{f1} and g_{f2} is the controller gains for each DOF. k_{nl1} and k_{nl2} are cubic stiffness terms for the first and second DOFs, respectively.

The dynamic response of the parallel configuration is presented in Figure 13. The control authority for four different scenarios is tested for a weakly coupled 2DOF system. In the first and second scenario, the HPF keeps the first DOF at the first state while switching the second DOF forward and backward from one state to another. In the third and fourth scenario, the first DOF is attracted to the second state while the second DOF switches forward and backward between the states.

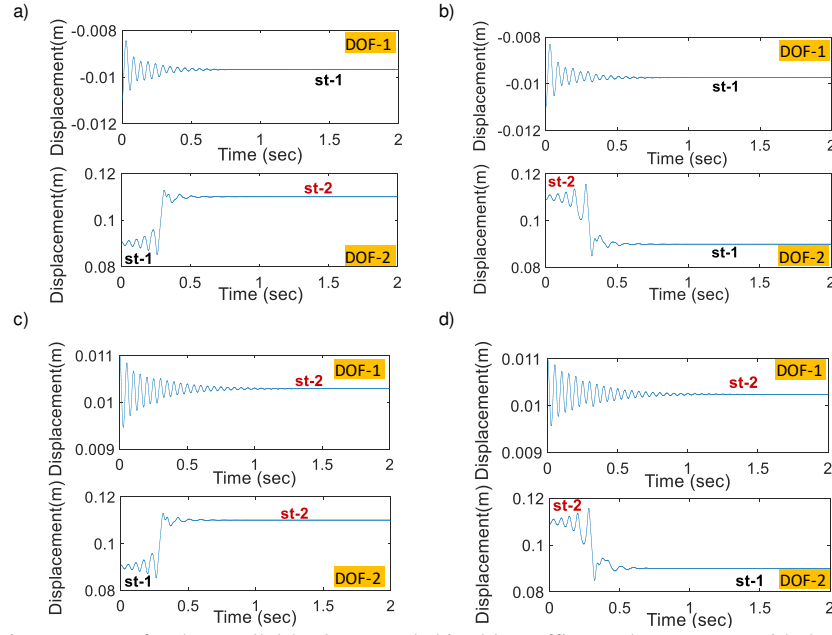

Figure 13: Example time response for the parallel 2DOF cascade bistable Duffing-Holmes system with the hybrid controller: a) DOF-1@st1 and DOF-2 st1->st2, b) DOF-1@st1 and DOF-2 st2->st1, c) DOF-1@st2 and DOF-2 st1->st2 and d) DOF-1@st2 and DOF-2 st2->st1.

A parametric analysis is carried out to determine the controller parameters that satisfy the desired switch properties for different cases. The proposed schematic for parallel configuration can be realized when two DOFs achieve forward, backward, converse state transfer. In the analysis, two controller parameters ζ_{npf} and g_{npf} are chosen since they have the major effect on switching behavior. In the analyses, the ζ_{npf} and g_{npf} are equal for both DOFs – they are swept through a range to determine the optimum values that satisfy the desired switching behaviors. Figure 14 presents a parametric analysis for the parallel configuration.

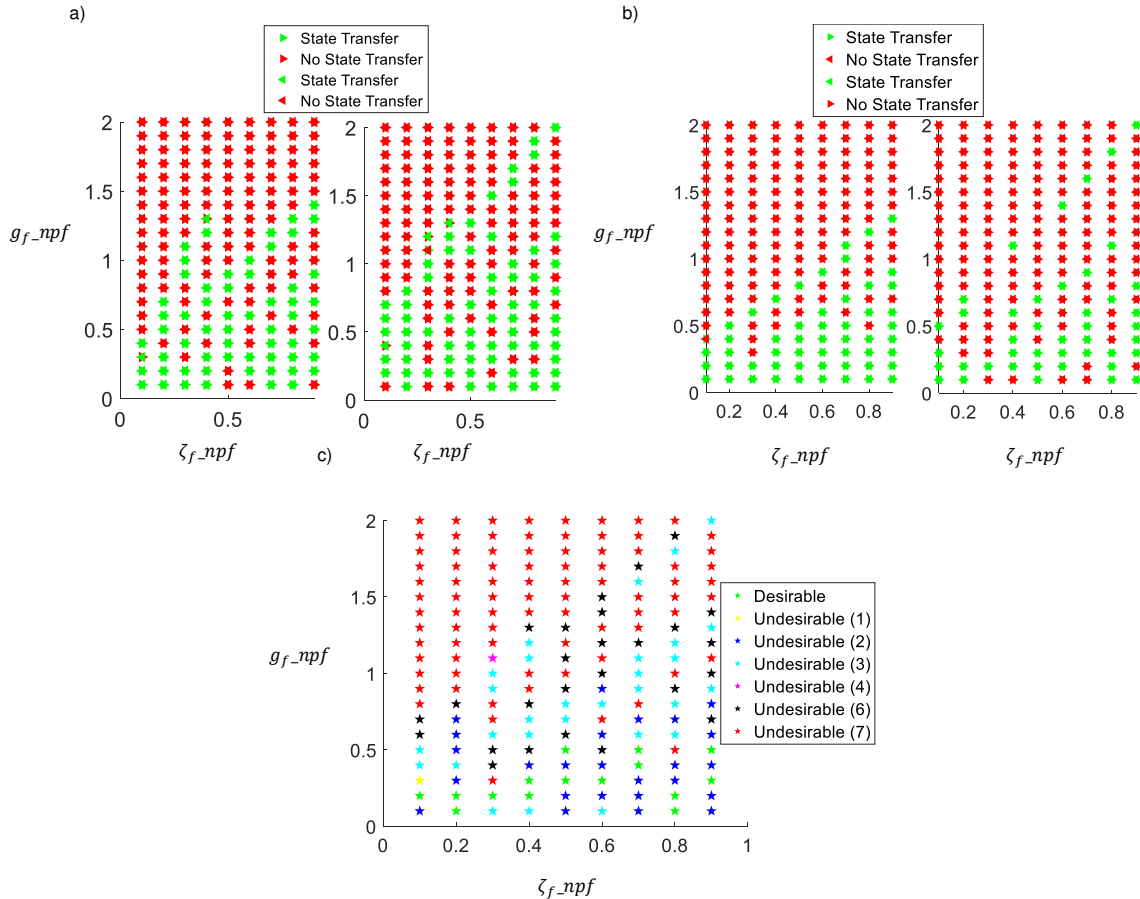

Figure 14: Parametric analysis for the series 2DOF cascade bistable Duffing-Holmes system with the hybrid controller a) Forward (DOF-1 and DOF-2: st1->st2) and Backward (DOF-1 and DOF-2: st2->st1) state transfer case, b) Converse State transfer case (DOF-1: st1->st2 and DOF-2: st2->st1, vice versa), c) all cases together.

Figure 14a presents a forward and backward state transfer behavior with respect controller parameters. The triangle pointing left or right shows the configuration of controller. The green and red colors indicate that initial configuration successful and unsuccessful, respectively, as described previously. Figure 14b demonstrates the analysis carried out for converse state transfer where DOF-1 is set to achieve state transfer from state 1 to state 2 while DOF-2 is set to achieve state transfer from state 2 to state 1. Also, vice-versa case simulation is presented in this figure. Figure 14c demonstrates the behavior of controller for all cases mentioned above. The green color indicates the controller parameters that achieve convergence to the desired state for all scenarios. The other colors in the figure are undesirable with the number of unsatisfied case indicated in the legend. Figure 15 shows the time responses for desired configuration.

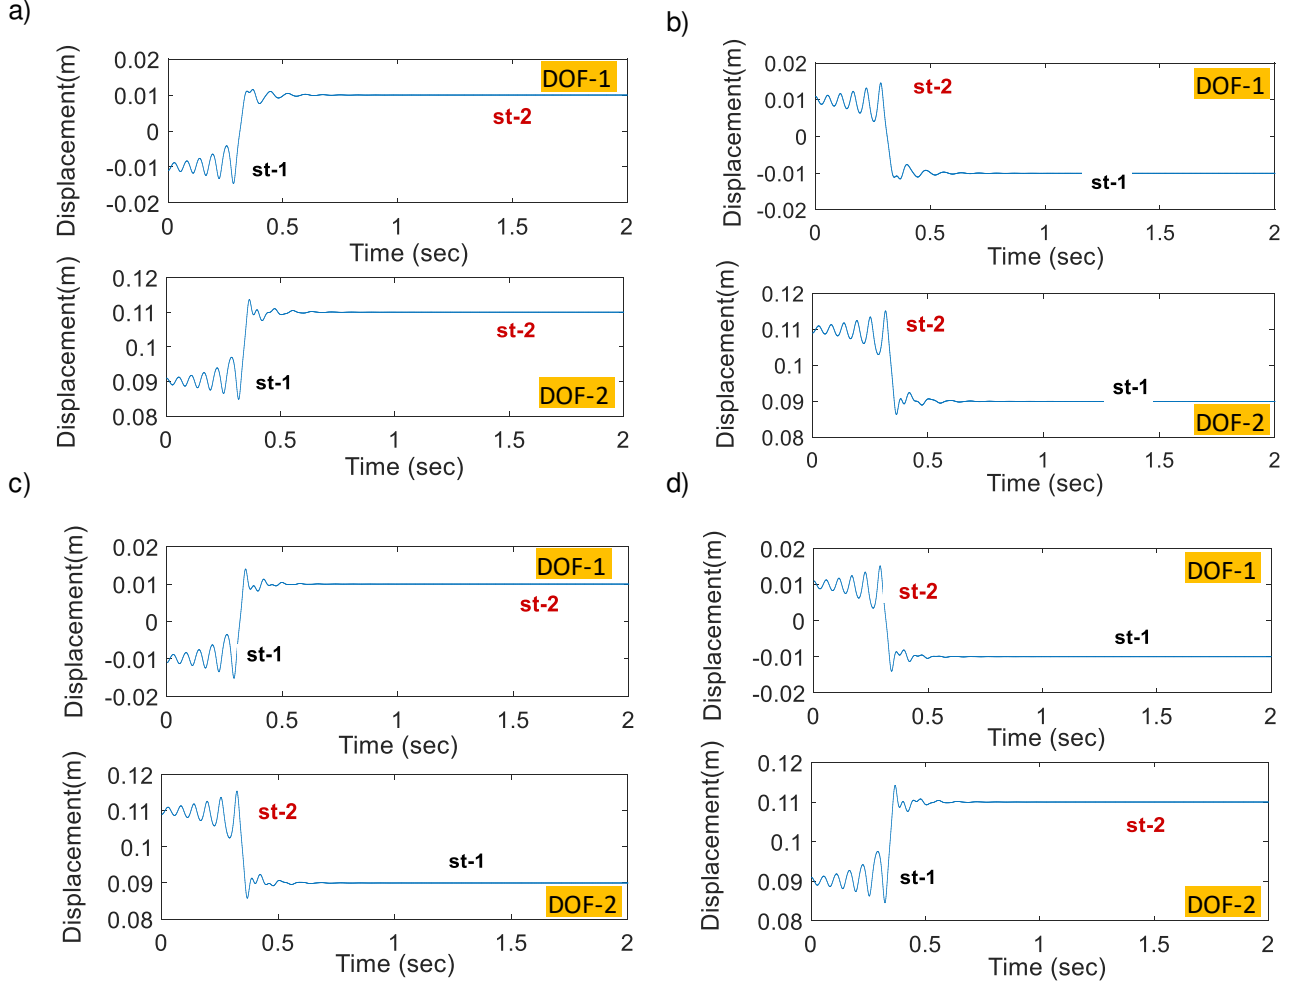

Figure 15: Time response for the parameters $\zeta_{f_{npf}} = 0.5$ and $g_{f_{npf}} = 0.3$ that achieves all scenarios of parallel configuration.

Conclusions

A multi degree of freedom metamaterial concept that utilizes the hybrid position feedback controller is introduced. An arbitrary number of bistable “segments” or “material elements” are attached to each other in a serial or parallel manner to generate a “distributed” bistable structure. The initial results, derived for 2DOF systems, show the merit of the proposed concept which can be applied to many applications. Due to the simplicity of the hybrid controller, the physical implementation of the proposed approach can be realized using simple circuit elements distributed in the material domain. The proposed metamaterial concept can be used in various applications: locomotion in bioinspired systems, undulatory motion, morphing aerodynamic surfaces, wave guiding, and vibration attenuation. The concept can also be used in energy harvesting to enable maximum power extraction for a given vibratory input.

Effect of Topology upon Relay Synchronization in Multilayer Neuronal Networks

Fenja Drauschke*, Iryna Omelchenko*, Jakub Sawicki*, and Eckehard Schöll*

**Institut für Theoretische Physik, Technische Universität Berlin, Germany*

Summary. Relay synchronization is a dynamical phenomenon occurring in complex networks when remote parts of the network synchronize due to their interaction via a relay. This phenomenon can be observed in lasers, electronic circuits, biological systems. We investigate relay synchronization scenarios in a three-layer network and elaborate the effect of inhomogeneous network topology of the individual layers.

Complex networks are currently of great interest, since they allow to model various types of real-world systems, such as social networks, economical, biological, financial, transportation systems, as well as neural activity in the brain [1]. In many cases the network can be divided into several similar parts, called layers, where interaction inside the layers and between the layers can be qualitatively different [2]. Multiplex networks are a special class of such multilayer structures, where each layer consists of the same number of nodes and only one-to-one interaction between the corresponding nodes of neighbouring layers are allowed [3].

Relay (or remote) synchronization between layers which are not directly connected is an intriguing phenomenon, which has some similarities with relay synchronization of chaotic lasers [4]. In neuroscience various scenarios have been uncovered where specific brain areas act as a functional relay between other brain regions, having a strong influence on signal propagation, brain functionality, and dysfunctions [5, 6], as well as visual processing [7].

We examine relay synchronization in a three-layer neuronal network, where the dynamics of individual nodes is governed by the FitzHugh-Nagumo system, widely used to describe spiking dynamics of neurons. In the simplest configuration, the individual layers have a nonlocal ring topology, where each node interacts with its neighbours within some fixed coupling range. In such a network, we observe relay synchronization when spatio-temporal patterns of the two outer layers synchronize, but the middle layer which transfers the signal, performs different dynamics. Later on, we replace regular links with random shortcuts, which results in the formation of a small-world topology inside the layers. With the irregular topology in the layers we uncover dynamical scenarios of relay synchronization. In the focus of our study are chimera states- patterns of coexisting coherent and incoherent domains [8, 9, 10, 11], which can be observed in isolated layers of the network [12].

Our model is described by the following system of differential equations:

$$\dot{\mathbf{x}}_i^m = \mathbf{F}(\mathbf{x}_i^m(t)) + \frac{\sigma_m}{L_i^m} \sum_{j=1}^N \mathbf{G}_{ij}^m \mathbf{H}(\mathbf{x}_j^m(t) - \mathbf{x}_i^m(t)) + \sigma_{ml} \sum_{l=1}^3 \mathbf{H}(\mathbf{x}_i^l(t) - \mathbf{x}_i^m(t)), \quad (1)$$

where $i = 1, \dots, N$ numbers the nodes inside each layer, $m = 1, 2, 3$ labels the layer, $\mathbf{x} = (x, y)^T$ is a state variable, and the local dynamics is described by the FitzHugh-Nagumo system $\mathbf{F}(x, y) = \left(\frac{1}{\varepsilon} (x - \frac{x^3}{3} - y), x + a \right)^T$. The adjacency matrices \mathbf{G}^m define the topology of each layer, and L_i^m is the number of links belonging to the i th node of the m th layer. σ_m is the strength of the couplings inside the layers, and σ_{ml} the strength of the couplings between the layers. The matrix \mathbf{H} defines the interaction scheme between the two-dimensional individual systems. Usually, we allow not only direct, but also cross coupling between the variables x and y . Fig. 1 shows schematically the structure of the three-layer network, where each layer has a nonlocal coupling topology, the outer layers are shown in grey, and the middle relay layer is shown in red. As a measure for synchronization between the layers we employ the global synchronization error:

$$E^{ij} = \lim_{t \rightarrow \infty} \frac{1}{NT} \int_0^T \sum_{k=1}^N \|\mathbf{x}_k^j(t) - \mathbf{x}_k^i(t)\| dt, \quad (2)$$

which takes values close to 0 when the patterns in the layers $m = i, j$ are synchronized. When coherent and incoherent domains coexist spatially in each layer, we observe nontrivial synchronization scenarios, where the coherent domains of

Figure 1: Schematic structure of a three-layer network

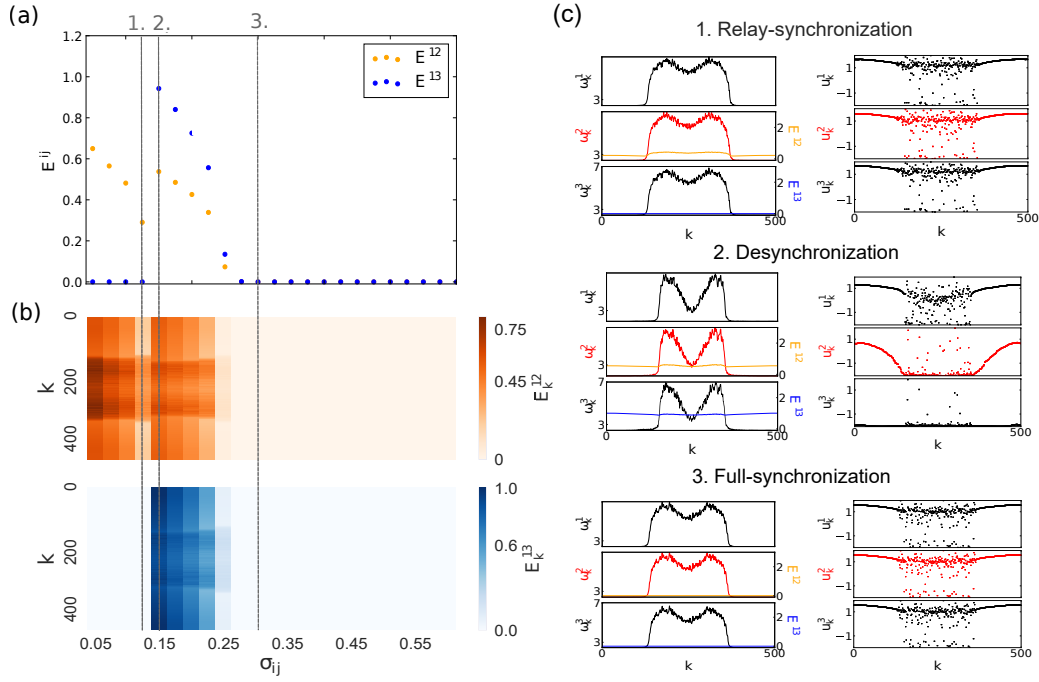

Figure 2: Scenario of synchronization transitions depending on the inter-layer coupling strength σ_{ij} . (a) Global synchronization error; (b) local synchronization error; (c) mean phase velocity profiles and inter-layer synchronization errors (left column) and snapshots (right column) for three values of σ_{ij} marked by vertical lines in (a), (b).

the patterns synchronize while the incoherent domains perform different dynamics. To distinguish this special kind of partial synchronization, we introduce the local synchronization error

$$E_k^{ij} = \lim_{t \rightarrow \infty} \frac{1}{T} \int_0^T \|\mathbf{x}_k^j(t) - \mathbf{x}_k^i(t)\| dt. \quad (3)$$

When the topology of the layers in the network is regular, we observe complete relay synchronization of chimera patterns in the outer layers, as well as partial relay synchronization, where only the coherent domains of patterns synchronize [13]. If we change the topology of the outer layers by replacing the regular links with random shortcuts, we find the scenarios shown in Fig. 2. Here the global and local inter-layer synchronization errors for increasing coupling strength between the layers, and examples of snapshots of chimera states and their mean phase velocities are depicted. We analyze the role of the system parameters and uncover parameter regions where full and partial relay synchronization occurs. Our results may be useful for understanding remote synchronization in brain networks.

Summary. Mechanical ventilators are medical devices used to assist patients to breathe. The aim of this paper is to develop a control approach that compensates the pressure drop over the hose that connects the ventilator to the patient. In [1], a similar strategy is considered assuming a linear system model, which is valid in a small operating range. To achieve the desired performance in the entire operating range, the quadratic nature of the resistance of an actual hose is considered in this paper. Using a quadratic hose model and a recursive least-squares estimator, the control law proposed in [1] is significantly improved. Through an experimental case study, a significant gain in pressure tracking performance is shown.

Background

Mechanical ventilation is commonly used in Intensive Care Units (ICUs) to save lives of patients who are unable to breathe by themselves. To assist these patients a mechanical ventilator is used. A schematic overview of a mechanical ventilator, with a single-hose setup, and a patient is depicted in Figure 1.

In this paper, the ventilation setup as depicted in Figure 1 and Pressure Controlled Ventilation (PCV) of sedated patients is considered. In PCV, the goal is to ensure that the pressure near the patients airway, i.e., p_{aw} , follows a reference as shown in Figure 2. This reference has two different pressure levels to ensure that air flows in and out of the lungs. Therewith, inspiration and expiration of the patient are supported. In practice, damage to the lung tissue should be prevented, e.g., by overshoot in pressure. Therefore, the pressure tracking performance should be accurate.

Previous work and open challenges

The control goal is to ensure that the airway pressure p_{aw} , see Figure 1, tracks the target pressure p_{target} . This is achieved by controlling the blower outlet pressure p_{out} . The airway pressure near the patient's mouth is defined as $p_{aw} = p_{out} - \Delta p$, with Δp the pressure drop over the hose. In [1], a novel adaptive control law is proposed that compensates for this pressure drop. A block scheme of this control law is shown in Figure 3. During ventilation, a linear hose resistance, i.e., \hat{R}_{lin} , is estimated using a recursive least-squares estimator. This estimate in combination with the measured flow is used to compute an estimate of the pressure drop over the hose, i.e., $\Delta \hat{p} = \hat{R}_{lin} Q_{out}$. Then, $\Delta \hat{p}$ is used to increase the blower outlet pressure, i.e., $p_{out} = p_{target} + \Delta \hat{p}$. Theoretically, this results in perfect tracking, independent of the patient, leak, or hose parameters, for time-varying target pressures.

Although the results in [1] are promising for use-cases with relatively small flow variations, in an experimental case study it is observed that for large flows performance deteriorates. This is caused by the typically non-linear hose characteristics, see Figure 4. This figure shows that the linear model 1 is an accurate representation of the hose resistance for the low flow regime. However, for large flow variations the linear models show a significant deviation from the measured values. It is clearly shown that a quadratic hose model is a better representation of the measured hose characteristics. This quadratic hose model is defined as follows:

$$\Delta p = R_{lin} Q_{out} + R_{quad} Q_{out} |Q_{out}|, \quad (1)$$

where R_{lin} and R_{quad} are unknown. Combining this non-linear hose resistance model with a linear model for the patient lung dynamics results in a non-linear dynamical model of the patient-hose system. The exact model is omitted for brevity. In the following sections, it is shown how the quadratic hose parameters are estimated online and, subsequently included in the control law to accurately compensate for the pressured drop over the hose and therewith improve performance.

Figure 1: Schematic representation of the blower-hose-patient system of the considered ventilation system.

Figure 2: Airway pressure (p_{aw}) during one breathing cycle of pressure controlled ventilation.

Figure 3: Block diagram of the considered control approach. Figure 4: Quadratic characteristics of a typical hose system.

Proposed control strategy

In this paper, the following quadratic-hose model is included in the control law depicted in Figure 3:

$$\Delta \hat{p} = \hat{R}_{lin} Q_{out} + \hat{R}_{quad} Q_{out} |Q_{out}|. \quad (2)$$

To complete the adaptive control law an estimator is used to obtain estimates \hat{R}_{lin} and \hat{R}_{quad} of the two hose parameters. These parameters are obtained using a Recursive Least Squares (RLS) estimator with exponential forgetting factor, see [2]. The considered estimator dynamics are given by:

$$\dot{\hat{\theta}}(t) = P(t) \frac{\Delta p(t) - \hat{\theta}(t) \phi_0(t)}{m^2} \phi_0(t), \text{ and } \dot{P}(t) = \beta P(t) - P(t) \frac{\phi_0(t) \phi_0^T(t)}{m^2} P(t), \quad (3)$$

where $\hat{\theta}(t) = \begin{bmatrix} \hat{R}_{lin}(t) \\ \hat{R}_{quad}(t) \end{bmatrix}$, $\Delta p(t) = p_{out}(t) - p_{aw}(t)$, $P(t) = \begin{bmatrix} P_{11}(t) & P_{12}(t) \\ P_{21}(t) & P_{22}(t) \end{bmatrix}$, $\phi_0(t) = \begin{bmatrix} Q_{out}(t) \\ Q_{out}(t) |Q_{out}(t)| \end{bmatrix}$, m is the scalar normalization parameter, and β is the scalar exponential forgetting factor.

Experimental results

The overall approach is implemented on an experimental ventilation setup, schematically depicted in Figure 1, and the obtained results are shown in Figures 5a and 5b. In Figure 5a, it is clearly seen that the tracking performance upon convergence is improved significantly. Furthermore, Figure 5b shows that the oscillations in the estimates are reduced. Concluding, performance is significantly increased by compensating for the non-linear hose characteristics.

Conclusions

This paper clearly shows that extending the adaptive control strategy in [1] with a non-linear (quadratic) hose model can significantly improve pressure tracking performance. This means that pressure support of mechanically ventilated patients can be improved by compensating for the non-linear hose characteristics.

Summary. This work presents a novel approach towards synchronization analysis of nonlinear systems, diffusively coupled via a networked communication channel. The system under consideration is a two-agent nonlinear system, under the constraint that information is transmitted between the two systems using an aperiodic communication strategy. The system setting is remodelled as the feedback-interconnection of a continuous-time system, and an operator that captures the perturbations introduced by communication constraints. By studying the properties of the remodelled system, i.e., the feedback-interconnection, in the framework of Dissipativity Theory, we provide a novel stability criterion that guarantees exponential synchronization.

Introduction

In many natural and practical circumstances, the phenomenon of synchronization has caught the attention of researchers and scientists from various fields. Typical examples include flashing fireflies, firing neurons, etc. In control theory, synchronization is a topic of interest in areas such as master-slave synchronization of nonlinear systems [Nijmeijer and Mareels, 1997]. In practical applications such as cooperative control of multi-agent systems [Olfati-Saber et al., 2007], synchronization can be analyzed with a control theoretic approach for networks of nonlinear systems [Pogromsky et al., 2002]. In such contexts, synchronization problems become more complex due to uncertainties introduced via the networked communication channel. For example, delays introduced in the network increase the complexity of synchronization problems [Steuer and Nijmeijer, 2011]. In addition to delays, individual systems could be connected via sampled-data coupling.

In recent years, master-slave synchronization problems of linear sampled-data systems have been studied, and different approaches have been proposed to study the relation between sampling period, coupling strength, and synchronization [Hua et al., 2015]. In existing results, it is typically considered that individual systems have the same sampling frequency. However, in practical scenarios, individual systems usually transmit information at different frequencies over a network, depending upon the communication channel, data traffic, etc. In this work, we consider a bidirectionally coupled, sampled-data, two-agent nonlinear system, wherein individual systems transmit information over a networked communication channel, at possibly different, aperiodic frequencies.

Problem Statement

We consider a two-agent interconnected system as shown in Figure 1a, wherein the dynamics of individual sub-system Σ_i , $i = 1, 2$, is of relative degree one, and is given by

$$\begin{aligned} \dot{x}_i(t) &= f(x_i(t)) + Bu_i(t), \\ y_i(t) &= Cx_i(t), \quad i = 1, 2, \end{aligned} \quad (1)$$

where $x_i \in \mathbb{R}^n$, $u_i, y_i \in \mathbb{R}^m$ are the state, input, and output, respectively. The function $f: \mathbb{R}^n \mapsto \mathbb{R}^n$ is a sufficiently smooth vector field, and B and C are matrices with appropriate dimensions, with $CB =: b \in \mathbb{R}^{m \times m}$, b being positive definite and without loss of generality, diagonal. The i^{th} output is transmitted to the j^{th} sub-system only at instants given by the sequence $s_{k+1}^i = s_k^i + h_k^i$, $h_k^i \in [\underline{h}_i, \bar{h}_i]$, $k \in \mathbb{N}$, $i = 1, 2$. Without loss of generality, we consider $s_0^i = 0$, $i = 1, 2$.

Assumption 1: The i^{th} sub-system has access to local output information at time instants $t = s_k^j$, $j \neq i$, $k \in \mathbb{N}$.

The aforementioned assumption reflects a practical scenario wherein individual systems can be sampled locally at a high frequency, but data transmission over a networked communication channel occurs at a lower frequency, depending on network induced constraints or requirements. Exploiting this assumption, we have that Σ_i , $i = 1, 2$, has access to local information at instants s_k^j , $j \neq i$. Consequently, the synchronizing coupling is designed as

$$\begin{aligned} u_1(t) &= -\sigma(y_1(s_k^2) - y_2(s_k^2)), \forall t \in [s_k^2, s_{k+1}^2), \\ u_2(t) &= -\sigma(y_2(s_k^1) - y_1(s_k^1)), \forall t \in [s_k^1, s_{k+1}^1), \end{aligned} \quad (2)$$

where $\sigma \in \mathbb{R}_+$ is the constant coupling strength. Since $CB > 0$, there exists a coordinate transformation so that the i^{th} sub-system dynamics are given by

$$\Sigma_i : \begin{cases} \dot{z}_i(t) &= q(z_i(t), y_i(t)), \\ \dot{y}_i(t) &= a(z_i(t), y_i(t)) + bu_i(t), \end{cases} i = 1, 2, \quad (3)$$

(a) Bidirectionally coupled systems Σ_1 and Σ_2 under asynchronous sampled-data transmission.

(b) System shown in Figure 1a represented as a feedback-interconnection.

Figure 1: (a) Systems Σ_1 and Σ_2 coupled via a networked communication channel and, (b) an equivalent feedback-interconnection representation.

where $z_i \in \mathbb{R}^{n-m}$, $u_i, y_i \in \mathbb{R}^m$, $q: \mathbb{R}^{n-m} \times \mathbb{R}^m \mapsto \mathbb{R}^{n-m}$, and $a: \mathbb{R}^{n-m} \times \mathbb{R}^m \mapsto \mathbb{R}^m$.

Assumption 2: The solution of the closed-loop system (3), (2) is ultimately bounded.

Definition 1: The bidirectionally coupled system given by (3), (2) is said to synchronize if $\lim_{t \rightarrow \infty} \|e(t)\| \rightarrow 0$, where $e(t) = [e_y^T(t) \ e_z^T(t)]^T$, and $e_y(t) = y_1(t) - y_2(t)$, $e_z(t) = z_1(t) - z_2(t)$, for any initial conditions $(z_1(0), y_1(0))$ and $(z_2(0), y_2(0))$.

Assumption 3: (Demidovich Condition [Pavlov et al., 2005]) There exists a positive definite matrix $P \in \mathbb{R}^{(n-m) \times (n-m)}$, such that the internal state dynamics given by $\dot{z}_i(t) = q(z_i(t), y_i(t))$, $i = 1, 2$, satisfies

$$P \frac{\partial q}{\partial z_i}(z_i, y_i) + \frac{\partial q^T}{\partial z_i}(z_i, y_i) P \leq -\delta I_{n-m}, P = P^T > 0, \delta > 0. \quad (4)$$

In this work, we provide conditions that guarantee exponential synchronization of the coupled system (3), (2).

Main Result

The system (3), (2) shown in Figure 1a is remodelled such that the effects introduced due to aperiodic sampling are decoupled from the continuous-time network, as shown in Figure 1b. In Figure 1b, the operator \mathbf{G} represents the dynamics of the system (1) in the absence of sampling, i.e., \mathbf{G} represents a ‘continuous-time’ version of the system (3), (2). Additionally, the operator Δ captures the error induced in the system due to asynchronous sampling. Consequently, the feedback-interconnection shown in Figure 1b represents the bidirectionally coupled, sampled-data system configuration shown in Figure 1a, by considering the effects of sampling as a perturbation to the continuous-time system operator \mathbf{G} . By studying the properties of the feedback-interconnection $\mathbf{G} - \Delta$, we provide conditions that guarantee exponential stability of the error dynamics $e(t)$, i.e., exponential synchronization of the system (3), (2). We adapt the result provided in [Omran et al., 2016], wherein a dissipativity based framework was employed to prove asymptotic stability of nonlinear systems with aperiodic sampled-data control. The properties of operator Δ are characterized by a function \mathcal{S} that satisfies

$$\int_0^t \mathcal{S}(\theta, e_y(\theta), \phi\{y_1(\theta), y_2(\theta), z_1(\theta), z_2(\theta)\}, w(\theta)) d\theta \leq 0, \forall t \geq 0, \quad (5)$$

where

$$\begin{aligned} \mathcal{S}(t, e_y(t), \phi\{y_1(t), y_2(t), z_1(t), z_2(t)\}, w(t)) \\ := w^T(t) R w(t) - \gamma^2 (\phi(y_1(t), y_2(t), z_1(t), z_2(t)) - 2b\sigma e_y(t) + b\sigma w(t))^T R (\phi(y_1(t), y_2(t), z_1(t), z_2(t)) \\ - 2b\sigma e_y(t) + b\sigma w(t)), \end{aligned} \quad (6)$$

with $\gamma^2 = \frac{4(\bar{h}_1^2 + \bar{h}_2^2)}{\pi^2}$, $w(t) = (\Delta \dot{e}_y)(t)$, and $\phi(y_1(t), y_2(t), z_1(t), z_2(t)) = a(z_1(t), y_1(t)) - a(z_2(t), y_2(t))$. For a positive definite storage function V , if the condition

$$\dot{V}(e(t)) + \alpha V(e(t)) \leq e^{-\alpha t} \mathcal{S}(t, e_y(t), \phi\{y_1(t), y_2(t), z_1(t), z_2(t)\}, w(t)), \forall t \geq 0, \alpha > 0, \quad (7)$$

holds, then the system setting given by (3), (2), synchronizes exponentially with a decay rate of at least $\alpha/2$.

Constrained input modulation for impulse-based motion control

Michael Ruderman

Department of Engineering sciences, University of Agder, 4604, Norway

Summary. We revisit the impulse-based motion control, introduced in [9], from a viewpoint when the control signal is constrained by the actuator limits. We demonstrate how the impulsive control [9] is modulated for the weighted input impulses, and what the consequences it has for the control performance. In addition, the state transients as a jumping map are discussed, when the amplitude-bounded (modulated) impulses can no longer guarantee the asymptotic convergence, and the stable limit cycles can appear instead.

Introduction

Hybrid control systems (see for example [6, 7] and references therein) allow for both continuous and discrete dynamics, while the discrete control actions may appear in form of the continuously or event- or state-dependent switching of the bounded control value or, alternatively, in form of the discrete impulses with finite energy content. Intensive research on the possibly uniform and generalized description of the hybrid dynamical systems and, especially, on their stability analysis and stabilization was performed already one and half decades ago. Here we exemplarily refer to the several available seminal (correspondingly tutorial) works like [4], and special issues like introduced in [1].

Impulsive dynamics (see e.g. [3] for basics) appear quite often in evolution of the natural processes, where some short-term perturbations (or generally stimuli) act instantaneously in the form of impulses and, thus, give rise to instantaneous jumps of the thereby affected dynamic states. A classical academic example is the bouncing ball (see for example in [4]), while in engineering, the various vibro-impact [3] systems can be found, for example, in the mechanical play-pairs also known as backlash [10]. When it comes to impulsive control actions, then the input impulse, or impulsive force cf. [3],

$$p_0 = \lim_{\Delta t \rightarrow 0} \int_{t_0}^{t_0 + \Delta t} u(\tau) d\tau \quad (1)$$

at the controlling instant t_0 is, to say, scaling the Dirac measure δ_{t_0} , so that the impulsive control effort $u = p_0 \delta_{t_0}$ cannot be a function of time. Analysis of such control systems may require to properly denote and handle the impulsive differential equations (see e.g. [5]). At the same time, introduction of a supplementary jump (or jumping) map (cf. the unified modeling framework provided in [2]) of the state transitions at all $t = t_0$ enables the further use of conventional system notations for all $t \neq t_0$ by means of e.g. ODEs or, correspondingly, state-space equations. In applications, one cannot expect that the impulse magnitude will keep a well-specified control action $u(\cdot)$ always below some finite actuator constraint. Therefore, once the input signal is inherently bounded $|u(\cdot)| < U$ by some positive system constant U , an impulsive control cannot be directly implemented, no matter which particular control strategy is lying behind.

Hybrid impulsive motion control, addressed in this work, was introduced in [9] while some preliminary formulation, including an experimental case study, was demonstrated before in [11]. The impulsive control was proposed for systems of the second order with uncertain upper-bounded damping, while the state axes represent the guard conditions that trigger a dedicated impulsive control action as soon as one of the both is crossed. One can notice that other impulsive controls were also proposed formerly in [8] and [12], for the mechanical systems with friction. In either approach, however, an impulsive action occurs first when a motion trajectory falls on the position axis, which implies several zero velocity (and subsequent re-acceleration) phases before it converges to the origin. In the following, we will briefly summarize the impulse-based control [9], for convenience of the reader, and then address the impulse modulation for bounded inputs.

Impulse-based motion control

The impulse-based motion control [9] is given by

$$m\ddot{x} + d\dot{x} + kx = \underbrace{-\alpha \operatorname{sign}(\dot{x}) \frac{d}{dx} \operatorname{sign}(x) - \beta \operatorname{sign}(x) \frac{d}{d\dot{x}} \operatorname{sign}(\dot{x})}_{\equiv u}, \quad (2)$$

where the continuous system dynamics is shaped by the inertial mass $m > 0$ and uncertain (or in the worst case unknown) stiffness and damping constants $k, d > 0$, respectively. Note that the upper-bound of the damping coefficient $d < D$ needs to be known. The discrete control value u is parameterized by $\alpha, \beta > 0$ and is acting only when the motion trajectory crosses one of the state axes, i.e. at $(0, \dot{x}_0)$ or $(x_0, 0)$. This provides a disjoint jump set $\mathcal{D} = \dot{X}_0 \cup X_0 = \{(x, \dot{x}) \in \mathbb{R}^2 \mid x = 0 \cup \dot{x} = 0\}$ and makes both control actions (on the right-hand side of (2)) respectively disjunctive and, therefore, simultaneously appearing only in zero equilibrium $(x, \dot{x}) = \mathbf{0}$, while $\operatorname{sign}(0) = 0$ is defined. The proposed control system (2) is well fitting into the autonomous-impulse hybrid systems framework [2] and, thus, can be fully described by $\dot{\mathbf{x}} = f(\mathbf{x})$ if $\mathbf{x} \in \mathcal{C}$ and $\mathbf{x}^+ \in J(\mathbf{x})$ if $\mathbf{x} \in \mathcal{D}$, where the flow and jump maps are f and J , respectively. The belonging flow and jump sets are disjoint so that $\mathcal{C} = \mathbb{R}^2 \setminus \mathcal{D}$. The parametric conditions for the gains are $0.5m|\dot{x}_0| \leq \alpha < m|\dot{x}_0|$ and $\beta = 0.5|x_0|D$, while a state value during last crossing of the orthogonal axis is denoted by the subindex zero, i.e. x_0 and \dot{x}_0 correspondingly. For further details on and analysis of the impulse-based motion control we refer to [9].

Modulation of bounded control input

The impulsive control action in (2) requires a control effort $|u| = 2\alpha\delta(\dot{x}_0) \vee 2\beta\delta(x_0)$, where $\delta(\cdot)$ is the Dirac delta function, cf. with eq. (1). Recall that the Dirac delta function can be seen as distributional derivative of the sign-function, weighted by factor 2, and can then be defined and constrained to satisfy the identity as follows:

$$\delta(y) = \begin{cases} \infty, & \text{if } y = 0, \\ 0, & \text{if } y \neq 0; \end{cases} \quad \int_{-\infty}^{\infty} \delta(y) dy = 1; \quad \delta(y_0) = \lim_{\Delta t \rightarrow 0} p_{\Delta t}(t_0). \quad (3)$$

Note that the last expression in (3) relates the Dirac delta function to the square pulse p of duration Δt and amplitude $(\Delta t)^{-1}$, cf. with an impulsive force in (1). Since the square pulse has unity 'strength' (or 'weight'), it is evident that for a constrained actuator (with $\max u = U$) the pulse duration $T \equiv \Delta t$ is required to be $T = 2(\alpha \vee \beta)U^{-1}$. That leads to an inevitable modulation of the discrete (impulsive) control as $u \mapsto u[x_0, \dot{x}_0](t_0 \leq t \leq t_0 + T)$. In order to analyze the impact of such control modification on the convergence performance of (2), cf. [9], one needs to evaluate

$$\mathbf{x}^+ = \exp(A(t_0 + T)) \mathbf{x}_0(t_0) \mp \int_{t_0}^{t_0+T} \exp(A(t - \tau)) B U d\tau, \quad (4)$$

which provides inhomogeneous (particular) solutions for $\mathbf{x}_0 = [0, \dot{x}_0]^T \vee [x_0, 0]^T$ at the time instant t_0 of the control pulse. Here $A \in \mathbb{R}^{2 \times 2}$ and $B \in \mathbb{R}^{2 \times 1}$ are the associated system matrix and input distribution vector resulting from the left-hand side of (2). Note that the sign before the integral in (4) changes depending on the quadrants in which the trajectory undergoes zero-crossing. The "−" sign captures either $x = 0$ crossing from the II-nd to the I-st quadrant or $\dot{x} = 0$ crossing from the I-st to the IV-th quadrant. And the "+" sign appears for the corresponding zero-crossings from the IV-th to the III-rd or from the III-rd to the II-nd quadrant. For an asymptotic convergence of the state trajectory towards zero equilibrium, driven by a sequence of the control impulses $u(t_{0,n})$ with $n = 1, \dots, N$ where $N \rightarrow \infty$, it is sufficient to demonstrate constant decrease of Euclidean norm of the state vector after each executed pulse, i.e. $\|\mathbf{x}^+\|_2 < \|\mathbf{x}_0\|_2$.

A symbolic solution of (4) is computable, yet cumbersome, so that solely several numerical observations are shown and discussed below. For the sake of simplicity, no linear damping is assumed, i.e. $d = D = 0$, so that the left-hand side of (2) represents a harmonic oscillator for the assigned $m = 0.1$ and $k = 10$. The initial values are assigned to be $[x, \dot{x}](t = 0) = [-0.001, 0.1]$, and the forward Euler solver with $\Delta t = 0.0001$ sec is used. The difference between the

converging unbounded control and that U -bounded, which runs into stable limit cycles, is demonstrated in the diagrams (a) and (b). An avoidance of limits cycles and, thereupon, further convergence towards zero equilibrium is demonstrated in the diagram (c) with variation of the α -parameter. A more detailed analysis of the parametric conditions of the occurrence or escape of the limit cycles calls for an explicit solution of (4), equally as for periodic solutions with impulses at $t_{0,n}$.

Abstract. This paper examines a linearisation algorithm developed for the nonlinear dynamics of the *FutureForge* manipulator - part of a state-of-the-art forging platform being built in Glasgow, Scotland. Building on previous work, the authors investigate means of obtaining approximate analytical solutions for the highly nonlinear system with a view to developing a practical control system in future work. This is done by a combination of algebraic approximation methods, a practical understanding of the machine's operating characteristics, as well as the application of a perturbation method. The devised method is verified by comparing the resulting approximate analytical solutions with numerical solutions to the nonlinear problem.

Keywords: Linearisation, Industrial Manipulators

1 Introduction

This work follows on from a previous piece of work involving many of the same authors [1]. Previously, the authors examined the design of a large-scale industrial manipulator for the *FutureForge* project commissioned by the Advanced Forming Research Centre (AFRC) in Glasgow, Scotland. The manipulator's intended purpose is to handle metallic workpieces through their treatment in a 2,000-tonne hydraulic press: carrying them to and from the press, positioning them in the press appropriately, and ensuring their precise placement throughout these movements. Since this earlier work's publication, the manipulator has been successfully installed at the AFRC and a working control system has been implemented by Clansman Dynamics Ltd. The work we describe in this paper contributes to the development of a digital twin of the manipulator that will be used to train operators in a virtual reality environment.

Figure 1: A schematic diagram of the *FutureForge* manipulator, depicting its configuration in its 2D planar workspace. This image previously appeared in the preceding work by Cartmell *et al.* [1].

Interestingly, the manipulator we are considering is rather unique in the field of industrial robotics. At first glance, it appears to be a serial system since the end-effector's position is governed by the positioning of three – apparently sequential – parallelogram linkages. Definitionally, serial manipulators are open kinematic chains of links, and, in many industrial examples, the motion of their end-effectors is actuated by revolute or prismatic actuators located at the joints between links

[2]. For configurations such as this, many powerful techniques have been developed to the end of solving the dynamics and kinematics involved. Such methods include Meldrum, Rodriguez, and Franklin's recursive approach to matrix inversion [3] and Saha's approach to decomposition of the inertia matrix [4]. Furthermore, several control approaches are based on this type of configuration also. These include Gazit and Widrow's "Back Propagation Through Links" method [5]; Ouyang and Zhang's virtual velocity-based method [6]; and, Talebpour and Namvar's application of adaptive control to serial manipulators in the context of satellite testing [7]. However, this manipulator may not be regarded as serial. Instead, the end-effector's position is driven by two actuators at its base. Therefore, the *FutureForge* manipulator might be thought of as a hybrid between a serial and a parallel manipulator. To be clear what we mean by this: the end-effector's position, in the planar workspace, is the result of a series of parallelogram configurations, these individually being closed-chain mechanisms; and, the configurations of each parallelogram are dictated by the parallelograms preceding them. We consider the linkage ordering as flowing from base to end-effector. In this way, the manipulator benefits from having a large workspace relative to its size and footprint [8]. Additionally, the parallelogram structure of the linkages allows it to carry heavier workpieces with greater accuracy [9]. The trade-off in realising these benefits is that the resulting system is significantly more complex to model analytically.

1.1 Summary and Influence of Previous Work

In the work preceding this [1], the authors discussed how the manipulator was intended to operate. Due to its novel design, actuating the hydraulics connected to link AD moves the end-effector purely horizontally. Similarly, the hydraulic actuator connected to point K causes vertical motion in the end-effector. One significant point to note, however, is that this "vertical actuation" does involve some variance in the end-effector's horizontal position such that its path is somewhat curved due to physical constraints of the mechanism. The authors derived the governing dynamics of the manipulator via Lagrangian mechanics and were able to solve this model numerically.

The model that resulted is expressed as a system of two governing equations: one for actuation of the cylinder connected at K (the "vertical case"); and, one for actuation of the cylinder connected to AD (the "horizontal case"). The generalised coordinates in the equations are the angles controlled by these two actuating cylinders: $\alpha(t)$, for the vertical actuation angle; and, $\beta(t)$, for the horizontal actuation angle. Thus, later in this present work when we refer to the "vertical actuation problem", we simply mean the ODE which is derived from the Lagrange equation

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \alpha'(t)} \right) - \frac{\partial L}{\partial \alpha} = Q_v \quad (1)$$

where Q_v is the generalised force applied through this cylinder at K. Similarly, the "horizontal actuation problem" refers to the ODE resulting from

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \beta'(t)} \right) - \frac{\partial L}{\partial \beta} = Q_h \quad (2)$$

in which Q_h is the generalised force applied through the cylinder connected to AD. Note that, in the above equations and throughout this paper, we use the prime notation to denote differentiation with respect to time, staying consistent with the previous work mentioned, thus $\alpha' = \frac{d}{dt}\alpha(t)$, and $\beta' = \frac{d}{dt}\beta(t)$.

The ODEs that result from these two applications of Lagrange's equation are highly nonlinear and exhibit coupling between the two actuation coordinates $\alpha(t)$ and $\beta(t)$. Moreover, they are incredibly cumbersome to manage analytically to the point of being intractable - the curious reader is referred to Eqs (44) and (79) in [1]. As such, the present work was begun to attempt a linearisation strategy which could yield approximate analytical solutions to the underlying dynamics. The resulting linearised model will then be used in a control system for the manipulator - to be implemented in a virtual reality (VR) model of the manipulator. Since the manipulator's operation will always be controlled by a human operator, it is the role of this mathematical model and control system to replicate effectively the physical behaviour of the manipulator as accurately as possible where the physical machine must be capable of submillimetre accuracy in end-effector placement.

At the end of the previous work, we outlined a means of simplifying these aforementioned equations. Firstly, the two governing equations are simplified by collecting their terms into the following groups (and arranging them in this order in Eqs (3) and (4)): linear and nonlinear inertia, linear and quadratic damping, nonlinear restoring force, and excitation. Applying these groupings, we simplify the equations considerably. For the vertical actuation problem, the resulting form of the governing equation is

$$a_1 \alpha'' + a_2 \cos(2\alpha) \alpha'' + a_3 \alpha' + a_4 \sin(2\alpha) (\alpha')^2 + a_5 \cos(\alpha) + a_6 \sin(\alpha) = Q_v, \quad (3)$$

and the horizontal actuation problem is

$$b_1 \beta'' + b_2 \cos(2\beta) \beta'' + b_3 \beta' + b_4 \sin(2\beta) (\beta')^2 + b_5 \cos(\beta) + b_6 \sin(\beta) = Q_h, \quad (4)$$

where the design specifications of the manipulator contribute to the constant a -terms in Eq (3) and b -terms in Eq (4). These specifications detail the individual component masses, lengths, and mass moments of inertia. From this point, the previous work introduced a small perturbation parameter, ε , into the governing dynamics via these constant terms. A development of this small parameter's introduction is elaborated on in Section 2.1. Then, we continue through Sections 2.2-2.4 to describe the linearisation process we have adopted. Finally, we discuss our results and conclusions in Sections 3 and 4 respectively.

2 Linearisation of the Governing Equations

2.1 Introduction of the Small Parameter

In the original governing equations, Eqs (3) and (4), the constant a and b -terms are functions of the design specifications of the manipulator: component lengths, masses, mass moments of inertia, and geometric offsets. By computing these specifications to find the numerical values of all a and b -terms, we can compare their magnitudes to introduce a small parameter, ε . This parameter is introduced to constants deemed significantly smaller than others. By this, we mean terms which are at least 100-times smaller than the largest constant in the same equation. Based on this approach, for Eq (3) we find that

$$a_2 = \varepsilon \bar{a}_2, \quad a_3 = \xi_{jf} + \varepsilon \xi_{af}, \quad a_4 = \varepsilon \bar{a}_4, \quad \text{and} \quad a_6 = \varepsilon \bar{a}_6. \quad (5)$$

Additionally, for Eq (4) we find

$$b_2 = \varepsilon \bar{b}_2, \quad b_3 = \varepsilon \xi_{jf} + \varepsilon^2 \xi_{af}, \quad b_4 = \varepsilon \bar{b}_4, \quad \text{and} \quad b_6 = \varepsilon \bar{b}_6. \quad (6)$$

In the previous work by Cartmell *et al.*, the linear damping was manually introduced into the governing equations to account for both the viscous joint friction and aerodynamic drag in a single “lumped”-parameter [1]. Now notice that we have also expanded the definition of these linear damping coefficients a_3 and b_3 . These expanded definitions split the two sources of drag so that they may be treated independently and can contribute to the $O(\varepsilon^0)$ and $O(\varepsilon^1)$ perturbation equations more appropriately. Notice the key difference between the substitutions in (5) and (6) is that the linear damping coefficient contributes to a higher order of perturbation equation for the horizontal problem than in the vertical problem. This is consistent with our strategy for introducing ε , however, it may be desirable to electively allow linear damping to contribute to the generating, $O(\varepsilon^0)$, problem for the horizontal actuation problem.

2.2 Transcendental-Algebraic Conversion

Referred to as the “TAC”, the transcendental-algebraic conversion step is intended to pave the way for the substitution of asymptotic expansions of α and β . In this step, each transcendental term is replaced with an algebraic approximation derived via appropriate Taylor Series expansions. For the vertical actuation problem, we compute Taylor Series expansions of $\cos(2\alpha)$, $\sin(2\alpha)$, $\cos(\alpha)$, and $\sin(\alpha)$. The centres of these expansions are at $\alpha = 0$ radians, the centre of the operational range of α , to benefit from the expansions' accuracy in both the positive and negative α directions. A MATLAB algorithm has been constructed to determine the minimum order of approximation required to ensure a maximum error of 0.1% in these approximations versus their respective target functions. Based on discussions with our industrial collaborators (the AFRC), this error requirement may be tightened or relaxed. Regardless, the method progresses in an identical fashion. The same approach is implemented for the horizontal problem, this time with the expansions centred at $\beta = \frac{\pi}{2}$ radians, the centre of the operational range of β .

To study the errors introduced by this step, we compute the numerical solutions of Eqs (3) and (4) and compare them to the numerical solutions of the approximated equations given by the TAC step. The impact of this approximation can be seen in each of the cases examined in Section 3 and is referred to in the included graphs as “Num (post-TAC)”. Given $\alpha \in [-0.305, 0.305]$ radians and $\beta \in [\frac{\pi}{3}, \frac{2\pi}{3}]$ radians, the errors depicted in Figures 2-17 are very small indeed. Nonetheless, given how these errors grow with time, the orders of approximations may require further considerations if very long durations of manoeuvres are to be simulated

2.3 Exploitation of the Excitation Function

Until this point, the excitations applied to the vertical and horizontal cases were defined as constants, Q_v and Q_h respectively. Here we define them as nonlinear functions of both the relevant actuation angle and time. This approach is not dissimilar to Hsu's exploitation of strategically tuned excitation functions, according to the brief description in Hsu's work in [10]).

For the manipulator to resist falling under its own weight, part of the total excitation must go towards balancing the gravitational restoring force. This component of the excitation is denoted by $R_v(\alpha)$ and $R_h(\beta)$ for the vertical and

horizontal problems respectively. However, for there then to be motion, there must also be an excitation beyond this gravity-balancing component. We represent this with a time dependent component in the two cases as $F_v(t)$ and $F_h(t)$ respectively. Thus, the revised definitions of the excitations are

$$Q_v = R_v(\alpha) + F_v(t) \quad (7)$$

for the vertical problem, and

$$Q_h = R_h(\beta) + F_h(t) \quad (8)$$

for the horizontal problem. Note that, to carry out its intended role, $R_v(\alpha)$ must equal the vertical restoring force.

$$R_v(\alpha) = a_5 \cos(\alpha) + a_6 \sin(\alpha) \quad (9)$$

The same is similarly true for the horizontal equivalent, $R_h(\beta)$, and the restoring force in the horizontal problem. Therefore, these two components of the excitations will balance any occurrence of the restoring forces throughout the perturbation equations, not just in the generating problem. This is also true for the horizontal case. Additionally, the time-dependent excitations, $F_v(t)$ and $F_h(t)$, will only contribute to the generating solutions. Note that other authors have previously adopted methods that involve assuming the absence of a gravitational restoring force [11]. In this section, we have provided a justification for this from an operational standpoint, rather than simply stating it as an *a priori* assumption.

2.4 Extraction of the Perturbation Equations from the Simplified Model

With the governing equations now suitably prepared, we can introduce one final pair of substitutions, the asymptotic approximations of $\alpha(t)$ and $\beta(t)$

$$\alpha(t; \varepsilon) \approx \alpha_0(t) + \varepsilon \alpha_1(t) \quad (10)$$

$$\beta(t; \varepsilon) \approx \beta_0(t) + \varepsilon \beta_1(t). \quad (11)$$

Substituting these into the revised governing equations and collecting the $O(\varepsilon^0)$ and $O(\varepsilon^1)$ terms, we find the following equations:

$$a_{0,2,1} \alpha_0'' + a_{0,1,1} \alpha_0' = a_{0,0,1} F_v \quad (12)$$

$$\begin{aligned} a_{1,2,1} \alpha_1'' + a_{1,1,1} \alpha_1' = & (a_{1,0,1} + a_{1,0,2} \alpha_0^2) \alpha_0'' \\ & - a_{1,0,3} \alpha_0' + (a_{1,0,4} \alpha_0 + a_{1,0,5} \alpha_0^3) (\alpha_0')^2 \end{aligned} \quad (13)$$

$$b_{0,2,1} \beta_0'' = b_{0,0,1} F_h \quad (14)$$

$$\begin{aligned} b_{1,2,1} \beta_1'' = & (b_{1,0,1} + b_{1,0,2} \beta_0 + b_{1,0,3} \beta_0^2) \beta_0'' \\ & + b_{1,0,4} \beta_0' + (b_{1,0,5} + b_{1,0,6} \beta_0 + b_{1,0,7} \beta_0^2 + b_{1,0,8} \beta_0^3) (\beta_0')^2. \end{aligned} \quad (15)$$

Eqs (12) and (14) are the generating problems for the vertical and horizontal cases respectively. Similarly, Eqs (13) and (15) are the $O(\varepsilon^1)$ dynamics of the vertical and horizontal cases. Note the subscripts utilised for the a and b constants in Eqs (12) to (15). These are used to usefully identify components of the solution and to identify their origin in the problem. This method of encoding the constants' origins and occurrences is inspired by [12] but is distinct from this approach as our work is significantly more limited although serving our purpose adequately. The three numbers used have different functions: the first refers to the ε -order of the problem that the constant first appears in; the second refers to the order of derivative multiplying the constant; and, the third is a simple counter. For example, the constant $a_{0,2,1}$ (i.e., with the subscripts 0, 2, and 1) is found in the $O(\varepsilon^0)$ problem, is the coefficient of the 2nd derivative of the dependent variable, and is the 1st coefficient with these previous two designators. By contrast, the constant $b_{1,0,5}$ is the 5th constant to occur in the $O(\varepsilon^1)$ horizontal problem on the right-hand side of the equation. Note this feature of the “0”-designator in our notation: since we have removed all occurrences of the gravitational restoring force from all levels of the manipulator's dynamics, the “0”-designator is not reserved for the coefficients of the dependent variables and can be freely used for terms arranged on the right-hand sides of Eqs (12)-(15).

As was mentioned briefly previously, a key difference between the horizontal and vertical problems is the relative insignificance of linear damping in the former. The result of this is seen in comparing the two generating problems. For the sake of illustration, we continue this paper with the assumption that linear damping should not contribute to the horizontal problem at the $O(\varepsilon^0)$ level. If this assumption needed to be changed, then the solution process for the horizontal case precisely follows the algorithm of the vertical case. From this point, the solution of the linearised system is relatively simple to compute analytically. As intended, both $O(\varepsilon^0)$ problems may be solved independently of their $O(\varepsilon^1)$ counterparts.

3 Results

To inspect the quality of our proposed linearisation algorithm, we compare the approximate analytical (AA) solutions to the numerical solutions of the governing equations at three points in the process. These three points for finding numerical solutions are: before any linearisation takes place, Eqs (3) and (4); immediately after the TAC step is undertaken; and, once the governing problems are stated as perturbation equations. We undertake four cases to examine, these are detailed in Table 1. Cases 1 and 2 consider relatively slow motions of the end-effector; while, Cases 3 and 4 consider faster, more abrupt motions. At the time of writing, we are seeking data from our industrial collaborators that describes manoeuvres undertaken in physical testing of the machine. When this becomes available, we will compare the model against this. However, for now we are only concerned with the efficacy of the linearisation process.

Case	ε	Initial Conditions				Vertical Actuation		Horizontal Actuation	
		$\alpha(0)$ (rad)	$\alpha'(0)$ (rad/s)	$\beta(0)$ (rad)	$\beta'(0)$ (rad/s)	F_v (kN)	t_v (s)	F_h (kN)	t_h (s)
1	0.001	-0.3054	0	1.0472	0	3	3	5	3
2	0.001	0.3054	0	2.0944	0	-3	3	-5	3
3	0.001	-0.3054	0	1.0472	0	30	1	50	1
4	0.001	0.3054	0	2.094	0	-30	1	-50	1

Table 1: Cases examined to test the suitability of the linearisation algorithm in the absence of physical test data.

Using the kinematic equations of the earlier work [1], we can inspect the impact of the errors found on the accuracy of the end-effector's placement. Using the expressions for the end-effector's Cartesian position, we can see that changes of over 1.8×10^{-4} radians in β result in the end-effector motion exceeding 1mm. Given our previously stated intent that the control system we will go on to implement should be accurate on a sub-millimetre scale, we can acknowledge that the absolute error in β should be less than this value. For α , the equivalent condition on the error is found as $\pm 3 \times 10^{-4}$ radians. This is also why the initial positions in Table 1 are rounded to 4 decimal places (since 0.0001 is less than either the α or β tolerance stated).

3.1 Case 1

In Case 1, we see the following approximations of the vertical actuation problem arise from our linearisation process. Note that the numerical values included in the equations listed in the following equation, and the rest of Section 3, are rounded to 5 significant figures since this is consistent with the initial conditions.

$$\begin{aligned}
 \alpha(t) \approx & -88.573 - 1.1043 \times 10^{-8} e^{-0.1699t} + 6.0005 \times 10^{-8} e^{-0.13595t} - 1.1744 \times 10^{-7} e^{-0.10196t} \\
 & + 3.5945 \times 10^{-7} e^{-0.067974t} + 88.2694 e^{-0.033987t} - 0.0017626 e^{-0.033987t} + 3.0000t \\
 & - 1.8765 \times 10^{-9} t e^{-0.13595t} + 8.7830 \times 10^{-9} t e^{-0.10196t} - 5.7442 \times 10^{-9} t e^{-0.067974t} \\
 & - 3.0007 \times 10^{-5} t^2 e^{-0.033987t} - 1.9186 \times 10^{-9} t^2 - 1.2755 \times 10^{-10} t^2 e^{-0.10196t} \\

 & - 7.3669 \times 10^{-14} t^4 - 1.4734 \times 10^{-13} t^4 e^{-0.033987t}
 \end{aligned} \tag{16}$$

Figure 2: Approximate solutions of the vertical problem for Case 1. Note the operational limits of α marked at ± 0.3054 .

Figure 3: The absolute error for each approximation in Fig 2 versus “Num (Original)” as a reference.

As can be seen, with a cursory glance at Fig 2, as well as in Fig 3, the approximate analytical solution and two numerical solutions are extremely close to the numerical solution of the original problem. The reason for the numerical solution of the linearised problem, “Num (Linearised)”, having a slightly larger error versus the target solution is simply that the

numerical method used naturally introduces numerical errors where the analytical method does not.

For the horizontal actuation problem, we initially see another very close resemblance between the four illustrated solutions in Fig 4. Note that the approximate analytical solution for this is given by

$$\begin{aligned} \beta(t) \approx & 1.0472 + 0.040710t^2 - 2.5948 \times 10^{-4}t^3 - 2.1092 \times 10^{-4}t^4 \\ & + 3.7226 \times 10^{-6}t^6 + 9.6805 \times 10^{-8}t^8 - 1.6916 \times 10^{-9}t^{10}. \end{aligned} \quad (17)$$

Figure 4: Approximate solutions of the horizontal problem for Case 1. Note the operational limits of β at $\frac{\pi}{3}$ and $\frac{2\pi}{3}$.

Figure 5: The absolute error for each approximation in Fig 4 versus “Num (Original)” as a reference.

However, under closer inspection, we see that the absolute error in each of these is significantly higher than in the vertical problem. There are two factors that contribute to this reduced accuracy through the linearisation process. The first, most significant, of these is the order of Taylor Series approximation used in the TAC step. This will have a significant impact on the horizontal actuation problem since the operational range of β is significantly larger. The second of these reasons is the lack of linear damping included in the generating problem. Although these two factors clearly contribute to reduced accuracy of the model, only a comparison with physical testing data will rule whether they are acceptable trade-offs or not. If they are found to be unacceptable, we can simply increase the approximation order at the TAC stage or be sure to include linear damping in the generating dynamics.

3.2 Case 2

Similarly to Case 1, we see greater accuracy in the vertical actuation problem than in the horizontal problem although the latter may still be satisfactorily accurate. The vertical approximate analytical solution for this is simply the solution for Case 1 multiplied by (-1) . Whereas, that of the horizontal actuation problem is

$$\begin{aligned} \beta(t) \approx & 2.09440 - 0.040710t^2 + 2.5949 \times 10^{-4}t^3 + 2.1092 \times 10^{-4}t^4 \\ & - 3.7226 \times 10^{-6}t^6 - 9.6805 \times 10^{-8}t^8 + 1.6916 \times 10^{-9}t^{10} \end{aligned} \quad (18)$$

where we note that $\beta(0)$ is simply the new initial condition and all other terms are the negatives of those in Case 1.

Figure 6: Approximate solutions of the vertical problem for Case 2. Note the operational limits of α marked at ± 0.305 .

Figure 7: The absolute error for each approximation in Fig 6 versus “Num (Original)” as a reference.

Figure 8: Approximate solutions of the horizontal problem for Case 2. Note the operational limits of β at $\frac{\pi}{3}$ and $\frac{2\pi}{3}$.

Figure 9: The absolute error for each approximation in Fig 8 versus “Num (Original)” as a reference.

3.3 Case 3

Case 3, as previously stated, is intended to be a more aggressive version of Case 1. What we are interested in here is how the approximations behave with a reduced duration of manoeuvre and with higher driving forces. The approximate analytical solution for the vertical actuation problem is as follows.

$$\begin{aligned}
 \alpha(t) \approx & -883.29 - 0.0011043e^{-0.16993t} + 0.0059833e^{-0.13595t} - 0.011665e^{-0.10196t} \\
 & + 0.035894e^{-0.067974t} + 882.69e^{-0.033987t} + 0.26223e^{-0.033987t} \\
 & + 30.012t - 1.8765 \times 10^{-4}te^{-0.13595t} + 8.7596 \times 10^{-4}te^{-0.10196t} - 5.6412 \times 10^{-4}te^{-0.067974t} \\
 & - 0.0010491te^{-0.033987t} \\
 & - 1.9138 \times 10^{-4}t^2 - 1.2755 \times 10^{-5}t^2e^{-0.10196t} + 5.7412 \times 10^{-5}t^2e^{-0.067974t} \\
 & - 7.6558 \times 10^{-5}t^2e^{-0.033987t} \\
 & + 1.7344 \times 10^{-6}t^3 - 4.3351 \times 10^{-7}t^3e^{-0.067974t} + 8.6763 \times 10^{-7}t^3e^{-0.033987t} \\
 & - 7.3669 \times 10^{-9}t^4 - 1.4734 \times 10^{-8}t^4e^{-0.033987t}
 \end{aligned} \tag{19}$$

Figure 10: Approximate solutions of the vertical problem for Case 3. Note the operational limits of α marked at ± 0.305 .

Figure 11: The absolute error for each approximation in Fig 10 versus “Num (Original)”.

We see, for the vertical problem, that the resulting errors are all extremely small as in previous results. Note that the only difference in this case is that the numerical solution of the fully linearised problem is now lower than the approximate analytical solution. The errors depicted here are so low, however, that we are not concerned with this subtle change.

Interestingly, the horizontal results are very similar to those of Case 1 too. This reinforces the idea that these errors can be reduced by a higher-order approximation in the TAC step – since the accuracy of this step is dependent on the physical range, in β , of the manoeuvre rather than on its duration directly. The analytical approximation for this is found to be as follows.

$$\begin{aligned}
 \beta(t) \approx & 1.0472 + 0.40710t^2 - 0.0025948t^3 - 0.021092t^4 \\
 & + 0.0037226t^6 + 9.6805 \times 10^{-4}t^8 - 1.6916 \times 10^{-4}t^{10}
 \end{aligned} \tag{20}$$

Figure 12: Approximate solutions of the horizontal problem for Case 3. Note the operational limits of β at $\frac{\pi}{3}$ and $\frac{2\pi}{3}$.

Figure 13: The absolute error for each approximation in Fig 12 versus “Num (Original)”.

3.4 Case 4

For Case 4, both vertical and horizontal actuation problems give very similar results to Case 3. The approximate analytical solution for the vertical actuation problem for Case 4 is equal to that of Case 3 multiplied by (-1) ; whereas, the horizontal problem is

$$\begin{aligned} \beta(t) \approx & 2.0944 - 0.40710t^2 + 0.0025948t^3 + 0.021092t^4 \\ & - 0.0037226t^6 - 9.6805 \times 10^{-4}t^8 + 1.6916 \times 10^{-4}t^{10} \end{aligned} \quad (21)$$

where the constant term is the value of the initial β -condition for Case 4 and the rest of the approximation is identical to that of Case 3 multiplied by (-1) .

Figure 14: Approximate solutions of the vertical problem for Case 4. Note the operational limits of α at ± 0.305 .

Figure 15: The absolute error for each approximation in Fig 14 versus “Num (Original)”.

Figure 16: Approximate solutions of the horizontal problem for Case 4. Note the operational limits of β at $\frac{\pi}{3}$ and $\frac{2\pi}{3}$.

Figure 17: The absolute error for each approximation in Fig 16 versus “Num (Original)”.

From the graphs illustrating the absolute errors in the horizontal problems for Cases 1 and 2, all errors are less than the β tolerance value (1.8×10^{-4} radians) up to 0.7 seconds. And, for Cases 3 and 4, all errors are less than this value up to 0.25 seconds. Through all of the examined cases, the error in α is below 5×10^{-5} radians throughout the time domains - well within the previously stated tolerance of 3×10^{-4} radians. These observations can be used to show that the linearisation algorithm supports the requirement of submillimetre accuracy in end-effector placement – particularly given the sharp, abrupt motions involved in manoeuvring a workpiece through the active forge.

4 Conclusion and Comments for Continuing Work

In this work, we have presented an algorithm for the linearisation of the governing dynamics of a large-scale industrial manipulator. The manipulator - as part of the *FutureForge* project commissioned by the AFRC - has a unique design that rules-out many established techniques which are designed around serial or parallel manipulators. Previous work led to the derivation of the nonlinear governing equations we have considered, and continuing collaboration with our industrial partners will see the presented algorithm undergo further fine-tuning. The presented algorithm sees a small perturbation parameter, ε , introduced to the governing dynamics via the relative magnitude of the constant coefficients. Then, the transcendental terms are approximated via algebraic expressions using appropriately ordered Taylor Series expansions. Observations about the machine's practical operations are then made to remove the restoring forces from consideration at all levels of the resulting perturbation problems. We then inspected the results achieved by comparing our approximate analytical solutions against numerical solutions to the original, nonlinear governing dynamics. By comparison with these numerical solutions, we also illustrated the errors introduced at the TAC stage and at the conclusion of the linearisation process. We found that the approximate analytical solutions for the vertical actuation problem are well-within the acceptable range of accuracy for the context of our work. The errors found in the horizontal actuation problem are notably larger, but these may still be acceptable pending comparison with physical test data from our industrial collaborators. In the instance that they are above the acceptable limits of error, we have noted suitable courses of action in Section 3.

Going forward, we are actively seeking to compare our simulations against the physical test data gathered by our industrial collaborators. In parallel with this, we are in the process of designing a suitable, robust control system for implementation in the digital twin model of this manipulator.

Acknowledgements. We wish to acknowledge the work of Clansman Dynamics Ltd (based in East Kilbride, Scotland) in constructing the *FutureForge* manipulator on behalf of the AFRC and for providing the necessary design specifications so that we could carry out our own work. We also acknowledge the funding contribution provided by Clansman Dynamics Ltd to the PhD studentship of D. Johnston. Additionally, V. Pakrashi would like to acknowledge Science Foundation Ireland Centre I-FORM.

Towards a simple calibration of a scour-depth sensor

Mohamed Belmokhtar*, Franziska Schmidt *, Christophe Chevalier *, Alireza Ture Savadkoohi† and Claude Henri Lamarque †

* Univ Paris Est, IFSTTAR, Champs-sur-Marne, France

† Univ Lyon, ENTPE, LTDS, CNRS UMR 5513, France

Summary. This extended abstract presents an innovative method for scour monitoring, based on the dynamic response of a bridge pile embedded in the riverbed. Apart from the mechanical and physical characteristics of the pile itself, soil-structure interaction (SSI) affects the dynamical behaviour of the system. This may result in a sensibility of the eigenfrequencies of the pile to soil conditions. As a consequence, analytical and numerical developments are carried out for an Euler-Bernoulli beam model (representing the pile), which is embedded in a Pasternak soil (springs with a shear layer) for SSI. Using Hamilton's Principle and endowing the non-linear boundary conditions, system frequencies are derived by seeking for non-trivial roots of the characteristic equation of the system.

Introduction

A majority of bridge collapses are due to hydraulic risks [1], among which scour. Today, several scour monitoring techniques exist [2], as for example:

- Water depth-measuring devices,
- Analyzing changes in dynamic behavior of structural elements (bridge pier or instrumented rod).

In this study, we will consider both technologies in order to characterize scour.

Evaluation of natural frequencies of the system

Let us consider an Euler-Bernoulli Beam partially embedded in a Pasternak-modelled Soil [3] (see Fig. 1): Hamilton's principle with specific boundary conditions leads us to a non-linear formulation. In fact, because of the external environment change, the formulation makes us deal with non-linear boundary conditions, in particular at the end of the pile in the soil.

In our investigation, we treat the general nonlinear problem in two sets of linear problems with two constitutive dynamical equations:

- An equation for the free part of the beam $x < 0$:

$$EI \frac{\partial^4 v}{\partial x^4}(x, t) + \rho A \frac{\partial^2 v}{\partial t^2}(x, t) = 0,$$

- and an equation for the embedded part of the beam $x > 0$:

$$EI \frac{\partial^4 v}{\partial x^4}(x, t) - g \frac{\partial^2 v}{\partial x^2}(x, t) + kv(x, t) + \rho A \frac{\partial^2 v}{\partial t^2}(x, t) = 0.$$

Figure 1: Mathematical model of the considered system.

In our study, we focus on the modal analysis of the structure. Then, using modal projection and by solving equation of eigenfrequencies numerically (Newton method), the response of frequency as a function of scour depth is plotted. This response is also compared with finite difference method. The first step of our investigation permits us to see that reaching to correct numerical results can be elaborating for being sure that the system is not attracted by another root. Even if it converges, this method may be long.

Equivalent cantilevered beam of the system

The straightforward method of the previous section is costly. When we plot the natural frequency as a function of scour-depth (Fig. 2), variations are similar to a behaviour of cantilevered beam of a given length. This observation results in the development of the concept of added free length " ϵ " in the cantilevered beam (see Fig. 3): an equivalent length can be defined.

This means that we can include a modification of the length, adding " ϵ ", to have the same frequency.

Figure 2: Variation of the first frequency with the normalized free length

The next step in our investigation is to introduce analytically this equivalent length to fix the same eigenfrequencies for the scour-depth sensor of a given length: this equivalent length can be obtained as a result of an asymptotic approach of the non-trivial function of which natural frequencies are solutions. The precision of this method depends on the depth of foundation and a coefficient which is linked to the SSI.

Figure 3: Equivalent cantilevered beam

Conclusions

Comparison between our analytical and numerical model and experimental results [4] are carried out to obtain the validation of the equivalent length as parameters of an inverse problem. It is shown that for deep foundations where the flexural rigidity of the beam is higher than the soil rigidity, the analytical model matches with the experimental results: depth sensor measures accurately the progression of scour depth. In the other case, non-linearities can no longer be treated with this method: the soil reaction itself has a nonlinear behavior.

Transient deformation of a beam travelling on a moving rough surface

Yury Vetyukov* and Jakob Scheidl*

**Institute of Mechanics and Mechatronics, TU Wien, Vienna, Austria*

Summary. In this paper we study the quasi-static deformation of a beam pressed against a moving rough surface by the field of gravity. While the beam is transported in the axial direction together with the travelling foundation, it deforms and slides in the lateral direction because of the misaligned linear bearings at the boundaries of the control domain. Considering small deflections and a geometrically linear beam model, we present a numerical approach to analyse the time evolution of the deformed state of the beam. Analytical solutions are obtained for several specific cases of the boundary conditions and validated against the numerical results.

Introduction

Lateral deformation of axially moving slender structures with frictional contact is usually undesired in technical applications such as rolling mills [1] or transport belts [2, 3]. The highly nonlinear frictional response encountered in these problems induces dynamical behaviour even at slow quasi-static motion, when inertial effects are negligible. Numerical simulation tools, created to investigate the mechanics or to develop a model-based controller design, rely on the mathematical models of moving contact of deformable bodies at non-material kinematic description. Simplified semi-analytical approaches allow, however, to better understand the nature of the arising phenomena and to validate the complicated numerical schemes. Thus, an analytical study of the motion of an endless beam, transported by a moving rough surface across a control domain, has been presented in [4]. The beam is forced to enter the control domain and to leave it through a pair of linear bearings, which are laterally misaligned relative to each other. The analysis shows, that, as long as the misalignment is small and the maximal friction force is sufficiently large, the stationary deformed configuration of the beam becomes self-similar with infinitely many segments of sliding friction in alternating directions.

It should be noted, that the time evolution of the deformation of the beam on a rough foundation because of the bending moment on a free end has been thoroughly analysed earlier in [5], where the appearance of self-similar solutions was demonstrated as well. A similar formulation with thermally induced bending moments and self-similar deformation pattern studied in [6] relates to the cool down of railway rails after hot rolling. Nevertheless, the presently considered moving contact problem with transport conditions is a novel formulation, described by a different mathematical model.

Problem formulation

In the present paper we extend the results of [4] by investigating the transient deformation of the beam owing to a given law of the lateral motion of the bearing at the entry to the control domain. The model problem is depicted in Fig. 1. The linear bearings, which constrain the motion of the beam at the boundaries, are considered as prismatic joints, such that the deflection w takes on given values and the slope vanishes there, $w' = 0$. The joint at the entry moves in lateral direction over time t according to a given law $w_0(t)$. Under the condition of perfect adhesion, the beam would be transported along the axial coordinate x with the velocity v of the travelling foundation and its deformed shape would become

$$w(x, t) = w_0(t - x/v). \quad (1)$$

However, the boundary conditions at the exit prismatic joint and the bending stiffness of the beam trigger sliding, thus creating a system with a non-trivial dynamic behaviour.

In the geometrically linear setting, small lateral deflections do not affect the axial velocity of a particle of the beam, which thus always coincides with the transport speed $\dot{x} = v$. The lateral component of the velocity of a particle

$$\dot{w}(x, t) = \partial_t w + v w' \quad (2)$$

comprises the local (Eulerian) time derivative $\partial_t w$, computed at a given axial position $x = \text{const}$, and a convective term featuring the derivative with the spatial coordinate $w' = \partial_x w$. The relative velocity \dot{w} between the particle and the foundation determines the Coulomb's dry friction force q according to

$$\dot{w} > 0 : q = -q_0, \quad \dot{w} = 0 : -q_0 < q < q_0, \quad \dot{w} < 0 : q = q_0 \quad (3)$$

Figure 1: Flexible beam transported across a control domain by a moving rough surface: 3D perspective and view from above

Figure 2: Time evolution of the segments of sliding (gray areas), parameters: $a = 1$, $q_0 = 1$, $v = 1$, unit length of the control domain; left: linear growth with $\bar{w}_0 = 1/300$ and $t_0 = 0.2$; right: harmonic excitation at the entry with $w_0 = \sin(4\pi t)/300$

with q_0 being the sliding friction force, which bounds the static friction force. Now we demand that the beam is in static equilibrium at all times:

$$aw'''' = q \quad (4)$$

with a denoting the bending stiffness of the beam. Complemented with specific boundary conditions, the equations determine the time evolution of the zones of stick and sliding friction as well as the motion of the beam.

Discussion of the solution strategies

The main difficulty in obtaining the solution in terms of $w(x, t)$ and $q(x, t)$ is that the nonlinear equations cannot be resolved for the time derivative $\partial_t w$, which would otherwise facilitate the direct time integration of the evolution law. A regularization with a small inertial term and second-order time derivative would prohibit an analytical solution and require a computationally costly numerical time integration with small time steps. The above outlined quasi-static problem may be tackled numerically in a very efficient manner using the non-material finite element formulation with the transport condition for the deflection field as discussed in [4].

While the stationary solution with $\partial_t w = 0$ in case of constant deflections at the boundaries of the control domain is extensively analysed in [4], the present study focuses on the transient behaviour in response to two distinct cases of the imposed deflection at the entry $w_0(t)$:

- Linear growth followed by constant deflection:

$$w_0 = \begin{cases} \bar{w}_0 t / t_0, & t < t_0 \\ \bar{w}_0, & t \geq t_0 \end{cases} \quad (5)$$

Sliding is inevitable during the growth stage $t < t_0$, as the boundary condition $w' = 0$ at $x = 0$ contradicts the full adhesion solution (1). One expects, that a "wave" of the length vt_0 shall be transported by the travelling foundation until it reaches the exit prismatic joint. However, a more complicated process with reverse sliding is suggested by numerical analysis at higher values of the amplitude \bar{w}_0 , see left part of Fig. 2. The stationary solution with alternating segments of sliding friction and a self-similar deformed configuration establishes over time during the subsequent transient stage.

- Harmonic excitation:

$$w_0 = \bar{w}_0 \sin \omega t. \quad (6)$$

As long as the amplitude \bar{w}_0 is small, sliding shall again take place only in the vicinity of the entry point. The length of the segment of sliding shall change in time according to a complicated law, which can approximately be established in an analytical solution. Numerical analysis suggests, however, that higher values of \bar{w}_0 result into more segments of sliding near the entry point, see right part of Fig. 2. Finding an estimate for the critical value of the amplitude, at which the solution changes qualitatively, is a challenging mathematical task.

Influence of Gyroscopic Effects on Nonlinear Dynamics of High-Speed Planetary Gears Having an Elastic Ring

Chenxin Wang and Robert G. Parker

Department of Mechanical Engineering, University of Utah, Salt Lake City, UT 84112, USA

Summary. Numerical simulations show that gyroscopic effects can significantly influence the nonlinear dynamics (resonances and parametric instabilities) of planetary gears having a deformable ring at high speed. Analytical solutions at resonances and parametric instabilities that include the gyroscopic effects are derived and used to explain the numerical results.

Introduction

Vibrations of planetary gears arise primarily from periodically changing sun-planet and ring-planet tooth mesh excitation as the gears rotate. A resonance occurs when a harmonic L of the mesh frequency Ω_m approaches a natural frequency ω_q (i.e., $L\Omega_m \approx \omega_q$). A parametric instability occurs when $L\Omega_m \approx \omega_p + \omega_q$, where ω_p and ω_q can be the same. Near resonances or parametric instabilities, vibrations can become large enough that nonlinear tooth separation occurs. The ring has substantial elastic deformation when it is designed to be thin for weight saving. Gyroscopic (i.e., Coriolis) effects become significant for high-speed systems, but their influence on the nonlinear dynamics of planetary gears having an elastic ring are not yet known.

This work derives closed-form solutions for the nonlinear dynamics of planetary gears with a deformable ring using the model in [1]. The model includes speed-dependent gyroscopic and centripetal effects. The tooth mesh excitation is modeled as time-varying stiffnesses that include tooth separation nonlinearity. Numerical integration of the dynamic model shows the significant impact of gyroscopic effects on the resonances and parametric instabilities at high speed.

Numerical results

Fig. 1 shows the RMS of dynamic ring-planet mesh deflection from numerical integration of a planetary gear system having a deformable ring without (black dashed line) and with (green dotted line) gyroscopic effects. The differences highlight the significant influence of gyroscopic effects. One resonance ($\Omega_m \approx \omega_4$) and one parametric instability ($\Omega_m \approx \omega_1 + \omega_2$) are present for the system without gyroscopic effects. When gyroscopic effects are included, an additional resonance at $\Omega_m \approx \omega_3$ occurs. For the resonance $\Omega_m \approx \omega_4$, the peak amplitude decreases and the peak resonant frequency shifts to the right with inclusion of gyroscopic effects. The parametric instability $\Omega_m \approx \omega_1 + \omega_2$ is absent for the system with gyroscopic effects.

Figure 1: RMS (mean removed) values of dimensionless ring-planet mesh deflection from numerical integration of a planetary gear system having a deformable ring without (black dashed line) and with (green dotted line) gyroscopic effects over a range of dimensionless mesh frequencies. These RMS results are identical for every planet. The arrows indicate results from increasing and decreasing speed simulations. The thick (red) and thin (blue) solid lines are the analytical results from Eq. (1) for the two resonances $\Omega_m \approx \omega_3$ and $\Omega_m \approx \omega_4$ and Eq. (3) for the one parametric instability $\Omega_m \approx \omega_1 + \omega_2$ for the system without and with gyroscopic effects.

Analytical explanation

Resonances

The amplitude-frequency relation for a resonance $L\Omega_m \approx \omega_q$ (whether the system is gyroscopic or not) is derived as

$$\Omega_m = \frac{\omega_q}{L} + \frac{\omega_q}{La_q} \left(2R_1 + R_2 a_q \pm \sqrt{4|R_3|^2 - (\nu_q a_q)^2} \right), \quad (1a)$$

$$R_3 = N \left(k_{s1}^{(L)} \bar{\Delta}_{s1}^{[q]} \Delta_{s,0} + k_{r1}^{(L)} \bar{\Delta}_{r1}^{[q]} \Delta_{r,0} \right), \quad (1b)$$

where a_q is the real-valued amplitude of the resonant mode, ν_q is the modal damping ratio, R_1 and R_2 are real-valued terms associated with tooth contact loss, N is the number of planets, $k_{j1}^{(L)}$ for $j = s, r$ are the L -th harmonic coefficients (complex-valued) of the first sun-planet and ring-planet mesh stiffness variations, $\Delta_{j,0}$ are the static sun-planet and ring-planet mesh deflections (real-valued and identical for every planet) due to the applied torque, $\Delta_{j1}^{[q]}$ are the first sun-planet and ring-planet modal mesh deflections (complex-valued), and the overbar denotes complex conjugate. Vanishing of the square root term in Eq. (1a) gives the peak resonant amplitude

$$a_{q,p} = 2|R_3|/\nu_q. \quad (2)$$

Eqs. (1b) and (2) explain why the resonance $\Omega_m \approx \omega_3$ does not occur for the system without gyroscopic effects but occurs for the system with them (Fig. 1). In the absence of gyroscopic effects, mode 3 is a mode where the modal sun-planet and ring-planet mesh deflections vanish (i.e., $\Delta_{sn}^{[3]} = \Delta_{rn}^{[3]} = 0$ for $n = 1, 2, \dots, N$) [2], such that the R_3 for this mode and the peak amplitude $a_{3,p}$ in Eq. (2) vanish. When gyroscopic effects are included, mode 3 becomes a mode with nonzero $\Delta_{sn}^{[3]}$ and $\Delta_{rn}^{[3]}$ [3]. This leads to nonzero R_3 in Eq. (1b) and nonzero $a_{3,p}$ in Eq. (2) and therefore the occurrence of the resonance $\Omega_m \approx \omega_3$ for the system with gyroscopic effects in Fig. 1.

Eq. (1) shows that gyroscopic effects shift the resonant frequencies by changing the natural frequencies. The ω_4 increases when gyroscopic effects are included, so the resonant frequency for $\Omega_m \approx \omega_4$ shifts to the right. This prediction matches the numerical results in Fig. 1.

Eqs. (1b) and (2) reveal that gyroscopic effects affect the peak amplitudes of resonances by changing vibration mode quantities. Gyroscopic effects change the modal mesh deflections $\Delta_{sn}^{[4]}$ and $\Delta_{rn}^{[4]}$. At high speed, this change is significant. This alters the values of R_3 in Eq. (1b). R_3 changes significantly for mode 4, which affects the associated peak amplitude $a_{4,p}$. As shown in Fig. 1, the analytical predictions capture this effect.

Parametric instabilities

The boundaries of the range of mesh frequencies for a parametric instability $L\Omega_m \approx \omega_p + \omega_q$ to occur are derived as

$$\Omega_m^{\{L,p,q\}} = \frac{(\omega_p + \omega_q)}{L} \pm \frac{\nu_p\omega_p + \nu_q\omega_q}{L} \sqrt{|D_{pq}^{(L)}|^2/(\nu_p\nu_q) - 1}, \quad (3a)$$

$$D_{pq}^{(L)} = N(k_{r1}^{(L)}\bar{\Delta}_{r1}^{[p]}\bar{\Delta}_{r1}^{[q]} + k_{s1}^{(L)}\bar{\Delta}_{s1}^{[p]}\bar{\Delta}_{s1}^{[q]}). \quad (3b)$$

Eq. (3a) gives that a parametric instability is eliminated by damping when

$$|D_{pq}^{(L)}| < \sqrt{\nu_p\nu_q}. \quad (4)$$

Eqs. (3) and (4) apply to both non-gyroscopic and gyroscopic planetary gears having a deformable ring.

Eqs. (3b) and (4) show that gyroscopic effects change the occurrence of a parametric instability by changing modal mesh deflections. The parametric instability $\Omega_m \approx \omega_1 + \omega_2$ for the system without gyroscopic effects has $|D_{1,2}^{(1)}| = 0.0211 > \sqrt{\nu_1\nu_2} = 0.02$. Therefore, this parametric instability is present in Fig. 1. When gyroscopic effects are included, the modal mesh deflections $\Delta_{j1}^{[1]}$ and $\Delta_{j1}^{[2]}$ for $j = s, r$ change so that $|D_{1,2}^{(1)}|$ decreases (see Eq. (3b)). This leads to $|D_{1,2}^{(1)}| = 0.0172 < \sqrt{\nu_1\nu_2} = 0.02$. The parametric instability $\Omega_m \approx \omega_1 + \omega_2$ is absent in Fig. 1 in the presence of gyroscopic effects.

Conclusions

Gyroscopic effects alter the occurrence of resonances, shift resonant frequencies, and change resonant amplitudes associated with nonlinear behavior induced by contact loss. These influences are significant for high-speed planetary gears having an elastic ring. A closed-form amplitude-frequency relation derived for the resonances of planetary gears without and with gyroscopic effects reveal how these effects change the resonant behavior by their influence on the natural frequencies and vibration modes. For example, changes of modal mesh deflections of a resonant mode can change the resonant amplitude and, sometimes, change whether a resonance occurs or not.

The influence of gyroscopic effects on parametric instabilities of planetary gears having an elastic ring is similarly substantial. The analytical results reveal that gyroscopic effects change the occurrence/absence of parametric instabilities and the mesh frequency range where a given instability occurs. These effects arise principally from changes to the modal mesh deflections of the participating modes.

Summary. Several experimental investigations have shown that drilling processes are likely to develop limit cycles at approximately integer multiples of the tool rotation frequency. As a consequence, the whirling oscillations generate N-lobed holes. In literature, linear models are presented to explain the onset of the instability and to analyze the exponential growth or decay of this whirling phenomenon. However, to predict the orbit of the limit cycles, more involved models are required, which take the relevant nonlinearities into account [1,2,3]. This work deals with a nonlinear drilling model. The cutting forces involve the so-called regenerative effect, which leads to a delay differential equation (DDE). Nonlinear rubbing effects, which occur at the contact under the cutting edge, are considered. Also, the contact at the bore hole wall is taken into account and its stabilizing effect on the drilling process is shown. The presented drilling model is able to predict the bore hole shape as well as the circularity of a real drilling process with high accuracy. The model can be used to optimize the drilling parameters and the shape of the tool in order to improve real drilling processes.

Motivation

Basically, two phenomena are distinguished in cutting tool vibrations: (i) Chatter which appears approximately at the tools torsion natural frequency and (ii) lateral oscillations at odd multiples of the tool rotation frequency.

Currently, often two machining steps are necessary to create bore holes with high precision: Drilling and finishing afterwards, for example by reaming, to reach the required accuracy.

To analyze and clearly understand the physical effects occurring in drilling processes and to optimize these processes (i.e. reducing the amplitudes of the lateral oscillations by optimization of the tool shape and cutting parameters), a nonlinear two degree of freedom model is applied in the current work. The model yields a system of coupled delay differential equations, which is solved numerically.

Physical Model

The drilling model includes the mass, structural damping and stiffness of the tool as well as external forces due to the contact with the workpiece. The external forces consist of the cutting force, the rubbing force and the contact force at the bore hole wall.

The cutting force is assumed to be proportional to the uncut chip area and obtained experimentally similar to an experimental setup introduced by Bayly *et al.* [1]. Since the uncut chip area depends on the current position of the tool and the position at the previous cutting-edge passage, a time delay is generated in the differential equations.

Rubbing occurs due to material compression under the cutting edge. Chiou and Liang [4] suggested a linear rubbing force model for turning processes. Their approach is extended to a nonlinear model and adapted to oblique cutting, which leads to a dependence on the feed rate, cutting velocity, current tool vibrations and tool wear.

Previous experimental investigations by Volz *et al.* [3] have shown a strong correlation between the land width of the tool, which supports it against the bore hole surface, and the amplitude of the lateral oscillations. Therefore, a model for the wall contact is introduced. On one hand, this contact model takes elastic effects into account. On the other hand, a nonlinear damper - similar to the rubbing force model - is integrated, which incorporates the energy dissipation in the contact.

Experimental Investigations

The cutting force model is based on experimental data. The drilling tests were conducted in aluminum alloy (AlSi7Mg0.3) using a 10 mm diameter sold carbide twisted drill with four lands, a TiAlN top coating and a ZrN deck layer. Since the uncut chip area increases linearly with the feed rate, cutting force tests with different feed rates were performed. The measured cutting forces are plotted over the corresponding uncut chip areas and the slope of this plot yields the approximately linear relation of the change in force per change in uncut chip area. In the numerical simulations, this slope is used as proportionality factor to calculate the cutting force on cutting lip segments with the aid of the current and the delayed tool position.

Simulation

The DDE is discretized with an implicit integration scheme, namely with a variable-step size, variable-order BDF solver. In order to handle the time delay, the following strategy has been applied.

The simulation time is split into equal intervals, where the interval length corresponds to the time delay. In each interval the simulation results (displacements and velocities) from the previous interval are known and used to take the delay part in the equations of motion into account, which may then be interpreted as an external time function. The problem is

the initialization of the simulation, because the initial conditions must be known as a function of time over one delay period. Therefore, the simulation is firstly started with the trivial solution of the DDE. In a second step, a rectangular-shaped external force is applied in order to initialize the lateral vibrations.

Results and Conclusions

In the simulations, the contact stiffness parameters used in the bore hole wall contact model as well as for the rubbing force model are adopted from a turning test presented by *Chiou and Liang* [4]; the parameters have been slightly modified and adapted to fit the drilling process. The feed rate, cutting velocity and pre-hole diameter are varied and the damping is increased successively to describe the behavior of chip flow and coolant water in the drilling process. The damping has no significant influence on the amplitude of the appearing limit cycles, but on the frequency of the oscillation and therefore on the bore hole shape.

A comparison between a simulation and measurements is depicted in *Figure 1*. In this case, the ratio between the limit cycle frequency and the tool rotational frequency is approximately three. A transformation from the tool tip movement to the outer cutting edges represent the emerging bore hole contour as a three-lobed hole. The shape and magnitude of the simulated bore holes (blue) show a high accordance with the experimental results (red) with respect to the circularity. For a better visualization, the plot is stretched by the factor 41 around the gauss circle of the simulated data (black solid line). The drilling experiments have been carried out with a pre-hole diameter of 4 mm. Note that the circularity is defined as radial distance between the outermost (outer blue dashed line) and innermost (inner blue dashed line) circles.

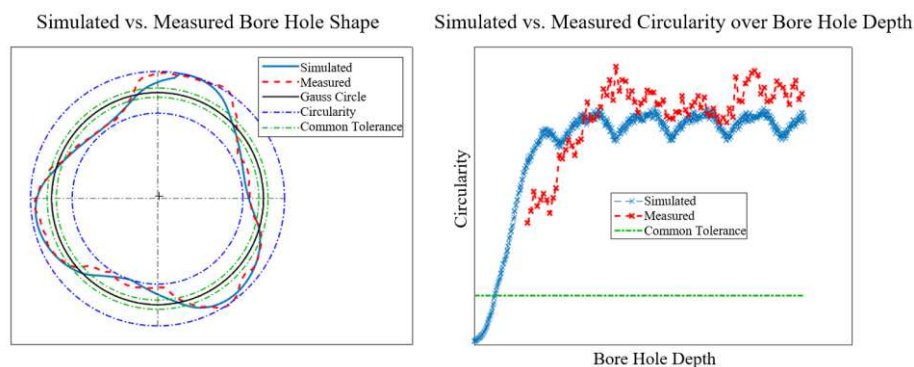

Figure 1: Left: Simulated (blue) vs. measured (red) bore hole shape at a specific bore hole depth. Right: Simulated (blue) vs. measured (red) circularity over bore hole depth and a common tolerance for drilling processes (green).

Summarizing: The presented drilling model is able to predict the circularity of drilling processes with a special consideration of lateral oscillations of the drilling tool tip. Within the validation of the implemented model, a high agreement of the results from the simulation with those from the machining tests could be achieved.

In a following step, a great range of parameter studies, including the cutting parameters and the shape of the tool, can be conducted with the numerical model to identify the most important parameters for improving the drilling process. Possibly the process can be optimized to reach a specified tolerance without an additional reaming step.

A Koopman View on the Harmonic Balance and Hill Method

Fabia Bayer* and Remco I. Leine*

**Institute for Nonlinear Mechanics, University of Stuttgart, Germany*

Summary. The Koopman operator provides a way to approximate the dynamics of a nonlinear system by a linear time-invariant system of higher order. In this paper, we aim to study nonlinear time-periodic systems and propose a specific choice of Koopman basis functions combining the Taylor and Fourier bases. This basis allows to recover all equations necessary to perform the Harmonic Balance Method as well as the Hill analysis directly from the linear lifted dynamics. The Mathieu equation and a more general Hill equation are used to exemplify these findings.

Introduction

In the recent years, the Koopman framework and especially its data-driven counterpart, the Extended Dynamic Mode Decomposition, have gained immense popularity [10, 3, 11, 7, 2]. This is due to its auspicious promise: Global representation of a nonlinear system by a linear operator. To this end, in the Koopman framework, the dynamical system is defined through the propagation of functions on the state space, also called observables, over time. While the corresponding operator is linear in its argument, the considered function spaces are usually infinite-dimensional. Therefore, in practice, a linear approximation is considered which is restricted to a finite-dimensional space spanned by a finite number of predefined basis functions. It is well-known that the approximation quality of this restriction strongly depends on the choice of basis functions.

Classically, the Koopman framework is applied to time-autonomous systems $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x})$ and the approximate linear dynamics obtained by the Koopman lift then takes the form $\dot{\mathbf{z}} = \mathbf{A}\mathbf{z}$. The incorporation of a time-dependent input $\mathbf{v}(t)$ into the dynamics, i.e. $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{v}(t))$ or simply $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, t)$, generally poses problems in the Koopman framework as the system can only be approximated by a linear time-variant system $\dot{\mathbf{z}} = \mathbf{A}\mathbf{z} + \mathbf{B}\mathbf{u}(t)$ if products of state and input are neglected.

In this paper we focus on nonautonomous systems for which the input is time-periodic, i.e. $\mathbf{v}(t) = \mathbf{v}(t + T)$. In particular, we propose a specific choice of observable functions which contains observables depending both on state and time. We demonstrate that this representation contains all frequency information of the system up to some chosen frequency order N_u . This means that this basis is a good choice for a Koopman lift, as it retains structural information.

After a short overview about Koopman theory, the specific periodic basis is introduced together with a matching inner product. It is demonstrated how all equations necessary for the Harmonic Balance Method as well as the Hill method follow from the Koopman lift in these specific observables. This means that the (approximate) stability information for the system is retained in the Koopman lift. The findings are illustrated using two variants of the Hill equation.

Koopman theory overview

Consider a nonautonomous time-periodic finite-dimensional dynamical system governed by $\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, t)$, where $t \in \mathbb{R}$ is the time, $\mathbf{x}(t) \in \mathcal{X} \subseteq \mathbb{R}^n$ is the state trajectory starting at $\mathbf{x}(t_0) = \mathbf{x}_0$ and $\mathbf{f} : \mathcal{X} \times \mathbb{R} \rightarrow \mathcal{X}$ is a smooth vector field which is T -periodic in t . The family of maps $\phi_t(\mathbf{x}_0, t_0) = \mathbf{x}(t)$ characterizes the flow of the system and assigns to each (initial) configuration (\mathbf{x}_0, t_0) the resulting state after time t has passed.

The Koopman framework [10] considers output functions $g(\mathbf{x}, t)$, also called observables. Any spaces of functions over the complex or real numbers are permitted in the general Koopman framework. In this work, we consider in particular the space \mathcal{F} of complex-valued functions $g : \mathcal{X} \times \mathbb{R} \rightarrow \mathbb{C}$ which are real analytic on \mathcal{X} and T -periodic in the last argument t . Given any function g , it may be of interest how its function values evolve along the trajectories of the system. For instance, in the Lyapunov framework, it is desired that function values of a Lyapunov candidate decrease over time for any starting point. The operator $K^t : \mathcal{F} \rightarrow \mathcal{F}; g \mapsto g \circ \phi_t$ performs this shift along the trajectory for arbitrary functions g from the considered function space. The family of all these operators for any t is called the Koopman semigroup of operators.

It is easy to see that for suitable \mathcal{F} , this Koopman semigroup contains all information about the system without explicitly knowing the vector field \mathbf{f} or the flow ϕ_t . In particular, if \mathcal{F} is chosen such that the identity function id is contained in the vector space, then the flow can be recovered easily by simply evaluating $K^t(\text{id})$. As a trivial counterexample, consider the one-dimensional vector space of constant functions. Any constant function will not change while being evaluated along an arbitrary trajectory of \mathbf{x} . Therefore, in this case, the Koopman operator semigroup is well-defined, albeit trivial. No information about the underlying system is retained. This example shows that an appropriate choice of function space is a crucial part of the Koopman framework.

Under the aforementioned assumptions for the particular function space \mathcal{F} and the vector field \mathbf{f} , there also exists the operator $L : \mathcal{F} \rightarrow \mathcal{F}, g \mapsto \dot{g}$ mapping an observable g to its total time derivative \dot{g} with

$$\dot{g}(\mathbf{x}, t) = \frac{\partial g(\mathbf{x}, t)}{\partial \mathbf{x}} \mathbf{f}(\mathbf{x}, t) + \frac{\partial g(\mathbf{x}, t)}{\partial t}. \quad (1)$$

This operator is called the infinitesimal Koopman generator. Again, for suitable \mathcal{F} , this representation alone is a sufficient way to describe the behavior of the dynamical system. In particular, if $\text{id} \in \mathcal{F}$, the vector field \mathbf{f} is easily recovered. In addition, the Koopman generator and the Koopman semigroup of operators are linear in the argument g , even if the governing differential equation is nonlinear. This comes at the cost of dealing with a mapping on an (infinite-dimensional) function space instead of the (finite-dimensional) state space.

On a finite-dimensional subspace $\mathcal{F}_{\hat{N}} \subset \mathcal{F}$ spanned by \hat{N} linearly independent basis functions $\{\psi_l\}_{l=1}^{\hat{N}}$, any projection $\Pi_{\hat{N}} : \mathcal{F} \rightarrow \mathcal{F}_{\hat{N}}$ defines a finite-dimensional approximation $\hat{L} : \mathcal{F}_{\hat{N}} \rightarrow \mathcal{F}_{\hat{N}}$ of L on $\mathcal{F}_{\hat{N}}$ by $L_{\hat{N}} := \Pi_{\hat{N}} L$. The approximation process and the subsequent approximation error are visualized in Figure 1. As the subspace $\mathcal{F}_{\hat{N}}$ generally is not closed w.r.t. L , the result of Lg must be projected back to $\mathcal{F}_{\hat{N}}$, introducing some approximation error. Again, the choice of basis functions for $\mathcal{F}_{\hat{N}}$ is crucial. Since $\mathcal{F}_{\hat{N}}$ is finite-dimensional, elements of $\mathcal{F}_{\hat{N}}$ can be represented by a

Figure 1: Schematic drawing of the infinitesimal Koopman generator L , its finite-dimensional approximation $L_{\hat{N}}$ and the matrix representation $\hat{\mathbf{A}}$.

column vector of coefficients $\hat{\mathbf{z}} \in \mathbb{C}^{\hat{N}}$. In Figure 1, this is visualized by the map $\Gamma : \mathcal{F}_{\hat{N}} \rightarrow \mathbb{C}^{\hat{N}}$. This map can be extended to observables $g \in \mathcal{F} \setminus \mathcal{F}_{\hat{N}}$. In this case, the resulting vector $\hat{\mathbf{z}}$ represents $\Pi_{\hat{N}}g$, which is the projection of g onto $\mathcal{F}_{\hat{N}}$.

The matrix representation of $L_{\hat{N}}$ is $\hat{\mathbf{A}} \in \mathbb{C}^{\hat{N} \times \hat{N}}$ with $\Gamma L_{\hat{N}}g = \hat{\mathbf{A}}\Gamma g$. This matrix also defines a linear time-invariant autonomous differential equation, namely

$$\dot{\hat{\mathbf{z}}} = \hat{\mathbf{A}}\hat{\mathbf{z}}. \quad (2)$$

This linear system is called the Koopman lift and describes the dynamics represented in $L_{\hat{N}}$, i.e. it is a finite-dimensional linear approximation of the original system dynamics. The Koopman lift matrix $\hat{\mathbf{A}}$ can be derived from the original nonlinear dynamics manually by using a column vector $\Psi := (\psi_1, \dots, \psi_{\hat{N}})^T$ of the basis functions of $\mathcal{F}_{\hat{N}}$, computing $\frac{d\Psi}{dt}$ and identifying terms linear in elements of Ψ after applying the projection $\Pi_{\hat{N}}$. If this projection is orthonormal, the matrix entry $\hat{\mathbf{A}}_{i,j}$ at i -th row and j -th column is given by $\hat{\mathbf{A}}_{i,j} = \left\langle \frac{d\psi_i}{dt}, \psi_j \right\rangle$, where $\langle \cdot, \cdot \rangle$ denotes the corresponding inner product.

Koopman lift for time-periodic systems

For smooth autonomous systems in the Koopman framework, it is customary to consider as basis functions a finite set of monomials $\psi_{\beta}(\mathbf{x}) = \mathbf{x}^{\beta}$, where $\beta \in \mathbb{N}^n$ is a multi-index and standard multi-index calculation rules (see, for example, [14, p. 319]) apply. As time-periodic functions are considered in the presented case, we propose in this paper to include as basis functions combinations of polynomial terms as well as Fourier terms of the correct base frequency, i.e. basis functions of the form $\psi_{\beta,k} := \mathbf{x}^{\beta} e^{ik\omega t}$, where $\omega = \frac{2\pi}{T}$. The functions $\{\psi_{\beta,k} | k \in \mathbb{Z}, \beta \in \mathbb{N}^n\}$ are an orthonormal system within the initially considered vector space \mathcal{F} w.r.t. the inner product

$$\langle g, h \rangle := \int_0^T \left(\frac{1}{(\beta!)^2} \sum_{\beta \in \mathbb{N}^n} \frac{\partial^{\beta} g}{\partial \mathbf{x}^{\beta}} \Big|_{0,t} \frac{\partial^{\beta} \bar{h}}{\partial \mathbf{x}^{\beta}} \Big|_{0,t} \right) dt. \quad (3)$$

By slight abuse of notation, the inner product is extended to vector-valued functions $\mathbf{g} \in \mathcal{F}^l$, $\mathbf{h} \in \mathcal{F}^m$ element-wise via

$$\langle \mathbf{g}, \mathbf{h} \rangle := \begin{pmatrix} \langle g_1, h_1 \rangle & \dots & \langle g_1, h_m \rangle \\ \vdots & \ddots & \vdots \\ \langle g_l, h_1 \rangle & \dots & \langle g_l, h_m \rangle \end{pmatrix}. \quad (4)$$

Let $N_{\beta}, N_{\mathbf{z}}, N_{\mathbf{u}} \in \mathbb{N}$ be integers which describe the assumed maximum polynomial order of the state and maximum frequency order of the state and input, respectively. Let $\{\beta_l\}_{l=1}^{N_{\beta}}$ be a set of multi-indices with $\mathbf{0} \notin \{\beta_l\}_{l=1}^{N_{\beta}}$. For the

sake of brevity, define $N = N_\beta(2N_z + 1)$. Consider now the specific finite-dimensional subspace $\mathcal{F}_N \subset \mathcal{F}$ spanned by $\Psi = (\Psi_z^T, \mathbf{u}^T)^T$ with

$$\Psi_z(\mathbf{x}, t) := (\mathbf{x}^{\beta_1} e^{i\omega N_z t}, \dots, \mathbf{x}^{\beta_1} e^0, \dots, \mathbf{x}^{\beta_1} e^{-i\omega N_z t}, \mathbf{x}^{\beta_2} e^{i\omega N_z t}, \dots, \mathbf{x}^{\beta_{N_\beta}} e^{-i\omega N_z t})^T \quad (5)$$

$$\mathbf{u}(t) := (e^{-i\omega N_u t}, \dots, e^0, \dots, e^{i\omega N_u t})^T. \quad (6)$$

It is reasonable to include the state \mathbf{x} itself in the basis such that there is a selector matrix $\mathbf{C}_z \in \mathbb{R}^{n \times N}$ containing some rows of the identity matrix with $\mathbf{C}_z \Psi_z(\mathbf{x}, t) = \mathbf{x}$. There exist other options to recover \mathbf{x} if \mathbf{C}_z is allowed to be time-dependent. However, for the considerations of this paper, choosing \mathbf{C}_z to be constant is sufficient. Using the projection defined by the inner product (3), the Koopman lift approximation of the nonlinear system with respect to the basis Ψ is governed by

$$\dot{\mathbf{z}} := \begin{pmatrix} \dot{\mathbf{z}} \\ \dot{\mathbf{u}} \end{pmatrix} = \langle \dot{\Psi}, \Psi \rangle \hat{\mathbf{z}} = \begin{pmatrix} \langle \dot{\Psi}_z, \Psi_z \rangle & \langle \dot{\Psi}_z, \mathbf{u} \rangle \\ \langle \dot{\mathbf{u}}, \Psi_z \rangle & \langle \dot{\mathbf{u}}, \mathbf{u} \rangle \end{pmatrix} \begin{pmatrix} \mathbf{z} \\ \mathbf{u} \end{pmatrix} =: \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ * & * \end{pmatrix} \begin{pmatrix} \mathbf{z} \\ \mathbf{u} \end{pmatrix}, \quad (7)$$

where $\mathbf{A} \in \mathbb{C}^{N \times N}$ and $\mathbf{B} \in \mathbb{C}^{N \times (2N_u + 1)}$ are constant matrices. The dynamics of \mathbf{u} is approximated by the lower rows of the large matrix in (7). Since \mathbf{u} is state-independent and its time history in (6) is known a priori, the lower rows of (7) are superfluous and the original nonlinear system is approximated by the LTI system $\dot{\mathbf{z}} = \mathbf{A}\mathbf{z} + \mathbf{B}\mathbf{u}$.

Koopman-based Harmonic Balance Method

In the standard Harmonic Balance Method (HBM), a periodic solution is approximated by its Fourier expansion up to order N_u with unknown parameters via

$$\mathbf{x}_p(t) = \sum_{k=-N_u}^{N_u} \mathbf{p}_k e^{ik\omega t} =: \mathbf{P}_{\text{hb}} \mathbf{u} \quad (8)$$

with \mathbf{u} as in (6) and $\mathbf{P}_{\text{hb}} = (\mathbf{p}_{-N_u}, \dots, \mathbf{p}_{N_u})$. The coefficients \mathbf{p}_k are then determined by equating the Fourier expansions of $\frac{d\mathbf{x}_p}{dt}$ from the definition (8) and $\mathbf{f}(\mathbf{x}_p, t)$ for every order up to N_u . With $(2N_u + 1)$ frequencies considered in total, this results in a system of $n(2N_u + 1)$ equations for the coefficients in \mathbf{P}_{hb} . While the left-hand side of the equation as well as linear components of \mathbf{f} are easy to handle, the nonlinear components can usually not be expressed analytically. The individual equations for each order are thus usually determined and simultaneously solved using the fast Fourier transform with an alternating frequency and time (AFT) scheme for nonlinear components of \mathbf{f} [4]. However, the equations for each order can also be isolated by projecting onto the corresponding basis function from the collection in \mathbf{u} through the inner product (3). Hence, the HBM approximates a periodic solution by solving the $2N_u + 1$ equations collected in

$$\left\langle \frac{d\mathbf{x}_p}{dt}, \mathbf{u} \right\rangle = \left\langle \mathbf{f}(\mathbf{x}_p(\cdot), \cdot), \mathbf{u} \right\rangle. \quad (9)$$

With this notation, it is remarked that the numerically cumbersome task of calculating the Fourier coefficients of the nonlinear components of \mathbf{f} is hidden in the definition of the inner product.

For Koopman-based HBM, again, a periodic orbit with unknown coefficients as in (8) is assumed. Now, the dynamics of a perturbation around this periodic orbit is regarded, i.e. the shifted system with state $\mathbf{y} = \mathbf{x} - \mathbf{x}_p$ is considered. Analogously to the original system, the shifted system can be lifted using the methodology as introduced above. This Koopman lift is of the form (7), with the \mathbf{A} and \mathbf{B} matrices depending on the parameters \mathbf{p}_k . Now evaluating only those rows of \mathbf{z} which directly approximate the state $\mathbf{y} \approx \mathbf{C}_z \mathbf{z}$ and using the linearity of the infinitesimal Koopman generator yields

$$\dot{\mathbf{y}}(t) \approx \mathbf{C}_z \dot{\mathbf{z}}(t) = \mathbf{C}_z \mathbf{A} \mathbf{z}(t) + \mathbf{C}_z \mathbf{B} \mathbf{u}(t) = \mathbf{C}_z \mathbf{A} \mathbf{z}(t) + \left\langle \mathbf{f} - \frac{d\mathbf{x}_p}{dt}, \mathbf{u} \right\rangle \mathbf{u}(t). \quad (10)$$

As $\mathbf{z} = 0$ implies $\mathbf{y} = 0$ and thus $\mathbf{x} = \mathbf{x}_p$, we have to require that $\dot{\mathbf{y}} = 0$ in this case. As the rows of \mathbf{u} are linearly independent, it follows from (10) that all entries of the inner product, or equivalently of the matrix \mathbf{B} , must then be zero. Thus, by comparing (9) and (10), the HBM equations are exactly given by $\mathbf{C}_z \mathbf{B} = \mathbf{0}$ for the Koopman lift as introduced.

Stability Analysis

When a periodic orbit \mathbf{x}_p is found (via HBM or otherwise), the next interesting question is that of its stability properties; that is, whether trajectories that start sufficiently close to the periodic orbit will approach it, stay close to it or tend away from it with increasing time. To evaluate the stability properties, the dynamics of a perturbation $\mathbf{y} = \mathbf{x} - \mathbf{x}_p$ from the periodic solution is considered. Substitution of this definition into the original system yields

$$\dot{\mathbf{y}} = \mathbf{f}(\mathbf{x}_p + \mathbf{y}) - \dot{\mathbf{x}}_p := \mathbf{J}(t)\mathbf{y} + \mathcal{O}(\|\mathbf{y}\|^2), \quad (11)$$

where $\mathbf{J}(t) = \frac{\partial \mathbf{f}}{\partial \mathbf{x}}|_{t, \mathbf{x}_p(t)}$ is the system Jacobian. This system has an equilibrium at zero, which corresponds to the periodic orbit of the original system, and the stability analysis of the periodic orbit reduces to the stability analysis of this equilibrium. To make qualitative (stability/instability) statements around the origin, it is usually sufficient to discard higher-order terms and only regard the linearized time-varying perturbation equation $\dot{\mathbf{y}} = \mathbf{J}(t)\mathbf{y}$. This will be the convention for the remainder of this paper unless stated otherwise.

The fundamental solution matrix $\Phi(t)$ is the solution to the variational equation

$$\dot{\Phi}(t) = \mathbf{J}(t)\Phi(t); \quad \Phi(0) = \mathbf{I} \quad (12)$$

and any state can be obtained via $\mathbf{y}(t) = \Phi(t)\mathbf{y}_0$. In particular, the fundamental solution matrix $\Phi(T) := \Phi_T$ is called the monodromy matrix of the system and its eigenvalues $\{\lambda_k\}_{k=1}^n$ are called Floquet multipliers [15]. The Poincaré map $\mathbf{y}_{k+1} = \Phi_T \mathbf{y}_k$ provides snapshots for the evolution of the perturbation \mathbf{y} , spaced at a time distance of T . Therefore, stability analysis of the linear time-periodic system reduces to stability analysis of the Poincaré map. Hence, if all Floquet multipliers are of magnitude strictly less than one, the equilibrium of the LTV system and thus the periodic solution of the original system are stable; if at least one eigenvalue has a magnitude strictly larger than one, they are unstable.

Alternatively to the Floquet multipliers, the stability properties of a time-periodic linear system can be characterized by the Floquet exponents. In the linear system as above there exist n solutions $\mathbf{y}_k(t) = \mathbf{p}_k(t)e^{\alpha_k t}$, where \mathbf{p}_k is T -periodic [15]. Hence, stability is characterized by the real parts of the Floquet exponents $\{\alpha_k\}_{k=1}^n$. If at least one Floquet exponent lies in the open right half plane, i.e. if at least one real part is larger than zero, the equilibrium is unstable. These Floquet exponents are not uniquely defined. It is easy to see that if $\mathbf{p}_k(t), \alpha_k$ generate a solution $\mathbf{y}_k(t)$, the same solution is generated by $\tilde{\alpha}_k = \alpha_k + il\omega$ and $\tilde{\mathbf{p}}_k(t) = \mathbf{p}_k(t)e^{-il\omega t}$ with $l \in \mathbb{Z}$. Hence, in total, there are infinitely many valid Floquet exponents, which can be categorized into n distinct groups. As all entries of one group have the same real part, it is sufficient for stability analysis to know any one entry from each of the n groups.

Hill method

When a periodic orbit is determined using the purely time-domain-based shooting method, the monodromy matrix is a direct byproduct of the continuation method [13]. In this case, the numerically obtained monodromy matrix can be evaluated directly to obtain the Floquet multipliers and their stability information.

When the Harmonic Balance Method is computed in the standard way, however, stability information about the identified limit cycle is unclear without further investigation. The Hill method offers a frequency-domain-based way to approximate the Floquet exponents of the linearized perturbation equation.

The Floquet exponents are eigenvalues of the infinite Hill matrix \mathbf{H}_∞ [8], which is constructed from the Fourier coefficients of $\mathbf{J}(t) = \sum_{k=-\infty}^{\infty} \mathbf{J}_k e^{i\omega k t}$ and reads as

$$\mathbf{H}_\infty = \begin{pmatrix} \ddots & \vdots & \vdots & \vdots & \ddots \\ \dots & \mathbf{J}_0 + i\omega \mathbf{I} & \mathbf{J}_{-1} & \mathbf{J}_{-2} & \dots \\ \dots & \mathbf{J}_1 & \mathbf{J}_0 & \mathbf{J}_{-1} & \dots \\ \dots & \mathbf{J}_2 & \mathbf{J}_1 & \mathbf{J}_0 - i\omega \mathbf{I} & \dots \\ \ddots & \vdots & \vdots & \vdots & \ddots \end{pmatrix}. \quad (13)$$

This infinite-dimensional eigenproblem has infinitely many discrete eigenvalues. They correspond identically to the Floquet exponents $\tilde{\alpha}$ for all $l \in \mathbb{Z}$ as introduced above and can be sorted into n groups, where the entries of each group differ by multiples of $i\omega$ [12]. However, in practice, only the eigenvalues of a finite-dimensional matrix approximation of \mathbf{H}_∞ can be computed numerically. The matrix

$$\mathbf{H} = \begin{pmatrix} \mathbf{J}_0 + iN\omega \mathbf{I} & \mathbf{J}_{-1} & \dots & \mathbf{J}_{-2N} \\ \mathbf{J}_1 & \mathbf{J}_0 + i(N-1)\omega \mathbf{I} & \dots & \mathbf{J}_{-2N+1} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{J}_{2N} & \mathbf{J}_{2N-1} & \dots & \mathbf{J}_0 - iN\omega \mathbf{I} \end{pmatrix} \quad (14)$$

of size $N \times N$ (recall $N = n(2N_u + 1)$) consists of the N most centered rows and columns of \mathbf{H}_∞ and approximates the original infinite-dimensional matrix. In the absence of truncation error, the eigenvalues of \mathbf{H} are some subset of the eigenvalues of \mathbf{H}_∞ , i.e. the Floquet exponents. Due to the inevitable error which generally comes with truncation, however, this does not quite hold. The N eigenvalues of \mathbf{H} will be called Floquet exponent candidates below.

The matrix \mathbf{H} has a block Toeplitz structure and for sufficiently large N_u , the bands near the diagonal dominate as the Fourier coefficients of \mathbf{J} tend to zero for N_u large enough. Loosely speaking, this means that some eigenvalues affiliated most with the central rows of \mathbf{H} are less impacted by the truncation and provide a better approximation to the Floquet exponents than others. The search for a selection criterion which determines the best approximation to the Floquet exponents from the Floquet candidates has received much attention in the literature [5, 16, 8, 12].

For sufficiently large N_u , it is proven that the candidates with lowest imaginary part in modulus converge to the true Floquet exponents [16]. An alternative criterion selects those candidates whose eigenvectors are most symmetric [8, 6], as

they should correspond most to the middle rows of the block Toeplitz matrix \mathbf{H} . Even though there currently is no formal convergence proof for this symmetry-based sorting method, numerical results indicate faster convergence than with the aforementioned eigenvalue criterion [1].

For both these criteria, all eigenpairs of the large matrix have to be computed first and then most of them are discarded. As the cost of solving an eigenvalue problem is of the order $\mathcal{O}(N^3)$, the computational cost of the approach is usually dominated by determining the eigendecomposition of a large matrix.

Koopman-based Hill method

Consider again the lifted perturbation dynamics (10) around a periodic solution. As explained above, for a periodic solution, the matrix \mathbf{B} should vanish and the autonomous system $\dot{\mathbf{z}} = \mathbf{A}\mathbf{z}$ remains. After the coefficients \mathbf{p}_k of the periodic solution are substituted into \mathbf{A} , it is a matrix with purely numerical entries. Let \mathbf{C}_H denote the real selection matrix sorting all terms in Ψ_z which are linear in \mathbf{x} such that

$$\mathbf{C}_H \Psi_z(\mathbf{y}, t) = \left(\mathbf{y}^T e^{iN\omega t}, \mathbf{y}^T e^{i(N-1)\omega t}, \dots, \mathbf{y}^T e^{-iN\omega t} \right)^T. \quad (15)$$

Entries in $\mathbf{C}_H \Psi_z$ are of the form $\mathbf{y} e^{-ik\omega t}$ and are sorted by ascending k ranging from $-N$ to N . Note that $\frac{\partial(\mathbf{C}_H \Psi_z)}{\partial t} = \Omega \mathbf{C}_H \Psi_z$ with $\Omega = \text{diag}(iN\omega, i(N-1)\omega, \dots, -iN\omega)$. The matrix $\mathbf{C}_H \mathbf{A} \mathbf{C}_H^T$ can be rearranged using the definition (7). After block-wise differentiation of $\mathbf{C}_H \Psi_z$, the Jacobian \mathbf{J} is expressed by its Fourier expansion. Finally, after identifying terms corresponding to $(\mathbf{C}_H \Psi_z)$ in the first argument of the inner product, it follows that

$$\mathbf{C}_H \mathbf{A} \mathbf{C}_H^T = \left\langle \frac{d(\mathbf{C}_H \Psi_z)}{dt} \mathbf{C}_H^T, \Psi_z \right\rangle = \left\langle \left(\frac{\partial \mathbf{C}_H \Psi_z}{\partial \mathbf{y}} \mathbf{J} \mathbf{y} + \frac{\partial \mathbf{C}_H \Psi_z}{\partial t} \right), \mathbf{C}_H \Psi_z \right\rangle = \mathbf{H}. \quad (16)$$

Thus, all stability information obtained for a time-periodic system by the Hill method is also contained in the Koopman lift of the system. In particular, if Ψ_z only contains terms that are linear in \mathbf{x} and not of higher polynomial orders, then \mathbf{C}_H is quadratic and orthogonal. This makes (16) a similarity transform and it can be concluded that the eigenvalues of \mathbf{A} are identical to those of \mathbf{H} , i.e. the Floquet candidates.

Examples

Two variants of the Hill equation $\ddot{x} + g(t)x = 0$ with $g(x)$ being 2π -periodic are used to exemplify and illustrate the properties discussed above. First, the Koopman lift for the scalar Mathieu equation with $g(t) = a + 2b \cos(2\omega t)$ is provided explicitly for the lowest possible N_u as an example for the structure both in the \mathbf{A} and the \mathbf{B} matrix. The stability properties of the Mathieu equation are then investigated using both a HBM variant and the Floquet exponents retrieved from the Koopman lift. Finally, a more complicated expression for g is analyzed to illustrate the impact of the choice of N_u .

Mathieu equation

As an example, consider the scalar Mathieu equation $\ddot{x} + (a + 2b \cos(2t))x = 0$. In the (a, b) -space, regions of stability and instability are separated by branches of nontrivial periodic solutions [9], which are visualized in a so-called Ince-Strutt diagram.

For treatment in the Koopman framework, the system is brought to first-order form with $\mathbf{x} = (x, \dot{x})^T$. The first-order dynamics is then of the form

$$\dot{\mathbf{x}} = \mathbf{J}(t)\mathbf{x} = \begin{pmatrix} 0 & 1 \\ -a - 2b \cos(2t) & 0 \end{pmatrix} \mathbf{x} = \left[\begin{pmatrix} 0 & 1 \\ -a & 0 \end{pmatrix} + \begin{pmatrix} 0 & 0 \\ -b & 0 \end{pmatrix} (e^{i\omega t} + e^{-i\omega t}) \right] \mathbf{x}. \quad (17)$$

The Fourier decomposition of $\mathbf{J}(t)$ can be read directly from (17). Assume a periodic solution $\mathbf{x}_p = \mathbf{x} - \mathbf{P}_{hb} \mathbf{u}$ with \mathbf{u} as in (6) and \mathbf{P}_{hb} collecting the \mathbf{p}_k from HBM column-wise. Choose a vector of basis observables Ψ_z which only contains terms linear in \mathbf{x} . For readability of the result, assume that Ψ_z is already sorted as in (15). Hence, in this case, \mathbf{C}_H is the identity matrix. The selection matrix \mathbf{C}_z is of the form

$$\mathbf{C}_z = \begin{pmatrix} 0 & \dots & 0 & 1 & 0 & 0 & \dots & 0 \\ 0 & \dots & 0 & 0 & 1 & 0 & \dots & 0 \end{pmatrix} \quad (18)$$

with a 2×2 identity matrix in the middle, surrounded by blocks of zeros with $2N_u$ columns each. Performing the Koopman lift (7) on $\mathbf{y} = \mathbf{x} - \mathbf{x}_p$ yields for $N_u = 1$ the linear time-invariant system

$$\dot{\mathbf{y}} \approx \mathbf{C}_z (\mathbf{A} \mathbf{z} + \mathbf{B} \mathbf{u}) = \mathbf{C}_z \begin{pmatrix} i\omega & 1 & 0 & 0 & 0 & 0 \\ -a & i\omega & 0 & 0 & -b & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & -a & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -i\omega & 1 \\ -b & 0 & 0 & 0 & -a & -i\omega \end{pmatrix} \mathbf{z} + \left[\mathbf{A}_{3:4} \begin{pmatrix} \mathbf{p}_{-1} \\ \mathbf{p}_0 \\ \mathbf{p}_1 \end{pmatrix} \mathbf{A}_{5:6} \begin{pmatrix} \mathbf{p}_{-1} \\ \mathbf{p}_0 \\ \mathbf{p}_1 \end{pmatrix} \mathbf{A}_{1:2} \begin{pmatrix} \mathbf{p}_{-1} \\ \mathbf{p}_0 \\ \mathbf{p}_1 \end{pmatrix} \right] \mathbf{u}, \quad (19)$$

Figure 2: Ince-Strutt diagram for the Mathieu equation. Stable (unstable) regions determined by Koopman-based Hill method of order 4 in white (gray). Transition curves, i.e. parameter combinations which admit nontrivial periodic solutions, determined by Koopman-based HBM (solid red) and numerically using a shooting procedure (dashed blue).

Figure 3: Stability charts for the more complicated Hill's equation (20). Stable (unstable) regions determined by Koopman-based Hill method in white (gray). Transition curves determined by direct numerical integration of the variational equation (12) in blue.

where $\mathbf{A}_{i:j}$ denotes the i -th to j -th rows of \mathbf{A} . Hence, all rows of \mathbf{A} reoccur in $\mathbf{C}_z \mathbf{B}$. The entries in \mathbf{A} do not depend on \mathbf{p}_k in this special case. This is because the original dynamics of the Mathieu equation is linear in the state. As the linear time-varying system has an equilibrium at $\mathbf{x} = \mathbf{0}$, the HBM equations coded in $\mathbf{C}_z \mathbf{B}$ are a homogeneous linear equation system for the parameters \mathbf{p}_k . The system only has nontrivial periodic solutions on the stability boundary curves. If the dynamical system has a nontrivial periodic solution, then the linear equation system resulting from HBM must have one as well. This means that the determinant of this linear equation system, or equivalently that of \mathbf{A} , must vanish. This is an approximate algebraic condition for the transition curves which separate stable and unstable regions in the Ince-Strutt diagram based on the HBM using the Koopman lift of the system.

In the \mathbf{A} matrix, the 2×2 block Toeplitz structure of (14) is clearly visible. With the Hill method, this can also be used to approximate the stability regions using the Floquet candidates found as eigenvalues of \mathbf{A} . Here, the eigenvalues of \mathbf{A} with lowest imaginary part in modulus were used as Floquet exponent approximations. For the case $N_u = 4$, the stability regions and transition curves found by the Koopman-based HBM and Koopman-based Hill method are pictured in Figure 2. In the white regions, the two eigenvalues of \mathbf{A} with imaginary part closest to zero both have a real part of zero, while in the gray regions, one has a real part larger than zero and the other has a real part smaller than zero. A comparison with numerically obtained transition curves using a shooting procedure based on [9] shows good approximation quality for the first instability tongues already for small N_u .

Below, we consider the more complicated Hill's equation

$$g(t) = a + b(\sin(t) + \sin(8t) + \cos(5t) + \cos(3t)) . \quad (20)$$

In contrast to the previous Mathieu equation, higher frequencies are part of the dynamics. This means that the matrix \mathbf{A} of the Koopman lift (or, equivalently, the \mathbf{H} matrix of the Hill method) exhibits a diagonal band structure only if N_u is chosen larger than before. Additionally, block symmetry in \mathbf{A} is lost. As expected it is visible in Figures 3a and 3b that low orders of N_u are now not sufficient to capture the dynamics. Higher orders of N_u , however, do capture the stability regions accurately.

Conclusion

In the Koopman framework, the choice of observables plays a crucial role for the accuracy of the final finite-dimensional Koopman lift. In this work, the connection between a specific choice of Koopman observables based on Taylor as well

as Fourier monomials and established frequency domain tools for the analysis of time-periodic nonlinear systems is highlighted. This connection motivates the use of this type of observables in a Koopman-based setting and provides some legitimization. In further research, this connection could be utilized to carry over structural insights from the original nonlinear system into its frequency representation.

Summary. Parametric instabilities are dynamical instabilities possibly arising when the mechanical state of a structure is periodically modulated in time. It is sometimes seen as a phenomenon to avoid for example with sailing ships (parametric rolling) but it can also be exploited to study vibrating fluids (Faraday waves [1]) or Nano-Electro-Mechanical Systems [2]. One well-known limitation in fully exploiting classic parametric instabilities based on small periodic modulation of a mechanical state is that inherent friction forces rapidly cancel sub harmonic parametric resonances. To overcome this drawback, we propose to "extremely" modulate the mechanical state of the system in order to enhance parametric instabilities and therefore allow for new promising dynamic functionalities. This original way of enhancing and controlling parametric instabilities is illustrated here through the numerical and experimental implementation of an electromagnetic pendulum. We find that it is possible to greatly enhance the number of sub harmonic instability regions and also that the width of these regions can be controlled.

Keywords : Parametric instabilities, structural vibrations, experimental vibrations, Meissner Equation, Floquet theory.

Experimental system under study

Our goal is to periodically vary a mechanical system between two very different states in order to enhance parametric instabilities, even in the presence of classic internal friction forces. For illustrative purposes, we set up in the lab the proof of concept shown in Fig.1a). The experiment consists of a magnetic pendulum that is symmetrically placed between two attracting electromagnets. When the electromagnets are off, the system is a simple pendulum characterized by a natural frequency $\omega_0 \approx 9$ rad/s as illustrated in the experimental plot of Fig.1c). When turning the electromagnets on through an electrical current I , the state of the pendulum can be drastically modified. In our example of Fig.1, when the control parameter I is slightly below I_{max} , our system is naturally oscillating with a slower natural frequency. Above $I = I_{max}$, our system is no more oscillating but diverging: attracted to the right or left electromagnet depending on the imperfections in our experiment. This mechanical system is therefore a simple first realization of what we coined an *extreme parametric oscillator*: with a single parameter, in this case I , we are drastically and easily changing the state of our system. In classical parametric oscillators, this extreme modulation is hardly reachable because the geometrical mechanical modulation parameters that come into play (the length of the pendulum or the effective gravity for example) are not easily varied on such scales [1][2].

Figure 1: The electromagnetic parametric oscillator under study. a) A pendulum whose mass is made of steel, is symmetrically placed between two identical attracting electromagnets that are periodically turned on (red energy states in b)) and off (blue energy states in b)). b) Simplified "Particle in a time-varying potential well" model. c) Evolution of the natural frequency of the pendulum for various value of the electrical current I in the two electromagnets when the later are separated by $L = 6$ cm. Below $I < I_{max}$, the pendulum is naturally oscillating if perturbed. Eventually, for I close to the diverging limit I_{max} , the natural frequency goes down. Above I_{max} the mass is no more oscillating but diverging.

To investigate the dynamic behavior of our extreme parametric oscillator, we periodically turn the electromagnets on or off with a period T , in a square wave fashion making the system modulate between two states (see Fig.2a)). Fig.2b) represents the experimental stability diagram of the pendulum in the modulation parameter space (T, I) . For some (T, I) , the system is dynamically stable (blue triangles), i.e. the pendulum is slightly vibrating (because of small imperfections) but stays close to the trivial vertical state. The crosses indicate the modulation parameters for which the mass was parametrically unstable, i.e. dynamically impacting the electromagnets. The color legend indicates the number of cycles the pendulum is doing in the emerging nonlinear vibrational regime. Modes with an integer number of M represent T -periodic unstable regions when the other M numbers represent $2T$ unstable regions. At relative low modulation amplitude, $I < 1$ A, the pendulum is often stable, except eventually for the first or second parametric instability regions. For "extreme" modulation amplitude such as $I \approx I_{max}$, it is possible to trigger highly sub-harmonic instability regions, here up to the 58th instability region ($M = 29$) when the current record demonstrated in a micro electromechanical device is found to be the 28th instability region [2].

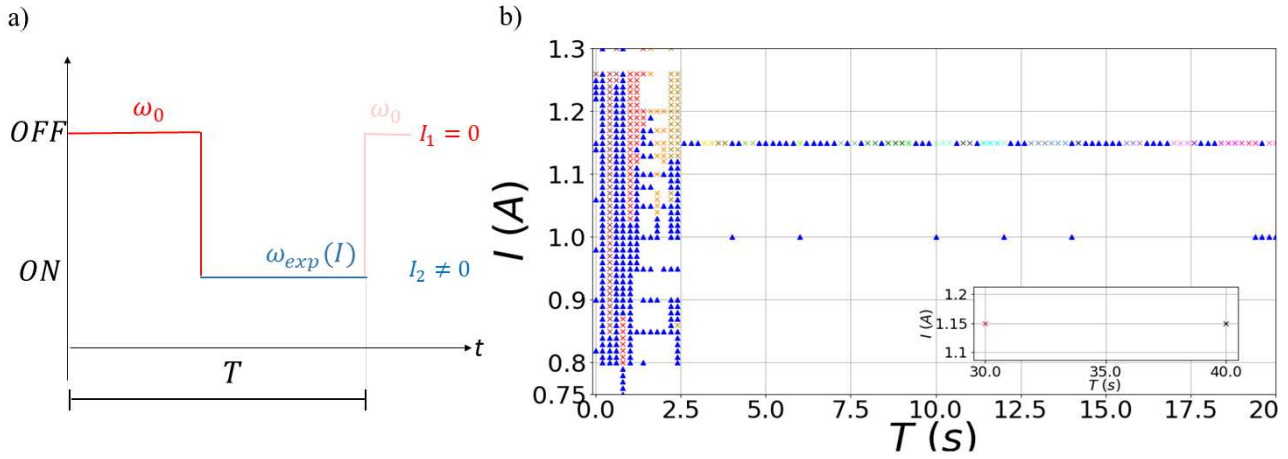

Figure 2: a) The electromagnets are turned on and off in a square wave fashion with period T . The amplitude of modulation is the electrical current I when the electromagnets are on. b) Experimental stability chart of the pendulum in the modulation parameter space (T, I) . Blue triangles represent stable states where the mass stays close to the middle of the electromagnets. Crosses represent unstable states where the pendulum dynamically diverges and eventually impact the electromagnets.

Model of an extreme time-periodic oscillator

The aforementioned experimental mechanical system can be seen as a non-damped pendulum that oscillates periodically between a natural frequency ω_0 and ω_{exp} following a square wave function. Based on the theoretical study of the Meissner equation[3] a linear theoretical model for the stability of the vertical pendulum can be obtained:

$$\ddot{\theta}(\tau) + (\alpha^2 + \beta^2 \text{sgn}(\cos(\tau))) \theta(\tau) = 0 \quad (1)$$

with α^2 and β^2 two dimensionless parameters. Fig.3 represents the stability of Fig.2b) represented in the analytical space (α^2, β^2) . With this experimental setup we are able to observe extreme periodic instability for the first time (large values for α^2 and β^2). For small values of α^2 and β^2 the model represents correctly the evolution of the experimental system. The alternation between stable and unstable analytical regions shows a good agreement with those found experimentally. In conclusion it is possible to trigger extreme parametric oscillations experimentally and to develop a corresponding linear theoretical model. This new approach could be promising for very large-band energy harvesting devices.

Figure 3: Analytical stability chart with experimental results presenting several instability regions. The numerical results represent the evolution of the real part of the Floquet exponent of equation (1) [4]. If it is equal to zero than the movement of the system is stable. Values larger than zero mean the solution of the system increases exponentially so the system is unstable. The blue triangles correspond to the experimental stable states and the red crosses correspond to the unstable ones. The red curve ($\alpha^2 = \beta^2$) represents the limit between systems that are naturally stable and systems naturally unstable (over the limit).

Summary. The dynamics of sealing elements within a reciprocating compressor is considered in a 2D model as described in [1]. Linear elastic effects of the sealing ring, periodically changing gas pressure loads driven by the external piston movement and dry wear at the moving contact surface between the ring and the piston rod are explicitly included. Two governing equations for the dynamical quantities of interest are specified, together with three small, non-dimensional parameters characterizing the problem. Following [3], an asymptotic analysis is sketched, involving two time scales, where rapid changes due to the compression cycle as well as slow changes due to wear are considered.

Introduction

We consider the dynamics of sealing elements typically used in industrial reciprocating compressors or pumps. So called packing elements seal the higher gas pressure in the compression chamber against the lower ambient pressure. These elements consist of one or more packing rings held in so called cups within a packing housing. The ring seals the gas pressure dropping from P_1 on the cylinder side to P_2 on the crank side by being pressed against the facing side of the cup on the right and to the moving rod below, see Figure 1, taken from [1]. Depending on the sealing efficiency, there is an (undesired) gas flow from left to right.

Figure 1: Gas pressure and contact forces acting on a sealing ring, taken from [1].

The rod is connected to a piston in the compression chamber and moves periodically in horizontal direction, driven externally by a motor running at a fixed frequency, creating a desired delivery pressure. This gives rise to a periodically changing pressure P_1 in the cup. Due to the dynamic contact between ring and rod, the process is subject to dry wear leading to material loss on the inner side of the ring.

Problem formulation and model

We completely adapt the analytical axisymmetric 2D model for the sealing ring from [1], see Figure 1. The ring material is described by Hooke's law and is assumed to be in a state of plane strain. Stresses and strains are functions of the radial coordinate r only. The contact force from the rod is uniformly distributed in (axial) z -direction, giving rise to a contact pressure P_c , and a ring wear that does not depend on z . In contrast to [1], we assume a periodically changing pressure P_1 on the upper side of the ring and a periodically moving rod on the lower side. Gas pressure effects over the contact surface, friction forces and inertial effects are ignored. Depending upon the contact pressure P_c , ring material is worn away over a large time compared to the compression period length. Archard's wear law is used to describe the wear process, where the long term wear rate and the course of the contact pressure P_c are the quantities of interest.

Due to the wear process the inner radius $R^{(i)}$ of the ring grows, and so does the displacement $u^{(i)}$ in radial direction as to fulfill the contact condition $R^{(i)} + u^{(i)} = D/2$ with D being the rod diameter. Combined with Archard's law, a governing equation for $R^{(i)}$ as a function of time may be derived, where the gas pressure P_1 is acting as an external excitation.

Asymptotic description

Writing down the equations in non-dimensional form, one can identify two small, non-dimensional parameters governing the problem:

$$\varepsilon := \frac{KV_0 P_D}{(D/2)\omega}, \quad \delta := \frac{P_D}{E}. \quad (1)$$

K is the wear coefficient from Archard's law, V_0 is a reference velocity (amplitude) of the rod movement, the discharge pressure P_D is serving as a reference pressure, ω is the angular frequency of the piston movement, and E is Young's modulus of the ring material. According to [1], for practical cases the relationship $\varepsilon = \mathcal{O}(\delta)$ is valid, i.e. ε being much smaller than δ .

Asymptotic investigations of the problem were already performed in [3], where the parameter ε (though defined slightly different) was identified. In [3], a somewhat idealized physical situation was investigated and analyzed by the method of multiple scales.

Introducing the non-dimensional quantity $\rho := R^{(o)}/R^{(i)}$ being the quotient of the constant outer ring radius $R^{(o)}$ to the time-dependent inner ring radius $R^{(i)}$, the following governing equation may be derived:

$$\frac{d\rho}{dt} = -\varepsilon \frac{\dot{p}_1 p_c \rho}{1 + \delta r_o \frac{\rho}{1-\rho^2} (p_c - p_1)}. \quad (2)$$

Here t is the dimensionless time, p_1 is the dimensionless gas pressure, p_c the dimensionless contact pressure, and r_o the dimensionless outer ring radius. The gas pressure in equation (2) may be considered as a given periodic excitation function with the (constant) frequency of the piston movement. Equation (2) is supplemented by a non-linear, algebraic equation resulting from the contact condition between ring and rod, involving the dynamical quantities ρ and p_c . Thereby, the quantity ρ is directly related to the wear rate.

The parameter δ expresses the relative size of the involved gas pressures compared to the material stiffness of the ring, being of the order of 10^{-2} in practical situations. The much smaller parameter ε characterizes the wear process taking place on a much slower timescale compared to the dynamics arising from the compression cycle. We address to tackle the problem by performing a coupled asymptotic expansion of the equations with respect to ε and δ , taking into account that $\varepsilon = \mathcal{O}(\delta)$. In analogy to [3], we introduce two timescales t and εt to seek for a solution within a multiple scales analysis.

Summary and conclusions

We considered the dynamics of a sealing element within a reciprocating compressor, being subject to dry wear on the moving contact between sealing ring and piston rod. Based upon previous works [1]-[3], we have specified two governing equations for the dynamical quantities ρ (a dimensionless inverse inner ring radius) and the dimensionless contact pressure p_c . These quantities are affected by rapid changes due to the piston movement and slow changes due to the wear process. A small parameter ε distinguishes between the two time scales and may serve as an asymptotic parameter for a calculation of perturbations to solve the governing equations.

Attractor Targeting by Dual-frequency Driving

Ferenc Hegedűs*, Péter Krähling*, Marcel Aron†, Werner Lauterborn‡, Robert Mettin‡ and Ulrich Parlitz†

Summary. A control technique to continuously drive a non-linear, harmonically excited oscillator between different kinds of periodic orbits is presented. The basis of the method is a temporary dual-frequency driving of the system. Results show that two periodic orbits existing at two different frequency values (single frequency driving) having arbitrary periodicity can be smoothly transformed into each other. The method is a proper tuning of the excitation amplitudes of a dual-frequency driving combining the two corresponding frequencies. The requirements are the suitable choice of the frequency pair and the matching of the torsion numbers of the bounding bifurcation points of the periodic orbits.

Introduction

In non-linear systems, multiple domains of periodic attractors might exist in a given parameter space [1]. These domains can overlap each other meaning that at their union, the system is even multi-stable [2]. The different stable solutions usually represent different system performances; for instance, a chemical reactor can have different chemical yield. Thus, it is important to be able to drive a system onto a desired stable state in its parameter space. The main aim of this study is to propose a technique that is suitable to smoothly drive a system from one periodic domain to another.

The method works for harmonically driven non-linear oscillators in the parameter plane of its driving amplitude A_1 and frequency ω_1 . The technique is based on the addition of a second harmonic component to the driving with amplitude A_2 and frequency ω_2 . With a proper tuning of the driving amplitudes, a periodic attractor exists at ω_1 with $A_2 = 0$ can be smoothly transformed onto another periodic orbit exists at ω_2 with $A_1 = 0$. That is, the beginning and the end of the transformation is a single frequency driven system, and the intermediate states have dual-frequency driving. Throughout the rest of the paper, the requirements of the transformation possibilities are discussed in general; and an example is presented based on the Keller–Miksis equation that is a second order ordinary differential equation describing the radial pulsation of a single spherical bubble [3].

The control technique

For simplicity, let us consider dual-frequency driven second order non-linear oscillators written as

$$\dot{x}_1 = f(x_1, x_2), \quad (1)$$

$$\dot{x}_2 = g(x_1, x_2) + A_1 \cos \omega_1 t + A_2 \cos \omega_2 t. \quad (2)$$

Assume that at fixed frequency ω_1 , there is a domain (section) of periodic solution with period p_1 in the A_1 parameter line (the amplitude of the second component is $A_2 = 0$). Similarly, assume that there is another segment of periodic solution with period p_2 in the A_2 parameter line ($A_1 = 0$) at frequency value ω_2 different from ω_1 . Both periodic segments are bounded by bifurcation points having torsion numbers q [4]. The schematic draw in Fig. 1A demonstrates such an example in the parameter plane of the excitation amplitudes A_1 and A_2 . There are two requirements for the existence of a set of solutions that connects the two segments of these periodic orbits (blue and red lines in Fig. 1A). Without a detailed derivation, the first condition is that the ratio of the periods and ratio of the employed frequencies must be equal:

$$\frac{p_1}{p_2} = \frac{\omega_1}{\omega_2}. \quad (3)$$

It must be stressed that periods of the orbits p_1 and p_2 are defined according to the period of the single frequency excitation $T_1 = 2\pi/\omega_1$ and $T_2 = 2\pi/\omega_2$, respectively. If the condition given by Eq. (3) holds, the periods of the two kinds of orbits presented in Fig. 1A by the blue and red lines become equal via employing the period of the dual-frequency driving T as a global Poincaré section. In this case, codimension-2 bifurcation curves might exist that connect the bifurcation point pairs (q_{11}, q_{21}) and (q_{12}, q_{22}) (see the black curves in Fig. 1A). For such an existence, the connected torsion numbers must be equal representing topologically the same local flow of the vector field along the black codimension-2 curves:

$$q_{11} = q_{21}, \quad (4)$$

$$q_{12} = q_{22}. \quad (5)$$

Figure 1: Panel A: Schematic draw of the transformation possibility between two periodic orbits with arbitrary periodicity in the parameter plane of the amplitudes of the dual-frequency driving. Panel B: Transformation between period-3 and period-5 orbits through the yellow surfaces. The employed model is the dual-frequency driven Keller–Miksis equation being a second order ordinary differential equation.

The control technique is demonstrated in Fig. 1B employing the Keller–Miksis equation being a second order non-linear oscillator. For the details of the equation, the reader is referred to the review paper [3]. The frequency combination used is $\omega_{R1} = \omega_1/\omega_0 = 5$ and $\omega_{R2} = \omega_2/\omega_0 = 3$, where ω_0 is the linear resonance frequency of the system. The periods of the orbits studied are $p_1 = 5$ and $p_2 = 3$. Thus, the condition given by Eq. (3) holds. In this figure, the saddle-node and the period doubling bifurcation points are marked by SN and PD respectively. Their torsion numbers are all equal: $q_{11} = q_{12} = q_{21} = q_{22} = 1$ fulfilling also the second requirement defined via Eqs. (4)-(5). The periodic orbits corresponding to the single frequency driving are highlighted by the blue (period-5 at $\omega_{R1} = 5$) and red (period-3 at $\omega_{R2} = 3$) curves. The yellow surfaces represent a set of periodic orbits connecting the period-3 and the period-5 orbits. Therefore, with a proper tuning of the amplitudes A_1 and A_2 of the dual-frequency driving, the system can be smoothly transformed between the period-3 orbits lying on the red curves and the period-5 attractors represented by the blue curves. Observe that the dual-frequency driving is temporary and that the initial and final state of the transformation relate to single frequency driving with different frequencies. It must be emphasized that with a different choice of frequency pairs, transformation can be achieved between other pairs of periodic orbits.

Conclusions

The main significance of the proposed control technique is that a given system can be driven to a desired periodic solution in excitation-amplitude–frequency-parameter plane. The advantage of the method is that direct attractor selection is possible meaning that the final state of the trajectory is not incidental (as in case of many control of multistability techniques). The disadvantage is that a detailed knowledge of the bifurcation structure of the periodic orbits is required to control the system confidently. It is worth mentioning that the technique is first identified in the previous paper of the authors [5]; however, only for a specific pair of periodic orbits and a generalisation was not discussed.

Broadband Stabilization with Combined Anti-Resonances

Zacharias Kraus*, Ahmed A. Barakat* and Peter Hagedorn*

**Dynamics and Vibrations Group, Technical University of Darmstadt, Darmstadt, Germany*

Summary. The study of anti-resonances in parametrically excited systems in the recent years was focused mainly on bimodal systems. Assuming it to be strictly a bimodal coupling phenomenon, anti-resonances in systems with multiple degrees of freedom (DoF) were seen as a generalization without added effects. Recent findings, however, hint at an interesting behavior when multiple anti-resonances arise in close vicinity of each other. In the present contribution, these effects will be discussed and assessed with perturbational methods, aiming at understanding the underlying phenomenon, which is expected to be advantageous especially in enhancing the robustness and intensity of vibration mitigation.

Introduction

Ever since the discovery of anti-resonance by Tondl [8], further research by Schmieg [7], until recent investigations conducted by Dohnal [1, 2] and finally comprehensive semi-analytical description by Karev [3, 4, 5], anti resonance was interpreted as coupling between two modes. However, recent findings suggest that multiple anti-resonances can not be viewed in isolation in all cases. Following [6], Lyapunov characteristic exponents (LCEs) are used to gain insight into the system's behavior. Floquet theory is applied to the parametrically excited system with excitation period time T , resulting in Floquet multipliers ρ_i , from which the LCEs λ_i can be derived by

$$\lambda_i = \frac{1}{T} \ln |\rho_i|. \quad (1)$$

Numerical Observations

In [6], it was shown that in systems with multiple degrees of freedom (MDoF), under the right conditions anti-resonances may appear at multiple excitation frequencies Ω . This is illustrated in Fig. 1, using the system introduced in [2, 9] and studied further in [6] as an example. The anti-resonances are approximately at the combination frequencies $\Omega = \Sigma_{21} = \omega_1 + \omega_2$ and $\Sigma_{32} = \omega_3 + \omega_2$.

Figure 1: LCEs λ_i of example system [6] over excitation frequency Ω for $\kappa = 1$, $\varepsilon_p = 0.15$. Two separate anti-resonances are visible.

The numerical results obtained by applying Floquet theory indicate that for a certain amplitude ε_p of parametric excitation, while having asymmetrically skewed excitation terms by a factor κ in a MDoF (see (2)), a minimum of the largest of the LCEs involved in anti-resonances $\max(\lambda_i)$ can be achieved. This leads to the anti-resonances laying on top of each other, as visible in Fig. 2.

Figure 2: LCEs λ_i of example system [6] over excitation frequency Ω for $\kappa = 0.729$, $\varepsilon_p = 0.158$. Two anti-resonances occur at the same frequency.

The exact relation between the values of all LCEs λ_i and the equivalent damping of the system is yet to be fully understood. Thus, numerical simulation of the system's amplitudes after an initial displacement is used to clarify the effects of the

two combined anti-resonances shown in Fig. 2. Fig. 3 shows the summed squares of amplitudes of all DoF of the example system. With the dashed line indicating the reference time at which the unexcited system's amplitudes become negligibly small, it is apparent that a stabilizing effect is not only caused around the frequency of anti-resonances but for all frequencies apart from resonances.

Figure 3: Summed squares of amplitudes in all DoF after initial perturbation recorded over time t and with respect to the parametric excitation frequency Ω . Reference time where unexcited system reaches negligibly small amplitudes shown with dashed line (---). Lighter shade means larger amplitudes.

Perturbation analysis

In order to get a better insight into the observed phenomenon, the system is to be analyzed analytically. As a first step, the system model is reduced for the sake of generalizing the studied system, which leads to a three-dimensional equation of motion

$$\ddot{\underline{u}} + \varepsilon \begin{pmatrix} \mu_1 & 0 & \mu_{13} \\ 0 & \mu_2 & 0 \\ \mu_{13} & 0 & \mu_3 \end{pmatrix} \dot{\underline{u}} + \left[\begin{pmatrix} \omega_1^2 & 0 & 0 \\ 0 & \omega_2^2 & 0 \\ 0 & 0 & \omega_3^2 \end{pmatrix} + \dots \right. \quad (2)$$

$$\left. \dots + (1 - \kappa) \begin{pmatrix} 0 & k_{12} & k_{13} \\ k_{21} & 0 & k_{23} \\ k_{31} & k_{32} & 0 \end{pmatrix} + \left[\begin{pmatrix} 0 & f_{12} & f_{13} \\ f_{21} & 0 & f_{23} \\ f_{31} & f_{32} & 0 \end{pmatrix} - \kappa \begin{pmatrix} 0 & f_{21} & f_{31} \\ f_{12} & 0 & f_{32} \\ f_{13} & f_{23} & 0 \end{pmatrix} \right] \varepsilon_p \cos(\Omega t) \right] \underline{u} = 0,$$

with the displacement \underline{u} , damping μ_i , eigenfrequencies of the undamped unexcited system ω_i^2 , off-diagonal stiffness terms k_{ij} , parametric excitation coefficients f_{ij} and frequency Ω , small parameter ε , amplitude of parametric excitation $\varepsilon_p = \mathcal{O}(\varepsilon)$ and asymmetry parameter κ .

The findings are to be analyzed using multiple scales. For this purpose, the displacement \underline{u} and asymmetry parameter κ are perturbed, described by a power series with respect to the small parameter ε :

$$\underline{u} = \underline{u}_0 + \varepsilon \underline{u}_1 + \varepsilon^2 \underline{u}_2 + \mathcal{O}(\varepsilon^3), \quad (3)$$

$$\kappa = 1 + \varepsilon \kappa_1 + \varepsilon^2 \kappa_2 + \mathcal{O}(\varepsilon^3).$$

The ongoing study aims then at using the outcomes of the multiple scales analysis in understanding the reason behind the stabilizing effect of coinciding anti-resonances at approximately all excitation frequencies. In this way, a generalization of this phenomenon can be achieved for a 3 DoF system and, moreover, extended to generic MDoF systems. Such an effect could be a powerful tool in mitigating vibrations in industrial applications.

Summary. We derive and investigate a system of equations describing the three-dimensional dynamics of a prolate and oblate achiral ellipsoidal particle subjected to a linearly polarized, electromagnetic excitation. A half-wave plate rotates the polarization direction of the transmitted light by an angle Ω and the linearly polarized electric field induces a dipole moment in the particle that depends on the product of the polarizability tensor and the electric field. To minimize energy, the induced dipole moment tends to align with the field yielding an optical torque. The basic assumption in the development of the equations of motion was that the given ellipsoid rotates around its center of mass with negligible inertia due low Reynolds number. The nanoscale dimensions of the given particle enable problem formulation in the Rayleigh regime which yields a set of three nonlinear equations for the angular velocities in terms of Euler angles. Transformation of the equations of motion to an autonomous dynamical system enabled a linear stability analysis of multiple coexisting equilibria corresponding to stable and unstable periodic orbits in the lab frame. A set of Hopf bifurcations in the autonomous system revealed existence of nonstationary quasiperiodic and chaotic motions in the lab frame governed by three nondimensional parameters.

Introduction

The advent of the laser sparked numerous research areas and one of these has been and manipulation of matter by light. In 1986 Ashkin and co-workers showed that a single tightly focused beam could be used to hold, in three dimensions, a microscopic particle near beam focus, which is now known as optical tweezers. The potential uses of contact free control of microscopic and nanoparticles has maintained high scientific interest for more than three decades. Major advances in the field have been coupled with technological innovations such as dynamic control using holographic optical tweezers, engineering of beam shapes and ultraprecise tracking techniques. Optical trapping at the micro [1] and nano [2] scales is well documented in several reviews. We note that the dynamics of tri-axial ellipsoids in shear flow reveal existence of periodic [3], quasiperiodic [4] and chaotic [5] solutions. However, to date ellipsoids immersed in a fluid and excited by a modulated optical field, have been shown to be periodic or quasiperiodic [6]. Thus, our aim in this work, is to provide a spatio-temporal physical model of the rotational dynamics of a triaxial nano-ellipsoid (Fig.1 left), to validate the existence of periodic and quasiperiodic rotations documented for long cylindrical achiral nanorods [7] and to determine existence of nonstationary chaotic rotations. We consider an achiral ellipsoidal particle with principal axes $(\mathbf{a}, \mathbf{b}, \mathbf{c})$ and permittivity (ϵ_2) suspended in a liquid of permittivity (ϵ_1) . A rotating frame of reference is attached to the particles mass center where the Eulerian angles (θ, ϕ, ψ) correspond to pitch, yaw and roll (Fig.1 left). The ellipsoid is nonmagnetic so the relative magnetic permeability can be considered as a unity.

Fig.1: Definition sketch of a nanoscale ellipsoid (left) and the bifurcation diagram for a spheroidal particle (right).

A linearly polarized impinging electric field goes through a half-waveplate that rotates the polarization direction. This exciting electric field induces a dipole moment that depends on the product of the polarizability tensor and the electric field. To minimize energy, the induced dipole moment tends to align with the field yielding an optical torque. The basic assumption in the development of the equations was that the given particle is trapped, i.e., not subjected to gradient force and rotates around its center of mass. Since the dimensions of the ellipsoid are significantly small compared to the wavelength of the exciting field, the phase is considered constant over the particle. Moreover, since the half wave plate rotates at an angular frequency which is much slower than the angular optical frequency the total torque is averaged over one optical cycle. Under the assumption of low Reynolds number, inertial terms are neglected [8], which means that the angular drag is equal to the total optical torque on the particle. For example, it has been shown that for planar rotational dynamics of dielectric nanorod, close to a critical frequency, the optical torque is a factor of much higher than the corresponding rotation due to Brownian motion during a given time interval [6]. Furthermore, we note that the bifurcation structure of a nano-spheroid ($a > b = c$) includes periodic rotations (Fig.1 right- $\Omega < 1$) or quasiperiodic motions (Fig.1 right- $\Omega > 1$) which have been demonstrated experimentally for a long cylinder [6].

Results

The non-dimensional equations governing the motion were constructed in the theoretical framework of Newtonian rigid body dynamics yielding a third-order autonomous system controlled by nondimensional parameters that depend on the particle material properties, and the angular drag coefficients (α, β) and an additional parameter that depends on the slow half wave plate rational frequency and the electric field magnitude (Ω). An investigation of the nonlinear dynamical response of ellipsoidal particles, with varying dimension and material properties, was carried out using linearization methodology yielding an eigenvalue problem. The analysis reveals a diverse local bifurcation structure (Fig.2 left) that includes coexisting bi-stable equilibria and a narrow range of limit cycle oscillations (Fig.2 right) due to subcritical Hopf threshold (depicted by the red line in Fig.2 left).

Fig.2: Stability map for a gold nano-ellipsoid with exciting frequency Ω as a function of a material parameter α (left) and time histories of limit cycle oscillations in the Eulerian frame where $\Phi = \phi - \Omega\tau$ (right).

Discussion

The classification of different solutions is portrayed in the Cartesian physical state space (Figs. 3,4). It is shown that equilibrium in the Euler angle autonomous system corresponds to a periodic solution in Cartesian space, whereas a periodic solution corresponds to a quasiperiodic Cartesian state space (Fig.3 blue triangles). Furthermore, nonstationary chaotic solutions were found between two secondary bifurcation thresholds (Fig.3 red squares). Moreover, additional quasiperiodic solutions were found for $\Omega > 1$ for which no equilibrium is reached in the Eulerian state space. It is noteworthy that the limiting case of a nano-spheroid is governed by a single non-dimensional parameter (Ω) and its bifurcation structure at steady state (Fig.1 right) does not include chaotic rotations. We note possible excitation with two frequencies may yield a region of chaotic interactions for incommensurate frequency ratios.

VSIV Experimental Analysis of a Catenary Riser Model in the Modal Space

Rafael Salles, Celso P. Pesce

Offshore Mechanics Laboratory, Escola Politécnica, University of São Paulo, Brazil

Summary. Vortex Self-Induced Vibration (VSIV) is a highly nonlinear fluid-structure interaction that can occur in catenary risers when there is an imposed motion at the structure hang-off point. The fluid-structure coupling shows persistent response, *i.e.* there is no lateral vibration mitigation after a post-critical in-plane induced oscillatory flow. The present study aims at analyzing multi-modal response of a small-scale catenary riser model using Galerkin's decomposition. The frequency ratio parameter, as the one used in linear oscillator resonance analysis, shows to be a strong control parameter altogether with the modal Keulegan-Carpenter number.

Vortex Self-Induced Vibration (VSIV) phenomenon

The Vortex Self-Induced Vibration (VSIV) belongs to the class of Flow Induced Vibration (FIV) phenomena in fluid-structure nonlinear dynamics study field. Generally, the VSIV occurs always on slender flexible structures, as risers and umbilical cables, that are launched in catenary-like configuration, so that an imposed movement at their top end, as those caused by gravitational waves, causes an oscillating movement at their configuration plane (henceforth called in-plane movement). As a result of such in-plane oscillations, vortex shedding is established and it induces lift forces that causes out of plane oscillating vibrations.

Some intermittent vibrations were firstly reported in experimental tests conducted within large-scale models of steel catenary risers (SCR) in Grant et al. [1], which later were further exploited by Le Cunff et al. [2] in their experimental campaigns with small scale SCR model. Initially, Le Cunff et al. [2] described the VSIV as Heave Induced Lateral Motion (HILM) and later experimental campaigns conducted by Fernandes et al. [3] broadened the scope of HILM renaming the phenomenon as VSIV. Fernandes et al. [3] also points out that the VSIV were observed in real riser structures of Petrobras P18 platform.

Over the last decade, the VSIV was observed and reported in small scale SCR models, as in Rateiro et al. [4] and Pesce et al. [5], in which multi-modal out of plane responses occurs due to in-plane movement caused by harmonic vertical displacements imposed at the top. Their experimental campaign shown that the structure dynamic response is highly nonlinear, coupling VSIV with internal resonance phenomenon and even parametric instabilities amid the multi-modal responses. VSIV was also reported in some recent papers Fu et al. [6].

The VSIV presents some idiosyncratic features: the synchronization amid in-plane and out-of plane oscillating movements is persistent, not occurring the structural and fluid oscillators decoupling as when the VIV reaches the post-critical regime; several lateral amplitude response peaks are observable and they are related to the cycle number control parameter, $N = f_b/f_n$ (f_b is the out of plane response frequency and f_n , the in-plane one), which always assumes integer values; the cycle number N values depends on the Keulegan-Carpenter number (KC), assuming larger values as the KC increases; and a jump phenomenon that decreases the N value as the in-plane movement velocity increases.

As a result of all features aforementioned, the out-of-plane response never fades away and can assume fairly large values of the structure diameter, $\mathcal{O}(D)$. Besides, the VSIV bares a close similarity to the responses observed in rigid cylinder subjected to oscillating flow, as shown in classical results obtained by Sarpkaya and Rabaji [7] and Sumer and Fredsøe [8]. This similarity is pointed out in several of VSIV idiosyncratic features, specially when regarding KC and N as strong control parameters to the cylinder persistent lateral response, which later in the present study will be complemented by the frequency ratio, $f^* = f_b/f_n$ (f_n is the natural frequency of the considered out of plane mode).

VSIV acting upon a small scale flexible cylinder model experimental response: modal approach

Experimental set-up

The small-scale flexible cylinder experimental model used in the present analysis is the same one already thoroughly discussed in Rateiro et al. [4] and Pesce et al. [5]; see Figure 1a. The experimental tests were conducted at the Institute for Technological Research (IPT) towing tank and the 3D model Cartesian displacement response was directly measured using underwater optical target tracking cameras; see [4]–[5]. The estimated measurement precision is of the order $\mathcal{O}(1mm)$; see Salles and Pesce [9]. In addition the effective traction at hang-off point is also obtained using a load cell; Figure 1b. Considering the displacement results at local reference frames comprised of the tangent and normal versors, \vec{t} and \vec{n} , respectively, which spans the catenary plane and the orthogonal binormal versor, \vec{b} , Figure 1c shows the multi-modal binormal dynamic response, due to the in-plane movement caused by the hang-off imposed motion. Particularly, in this selected case, the second out of plane mode shows up as the dominant response mode.

Galerkin's decomposition and VSIV modal response

Galerkin's decomposition acts as a spacial filter, grouping the nonlinear dynamic responses into a small number of modal series. The chosen modal basis was determined using a discrete beam model and a finite element solver. Considering the dominant in-plane modal series as an input for the multi-modal response out-of-plane, it is possible to broaden the concept of the Keulegan-Carpenter parameter, considering it as a modal value.

Figure 1: Flexible cylinder tests subjected to imposed movement at the top: a) experimental set-up; b) as-built model hang-off, displaying the actuator and a load cell; c) lateral amplitude spectrum of a selected case frequency response, showing multi-modal response, particularly with dominant second out of plane mode.

The frequency ratio amid dominant frequency response in-plane and the natural frequencies out-of-plane shows to be a strong control parameter, recovering a classical result of linear oscillators resonance response. The present study aims at analyzing the relation observed within all lateral modal peak-to-peak displacement, $2A_b^{(k)*}$ for all in-plane modal frequency ratios; see illustrative results in Figures 2a–b. By working on the modal-space, grouping the results into small ranges of modal-KC numbers, strongly similar modal responses are revealed, enlarging the analysis contained in [2]–[6], made in the configuration space, and broadening Sumer's & Fredsøe's [8] experimental results, obtained with a rigid cylinder mounted on linear springs in a given direction and forced to oscillate in the orthogonal direction. During the conference and in a full paper yet to come, much more results will be shown and discussed, as synchronisms, internal resonances and maps of typical orbits in the modal space.

Figure 2: Modal space VSIV results for $30.2 \leq KC^{(d)} \leq 34$: a) Peak lateral modal displacement (each lateral mode is depicted as a different colored marker) as a function of frequency ratio parameter considering the first in-plane mode; b) Modal orbit of selected out-of-plane mode against dominant in-plane modal response.

Dynamics and stability of a planar three-link swimmer with passive visco-elastic joint in Ideal fluid

Elon Tovi*, Yizhar Or *

*Faculty of Mechanical Engineering, Technion - Israel Institute of Technology, Haifa, Israel.

Summary. We study the nonlinear dynamics of a three-link swimmer model in ideal fluid, where inertial forces due to added mass are dominating while viscous drag forces are negligible. We consider an underactuated swimmer where one joint is periodically actuated while the other joint is passive and viscoelastic, with torsional spring and damper. The swimmer's motion depends significantly on the amplitude and frequency of the actuated joint angle. Optimal frequency is found where the swimmer's net displacement per cycle is maximized, under symmetric periodic oscillations of the passive joint. In addition, upon crossing critical values of amplitude and frequency, the system undergoes a bifurcation where the symmetric solution loses stability and asymmetric solutions evolve, for which the swimmer moves along an arc. We analyze these phenomena using numerical simulations and analytical methods of *Floquet* theory and *Hill's determinant*. The results demonstrate the important role of *parametric excitation* on stability of motion for flexible underactuated locomotion.

Introduction

Autonomous swimming robots have a promising potential for various applications such as surveillance and protection in marine environment, search and rescue missions, and maintenance operations within pipe systems of complex infrastructures [1], [2]. A common model assumes ideal fluid [3], [4], where the viscosity is negligible and the swimmer-fluid interaction is induced by reactive forces that represent added mass effect. Our previous work [4] used this model to study multi-link swimmers under kinematic input prescribing all joint angles, numerically, analytically and experimentally (Figure 1b). Inspired by biological swimmers in nature that utilize body flexibility, the recent work [5] studied a modified model of planar three-link swimmer having one passive viscoelastic joint (torsional spring + damper) and one actuated joint with oscillating angle $\theta_2(t) = \varepsilon \cos(\omega t)$, see Figure 1a. Unlike [4], in the semi-passive model [5] the excitation frequency ω and amplitude ε of the active joint have a significant effect on the response of the passive elastic joint and the resulting motion.

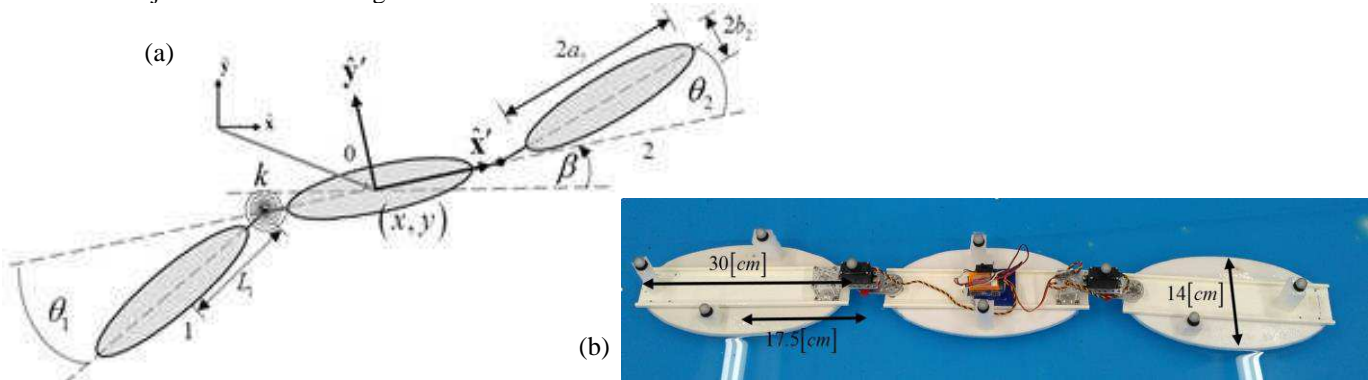

Figure 1: **(a).** Swimmer model – (x, y) are the position of the body-fixed reference frame origin. β is the rotation angle of the body-fixed reference frame. a_i and b_i are the major and minor radii of the elliptic links. θ_i are the relative angles between links. **(b).** Our previous experimental robotic swimmer with two actuated joint angles [4]

Results

In this work, we revisit the model in [5] and study its nonlinear dynamics and stability, both numerically and analytically. Numerical simulations of the system's nonlinear dynamics result in symmetric periodic motion, in which the passive joint angle $\theta_1(t)$ is oscillating symmetrically about zero while the swimmer's net motion is translation along a straight line (Figure 2, blue curves). For a fixed amplitude ε , An optimal frequency ω is found where the net displacement per cycle is maximized (Figure 3, top left). Analyzing stability of periodic solutions reveals a bifurcation point depending on input's amplitude and frequency, where the symmetric periodic solution loses stability and a pair of stable asymmetric solutions evolve, which involve oscillations of $\theta_1(t)$ about nonzero mean angle, resulting in net rotation such that the swimmer moves along an arc (Figure 2, red curves). Asymptotic analysis of the symmetric solution under small-angle assumption $\varepsilon \ll 1$ enables obtaining explicit expressions for the optimal frequency and displacement. Analyzing small variations about the symmetric periodic solution gives a Hill-type equation (linear time-periodic 2nd- order ODE) whose stability can be approximated using truncated Hill's determinant [6]. We obtain analytic conditions for the stability transitions depending on input's amplitude and frequency, which agree with the numerical simulations (Figure 4). Finally, we conduct additional numerical simulations in order to analyze added effects of nonzero initial momentum, drag forces, and tension spring mechanism at the passive joint.

Figure 2: Transient simulations – Left: trajectories in joint-angles plane. Right: trajectories in x-y plane. **Blue:** symmetric solution, **Red:** asymmetric solution. Simulations with the same amplitude and initial condition and different frequencies result in significantly different solutions trajectories.

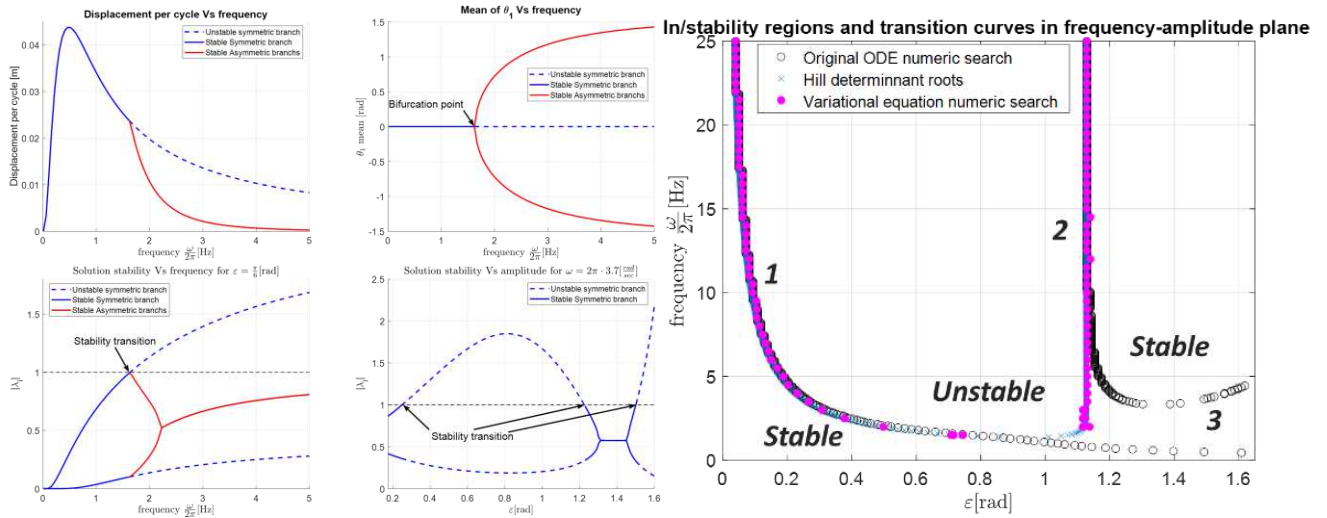

Figure 3: Steady state solution parameters in ω and ε – Optimal frequency is found where the net displacement per cycle is maximized. A bifurcation point depending on input's amplitude and frequency occurs, where the symmetric solution loses stability and a pair of stable asymmetric solutions evolve. Stability transitions involve Floquet multipliers crossing $|\lambda_i|=1$.

Figure 4: Stability and instability regions and transition curves in frequency-amplitude plane – The analytic stability transition condition of Hill's determinant predicts the first and second stability transitions. A third transition at higher amplitudes is not captured by the asymptotic analysis.

Effect of Piezoelectric Coupling on Dynamical Transitions of a Flexible Beam in Viscous Flow

Rajanya Chatterjee*, Chhote Lal Shah†, Sayan Gupta*, and Sunetra Sarkar †

*Department of Applied Mechanics, IIT Madras, India

†Department of Aerospace Engineering, IIT Madras, India

Summary. The effect of the piezoelectric coupling on the dynamical transition of a bimorph cantilever beam in free stream flow at low Reynolds number is numerically investigated in the present study. The results are simulated numerically by using an in-house three-way coupled Immersed Boundary Method (IBM)-based Fluid-structure Interaction (FSI) solver. The effect of piezoelectric coupling at low mass ratios is found to be negligible, as they exhibit periodic dynamics irrespective of the presence of piezoelectric. Without piezoelectric coupling effect, at higher mass ratio of 5.0, the system retains the periodic dynamics. Interestingly, when the piezoelectric coupling effect is introduced, the system transitions from periodic to aperiodic state at the same mass ratio. This study is of importance as it gives insights on the effects of mass ratio at which the efficient energy harvesting of such systems from the piezoelectric material can be possible.

Introduction

The recent advances in the research of alternate energy harvesters, in view of the global depletion of conventional energy resources, is not limited to the large scale solar power or wind energy harvesters. The small scale energy harvesters, powering micro electronic devices to automating small bio-mimetic robots have also been gaining attention from a range of research fields. The energy harvesting strategy from flow induced vibration of flexible flappers, using piezoelectric materials, is one such area, where the system requires a study in fluid structure interaction (FSI), vibration energy harvesters, as well as non linear dynamical characterization of the multiple parameters involved in it. A number of studies in the past and recent times, have contributed towards the development of these flow harvester models, from rigid cylinders with piezo patches in Zhu et al.[1] to more complex bluff body-flexible splitter plate models of Akaydin et al. [2]. In the current study, a flexible cantilever beam model, layered with PZT-5A on both sides (bimorph), has been placed in a viscous fluid, with an oncoming free stream velocity taking the beam to flutter for certain parametric regime. A study on the flutter condition by varying the stiffness and inertia parameters, for an FSI problem was presented in Akcabay et al.[3] and the energy harvesting potential was discussed. However, the authors have not commented on the effect of piezoelectric coupling in the dynamical transition of the system. Therefore, the present study intends to give a comparative analysis on the effect of the presence of piezoelectric coupling on the flutter conditions and energy harvesting capability.

Computational Methodology

A flexible beam layered with PZT-5A on both sides considered in the present study is inextensible where the length of the beam is $L_s = 1.0$. The leading-edge of the beam is fixed and the rest of the body is free to oscillate in the fluid. The non-dimensional governing equation of motion for the flexible beam is given by [3]

$$\beta \frac{\partial^2 \mathbf{X}}{\partial t^2} = \frac{\partial}{\partial s} \left(T_s \frac{\partial \mathbf{X}}{\partial s} \right) - \frac{\partial^2}{\partial s^2} \left(\gamma \frac{\partial^2 \mathbf{X}}{\partial s^2} \right) + \nu V \frac{d}{ds} [\delta(s) - \delta(s - L)] + \mathbf{F}, \quad (1)$$

where $\mathbf{X} = (X(s, t), Y(s, t))$ is the instantaneous position of the beam, s is the arc length, δ is a Dirac-Delta function, $\beta = \rho_s q / \rho_f L_s$ is the mass ratio (ρ_s , ρ_f and q are the structural density, fluid density and thickness of the beam, respectively). $\rho_f U_\infty^2 L_s$ is used to non-dimensionalize tension coefficient (T_s), $\rho_f U_\infty^2 L_s^3$ is used to non-dimensionalize bending stiffness (γ), t is the non-dimensional time, V is the voltage output non-dimensionalized by $L_s U_\infty (\rho_f / \epsilon)^{1/2}$, ν is the piezoelectric coupling term non-dimensionalized by $L_s U_\infty (\rho_f \epsilon)^{1/2}$ and \mathbf{F} is the Lagrangian forcing acting on the solid body non-dimensionalized by $\rho_f U_\infty^2$. The non-dimensional energy equation for bimorph is given by,

$$\frac{1}{2} \frac{\partial V}{\partial t} + \frac{q q_p}{Rb} V(t) = - \int_0^1 \nu \frac{q q_p (1 - q_p)}{2} \frac{\partial^3 \mathbf{x}}{\partial t \partial s^2}, \quad (2)$$

where q_p is ratio of the thickness of one piezoelectric layer with the total thickness of the beam (piezo+substrate), Rb is the non dimensional resistance of the piezoelectric circuit. The structural equation (eq.1) and the energy equation (eq.2) have been discretized by using finite difference method (FDM), details of which can be found in [6]. The viscous flow around the flexible beam is governed by the unsteady Navier-Stokes equations. The momentum conservation and continuity equations in non-dimensional form can be written as,

$$\frac{\partial \mathbf{u}}{\partial t} + \nabla \cdot (\mathbf{u} \mathbf{u}) = -\nabla p + \frac{1}{Re} \nabla^2 \mathbf{u} + \mathbf{f}; \quad (3)$$

$$\nabla \cdot \mathbf{u} - q_s = 0. \quad (4)$$

Where \mathbf{u} is the flow velocity vector non-dimensionalized by U_∞ , $Re = \rho_f U_\infty L / \mu$ is the Reynolds number and pressure p is non-dimensionalized by $\rho_f U_\infty^2$. The momentum forcing term \mathbf{f} is added throughout the solid domain to ensure no

slip and no penetration boundary condition is satisfied at the solid boundary and mass conservation is satisfied by adding a mass source/sink term (q_s) to the continuity equation [4]. The fluid, structure and energy equations are coupled in staggered manner where they exchange their information at every time-step.

Results and Discussions

The bimorph flexible beam has been kept in the free stream flow and the simulations are carried out for cases where, $\gamma = 10^{-2}$ and $Re = 200$ are kept constant. The model has been tested with and without piezoelectric coupling for a wide range of β values, and the case where the dynamical transitions due to electrical coupling is tangible, has been presented in this section. At the mass ratio of $\beta \in (0.05, 1.0)$, the system either settles to zero oscillation or shows a periodic flutter, which is unchanged with or without the piezoelectric coupling. However, for mass ratio as high as $\beta = 5.0$, the piezoelectric coupling plays a crucial role in the dynamical transitions. In the absence of piezoelectric coupling, the system exhibits periodic dynamics as shown in Figs. 1(a)-1(c). The tip displacement time history shows no modulation in the amplitude, signifying periodic dynamics (see Fig. 1(a)). The corresponding structural envelope shows mixed mode shape oscillations i.e. 1^{st} and 2^{nd} modes; see Fig. 1(b). The flow field shows the effect of periodic vibration giving rise to a $2p$ periodic vortex street (Fig.1(c)). However, the system transitions to an aperiodic state in the presence of piezoelectric

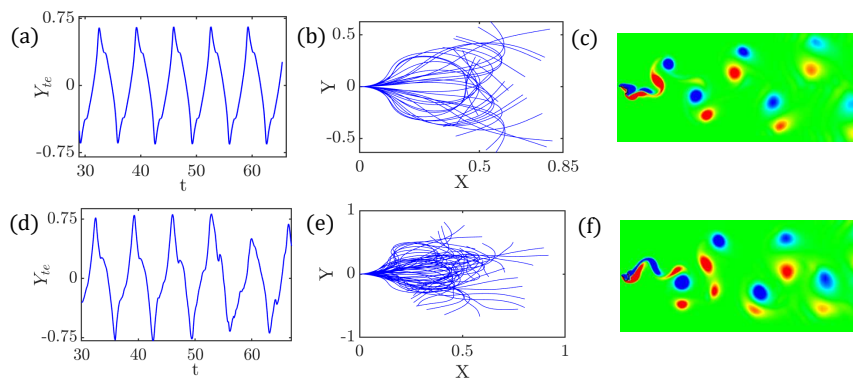

Figure 1: Time histories of beam-tip, beam envelopes and corresponding flowfields without piezo-coupling ((a)-(c)) and with piezo-coupling ((d)-(f)), respectively.

coupling as shown in Figs. 1(d)-1(f) where tip displacement time history shows modulation in the amplitude (Fig. 1(d)) and in the corresponding flow field the vortices are not well-organised (Fig. 1(f)), signifying the characteristics of aperiodic state. The irregular bending is also reflected in the the structural envelope (Fig. 1(e)). The effect of different coupling strengths (ν) are also being investigated currently in our group, to understand the effect of the different piezoelectric materials and will be presented in the the full length paper.

Conclusions

The effect of piezoelectric coupling in the dynamical transition of the three-way coupled FSI system is investigated in the present study. The system evinces periodic dynamics at the higher mass ratio of $\beta = 5.0$ in the absence of piezoelectric coupling. On the contrary, the system transitions to the aperiodic state in the presence of piezoelectric coupling. This study is of importance to identify the proper parametric regime in terms of mass ratio, piezoelectric coupling and bending rigidity in which the energy can be harvested efficiently. The authors are further investigating the effect of different dynamical state on the energy harvesting efficiency of the system.

Cantilevered Extensible Pipes Conveying Fluid: a Consistent Reduced-Order Modeling via the Extended Hamilton's Principle for Nonmaterial Volumes

Daniel de Oliveira Tomin*, Renato Maia Matarazzo Orsino[†] and Celso Pupo Pesce*

* *Offshore Mechanics Laboratory, Escola Politécnica, University of São Paulo, São Paulo, Brazil*

[†] *Mechanical Engineering Department, Mauá Institute of Technology, São Paulo, Brazil*

Summary. Applying the Extended Hamilton's Principle for nonmaterial volumes, a nonlinear reduced-order planar model of a cantilevered pipe conveying fluid is developed, consistently considering the effects of axial extensibility and conservation of mass associated to the internal flow. Unlike the corresponding inextensible pipe models, in which the term of transport of kinetic energy in the Extended Hamilton's Principle cancels out, in the present model such a term is not identically zero since the velocity of the flow along the pipe length is a function both of the generalized velocities and coordinates of the problem. The system dynamics is then investigated, assessing how extensibility and mass conservation affect dynamic bifurcations, by comparing root locus diagrams, and by simulating the resulting nonlinear model in some selected scenarios.

Introduction

One of the classical problems of Fluid-Structure Interactions (FSI) is the pipe conveying fluid, which is usually modeled as a flexible tube, with the use of the plug flow hypothesis for the velocity profile of the fluid. In general, the dynamic response is characterized by two types of motion depending on the internal flow velocity: stability around the static equilibrium position or dynamic Hopf bifurcations. As an open system, a proper mathematical formulation should be grounded on consistent variational principles, taking into account momentum and kinetic energy transport terms.

Benjamin [1] was responsible for the earlier investigations in this topic and considered the problem as a chain of articulated rigid pipes conveying fluid. He derived specific versions of Euler-Lagrange Equations and Hamilton's Principle for this system. Later, McIver [2] developed an extended form of Hamilton's Principle for open systems and confirmed Benjamin's work. In both studies, a term related to the transport of momentum appears.

Recently, the generalized forms of these principles were obtained by Irschik & Holl [3] and Casetta & Pesce [4]. In their derivation, an additional term related to the transport of the kinetic energy of the fluid through the nonmaterial surfaces appears, which was not present in McIver's formulation. When the inextensibility condition is assumed, the velocity of the internal plug flow relative to the pipe remains constant. Kheiri & Païdoussis [5] proved that, in this case, the term related to the transport of kinetic energy is identically zero, recovering McIver's formulation. However, when the axial extensibility of the pipe is considered, this term is not zero in the nonmaterial surface at the free end. Therefore, further discussion is needed to assess its theoretical and practical importance.

The present work proposes the formulation and analysis of a 2D reduced-order model for the cantilevered pipe conveying fluid, in which the extensibility is treated consistently, accounting for the conservation of fluid mass inside the pipe. Moreover, from Argand's type diagrams (root loci graphs) obtained through Lyapunov's indirect method, instabilities of the oscillatory modes are assessed. After these investigations, the nonlinear response in some selected scenarios is further analyzed through numerical simulations.

This introduction is followed by four sections, with the last of them bringing concluding remarks. The second section reviews the Extended Hamilton's principle for open systems. The third section describes the extensible pipe conveying fluid model, highlighting how the flow velocity expression is obtained by the application of the integral form of the conservation of mass, and deriving the equations of motion based on the definition of dimensionless variables and Galerkin's projection scheme. In the fourth section, some results are shown in the form of root loci diagrams obtained by a linearization around the static equilibrium, and on numerical integrations of the nonlinear equations of motion.

Hamilton's Principle for Open Systems or Nonmaterial Volumes

In the field of Continuum Mechanics, a material volume is understood as a volume whose closed boundary is moving with the material particles located in it. Because no transport of matter may occur, it can be also called a closed system. Whereas a nonmaterial volume - or a control volume in the terminology of Fluids Mechanics - is a fictional body which instantly coincides with a region defined by material particles; however, its control surface moves arbitrarily with respect to the material boundary, so that the particles accounted within the nonmaterial volume are not always the same, characterizing an open system. Although Hamilton's Principle and the Euler-Lagrange Equations are well formulated for material volumes or closed systems, the use of these variational approaches in problems where material transport exists is not straight-forward and needed further discussion.

According to Meirovitch [6], Hamilton's Principle for closed systems can be derived through the principle of virtual work for material volumes (D'Alembert's Principle). Assuming that δ denotes a variation in the context of Variational Calculus and $\frac{d(\cdot)}{dt}$ is the material derivative with respect to time t , it follows,

$$\delta T + \delta W - \frac{d}{dt} \int_V \rho (\mathbf{v} \cdot \delta \mathbf{p}) dV = 0, \quad (1)$$

where V is the the material volume and $T = \frac{1}{2} \int_V \rho(\mathbf{v} \cdot \mathbf{v}) dV$ is the kinetic energy associated with the material particles of mass density ρ , position \mathbf{p} with virtual displacement $\delta\mathbf{p}$ - which satisfies any imposed constraints - and velocity $\mathbf{v} = \frac{d\mathbf{p}}{dt}$. δW is the virtual work of the conservative and nonconservative forces.

By integrating (1) over the time interval $t_1 \leq t \leq t_2$ and considering that the configuration of the system is prescribed at the limit points (thus, $\delta\mathbf{p}(t_1) = \delta\mathbf{p}(t_2) = \mathbf{0}$), Hamilton's Principle for material volumes is obtained

$$\int_{t_1}^{t_2} [\delta T + \delta W] dt = 0. \quad (2)$$

McIver [2] was one of the first authors who derived an extended form of Hamilton's Principle for nonmaterial volumes by using Reynolds' transport theorem in the form below, developing the third term of Equation (1) in the form,

$$\frac{d}{dt} \int_V \rho (\mathbf{v} \cdot \delta\mathbf{p}) dV = \frac{d}{dt} \int_{V_u} \rho (\mathbf{v} \cdot \delta\mathbf{p}) dV_u + \int_{\partial V_u} \rho (\mathbf{v} \cdot \delta\mathbf{p}) (\mathbf{v} - \mathbf{u}) \cdot \mathbf{n} d\partial V_u. \quad (3)$$

Consider V_u as the the nonmaterial volume whose surface ∂V_u , with external normal unit vector \mathbf{n} , is moving according to a velocity field \mathbf{u} . Thus, McIver's statement of the principle of virtual work for open systems is obtained and the corresponding Hamilton's Principle can be derived through a similar mathematical procedure as described for material volumes,

$$\int_{t_1}^{t_2} \left[\delta T_u + \delta W - \int_{\partial V_u} \rho (\mathbf{v} \cdot \delta\mathbf{p}) (\mathbf{v} - \mathbf{u}) \cdot \mathbf{n} d\partial V_u \right] dt = 0. \quad (4)$$

McIver revealed an extra term related to the transport of momentum through the open boundary which is not present in closed systems, as observed when compared to Equation (2). Also, the author implicitly utilized $\delta T = \delta T_u$ with $\delta T_u = \frac{1}{2} \int_V \rho(\mathbf{v} \cdot \mathbf{v}) dV$ as the kinetic energy of the material particles within the nonmaterial volume V_u .

Later, it was found out that McIver's derivation does not recover the extended Euler-Lagrange equations for open systems obtained by Irschik & Holl [3]. In their paper, the authors derived the extended equations using the abstract concept of fictitious particles, which was first introduced in Truesdell & Toupin [7] for the generalization of Reynolds' transport theorem. These fictitious particles have some of same properties of their material counterparts like kinetic energy density, but their velocity is \mathbf{u} , the same of the control surface ∂V_u . Consider that \mathbf{r} represents their position and $\delta\mathbf{r}$ is the corresponding virtual displacement. Therefore, $\mathbf{u} = \frac{d\mathbf{r}}{dt}$. Further investigation of Hamilton's principle for nonmaterial volumes was then necessary.

This inconsistency was addressed in a paper by Casetta & Pesce [4]. Applying the concept of fictitious particles, the following mathematical statement can be proven

$$\begin{aligned} \delta T - \frac{d}{dt} \int_V \rho (\mathbf{v} \cdot \delta\mathbf{p}) dV &= \delta T_u + \int_{\partial V_u} \frac{1}{2} \rho (\mathbf{v} \cdot \mathbf{v}) (\delta\mathbf{p} - \delta\mathbf{r}) \cdot \mathbf{n} d\partial V_u \\ &\quad - \frac{d}{dt} \int_{V_u} \rho (\mathbf{v} \cdot \delta\mathbf{p}) dV_u - \int_{\partial V_u} \rho (\mathbf{v} \cdot \delta\mathbf{p}) (\mathbf{v} - \mathbf{u}) \cdot \mathbf{n} d\partial V_u. \end{aligned} \quad (5)$$

Replacing the first and the third terms of Equation (1) with Equation (5), a consistent form of the principle of virtual work for open systems is written. By integrating with respect to t over $t_1 \leq t \leq t_2$, the appropriate Hamilton's Principle was derived and Irschik & Holl [3] extended Euler-Lagrange Equations could be obtained. In this case, Hamilton's Principle for nonmaterial volumes is written as follows, [4]:

$$\int_{t_1}^{t_2} \left[\delta T_u + \delta W - \int_{\partial V_u} \rho (\mathbf{v} \cdot \delta\mathbf{p}) (\mathbf{v} - \mathbf{u}) \cdot \mathbf{n} d\partial V_u + \int_{\partial V_u} \frac{1}{2} \rho (\mathbf{v} \cdot \mathbf{v}) (\delta\mathbf{p} - \delta\mathbf{r}) \cdot \mathbf{n} d\partial V_u \right] dt = 0. \quad (6)$$

In contrast to Equation (4), not only a term for the transport of momentum appears, but also one related to the flux of kinetic energy through the control surface. Respectively, the third and fourth terms.

Whenever the last term of Equation (6) is equal to zero, McIver's form - Equation (4) - is recovered, which has been extensively utilized for the modeling of the pipe conveying fluid. In fact, take a system described by a set of a finite number of generalized coordinates q_i . Assume $(\cdot) = \frac{\partial(\cdot)}{\partial t}$. The following identities are valid: $\delta\mathbf{p} = \frac{\partial\mathbf{p}}{\partial q_i} \delta q_i = \frac{\partial\mathbf{v}}{\partial \dot{q}_i} \delta q_i$ and $\delta\mathbf{r} = \frac{\partial\mathbf{r}}{\partial q_i} \delta q_i = \frac{\partial\mathbf{u}}{\partial \dot{q}_i} \delta q_i$. In the case of an extensible pipe, from those identities, it can be proved that the last term in Eq (6) is nonzero, as outlined in the next section.

Extensible Pipe Conveying Fluid

Imagine a cantilevered, slender, cylindrical and flexible pipe constituted by an elastic linear material, that is subjected to large displacements and small strains in a 2D plane. Therefore, it can be considered as a Euler-Bernoulli beam with geometric nonlinearities. Its undeformed configuration is vertical. An internal axial, steady and incompressible flow is

Figure 1: The 2D model.

present and its velocity profile is modeled as a plug flow. No external fluid or hydrodynamic loads exist. The pipe is considered slender, so a singular position could be described by the centerline. The system is depicted in Figure 1a.

The fixed point of the centerline is adopted as the origin of a coordinate system (x, z) with corresponding unit vectors $(\mathbf{e}_1, \mathbf{e}_2)$, defining an orthonormal basis. The x -coordinate is parallel to the length of the tube in the reference position and aligned with the local gravitational field. Thus, its undeformed configuration is denoted by $(x_0, z_0) = (x_0, 0)$, with $x_0 = 0$ being the fixed end and x_0 the free end. The associated position vector is $\mathbf{R} = (x, z)$, displacements are $u = x - x_0$ and $w = z - z_0 = z$, s is the arc length coordinate along the centerline and $\kappa = \left| \frac{\partial \mathbf{R}^2}{\partial s^2} \right|$ is the curvature.

The unstretched pipe length is L , its bending stiffness is EI , axial stiffness EA , Poisson's ratio ν (volume change rate $b = 1 - 2\nu$) and linear mass m . Consider E as the Young's modulus, A as the sectional area (A_i is the internal area) and I as the area moment of inertia around the z -axis. The fluid linear mass is M and the flow has a velocity $U\boldsymbol{\tau}$, in which $\boldsymbol{\tau} = \frac{\partial \mathbf{R}}{\partial s}$ is the instantaneous tangent unit vector. The gravitational acceleration is g . The nonmaterial volume is constituted by the open surfaces $S_{ae} \cup S_{as}$ and the closed boundary S_f .

On the modeling of the internal flow velocity

If the pipe is considered inextensible, the velocity field U is equal to the constant U_0 . When the extensibility condition is utilized, Ghayesh, Païdoussis & Amabili [8] proposed an expression for U along the pipe length based on the conservation of the volumetric flow rate inside the pipe

$$U = U[q_i] = \frac{1 + \varepsilon[q_i]}{1 + b\varepsilon[q_i]} U_0, \quad (7)$$

where ε is the axial strain. As ε is a function of the generalized coordinates of the problem, so is U .

In the present work, the authors adopt the conservation of mass for incompressible flows applied in an infinitesimal volume of the tube (Fig. 1b) to obtain an generalized form for U . Consider that its length is ds and the velocities upstream and downstream are U and $U + dU = U + \frac{\partial U}{\partial s} ds$, respectively. Using the definition of $\frac{\partial U}{\partial s} ds = \frac{\partial U}{\partial s} \frac{\partial s}{\partial x_0} dx_0 = \frac{\partial U}{\partial x_0} dx_0$, $\varepsilon = \frac{ds - dx_0}{dx_0}$ and area variation due to Poisson effect through the volume change rate b , it can be proven that

$$U = U[\dot{q}_i; q_i] = U_0 - \int_0^{x_0} \frac{b(1 + \varepsilon[q_i])}{1 + b\varepsilon[q_i]} \frac{\partial \varepsilon[q_i]}{\partial t} dx_0. \quad (8)$$

Notice that the expression above is a function of both the generalized coordinates and velocities of the problem.

Derivation of the equations of motion

The equations of motion in the continuum are formulated up to polynomial cubic-order terms with Equation (6) and discretized with Galerkin's method, originating ODEs. The kinetic energy T_u accounts for the tube and fluid particles, so

$$T_u = \frac{m}{2} \int_0^L \dot{\mathbf{R}} \cdot \dot{\mathbf{R}} dx_0 + \frac{M}{2} \int_0^L (\dot{\mathbf{R}} + U\boldsymbol{\tau}) \cdot (\dot{\mathbf{R}} + U\boldsymbol{\tau}) dx_0. \quad (9)$$

Suppose, for the sake of simplicity, that the work of the nonconservative forces is identically null, thus $W = -V$, in which V is the potential energy related to the deformation of the pipe and the gravitational field

$$V = \frac{EA}{2} \int_0^L \varepsilon^2 dx_0 + \frac{EI}{2} \int_0^L (1 + \varepsilon)^2 \kappa^2 dx_0 - (m + M)g \int_0^L x dx_0. \quad (10)$$

Considering the nonmaterial volume, we can write $\mathbf{v} = \dot{\mathbf{R}} + U\boldsymbol{\tau}$ and $\mathbf{u} = \dot{\mathbf{R}}$, therefore, $\delta\mathbf{p} = \left(\frac{\partial \dot{\mathbf{R}}}{\partial \dot{q}_i} + \boldsymbol{\tau} \frac{\partial U}{\partial \dot{q}_i} \right) \delta q_i$ and $\delta\mathbf{r} = \frac{\partial \dot{\mathbf{R}}}{\partial \dot{q}_i} \delta q_i$. The transport terms are nonzero only if $x_0 = L$, so

$$\int_{\partial V_u} \rho (\mathbf{v} \cdot \delta\mathbf{p}) (\mathbf{v} - \mathbf{u}) \cdot \mathbf{n} d\partial V_\mu = MU \left[\left(\dot{\mathbf{R}} + U\boldsymbol{\tau} \right) \cdot \left(\frac{\partial \dot{\mathbf{R}}}{\partial \dot{q}_i} + \boldsymbol{\tau} \frac{\partial U}{\partial \dot{q}_i} \right) \right] (\boldsymbol{\tau} \cdot \boldsymbol{\tau}) \delta q_i \Big|_{x_0=L}, \quad (11)$$

$$\int_{\partial V_u} \frac{1}{2} \rho (\mathbf{v} \cdot \mathbf{v}) (\delta\mathbf{p} - \delta\mathbf{r}) \cdot \mathbf{n} d\partial V_u = \frac{M}{2} \frac{\partial U}{\partial \dot{q}_i} \left[\left(\dot{\mathbf{R}} + U\boldsymbol{\tau} \right) \cdot \left(\dot{\mathbf{R}} + U\boldsymbol{\tau} \right) \right] (\boldsymbol{\tau} \cdot \boldsymbol{\tau}) \delta q_i \Big|_{x_0=L}. \quad (12)$$

A discussion about the term related to the flux of kinetic energy - Eq. (12) - is also found in Kheiri & Païdoussis [5]. This term relies on the value of $\delta\mathbf{p} - \delta\mathbf{r} = \boldsymbol{\tau} \frac{\partial U}{\partial \dot{q}_i} \delta q_i$. If the pipe is ideally inextensible, $U = U_0$ and $\frac{\partial U}{\partial \dot{q}_i} = 0$. When the extensibility condition is utilized as in Ghayesh, Païdoussis & Amabili [8], Equation (7), the velocity U is not a function of the generalized velocities, therefore, it still cancels out. The present research proposes Equation (8) as an expression for U . Under this condition, $\frac{\partial U}{\partial \dot{q}_i} \neq 0$.

The polynomial cubic-order equations of motion in the continuum are derived following Variational Calculus techniques. Considering established dimensionless quantities well defined in the literature listed in Table 1, the PDEs can be rewritten and discretized via Galerkin's method.

Table 1: Dimensionless quantities.

Dimensionless parameter	Symbol	Definition
Undeformed coordinate	ξ	$\frac{x_0}{L}$
Axial coordinate and displacement	\hat{x}, \hat{u}	$\frac{x}{L}, \frac{u}{L}$
Transversal coordinate and displacement	\hat{z}, \hat{w}	$\frac{z}{L}, \frac{w}{L}$
Time	τ	$\left(\frac{EI}{M+m} \right)^{1/2} \frac{t}{L^2}$
Axial and flexural stiffness ratio	α	$\frac{EA}{EI} L^2$
Internal flow velocity	v	$\left(\frac{M}{EI} \right)^{1/2} U_0 L$
Quotient between linear masses	β	$\frac{M}{M+m}$
Gravitational and flexural stiffness ratio	γ	$\frac{M+m}{EI} g L^3$

For the proposed discretization, the ODEs are obtained assuming

$$\hat{u}[\xi; \tau] \cong \sum_{k=1}^N \psi_k[\xi] \hat{u}_k[\tau], \quad (13)$$

$$\hat{w}[\xi; \tau] \cong \sum_{k=1}^N \psi_k[\xi] \hat{w}_k[\tau], \quad (14)$$

in which ψ_k represents the family of projection functions

$$\psi_k[\xi] = \sqrt{2} \left(\frac{1 - \cos \Lambda_k \xi}{\Lambda_k} \right). \quad (15)$$

Each value Λ_k results from the characteristic equation $\cos \Lambda_k = 0$. With these definitions, fixed end boundary conditions $\hat{u}[\xi = 0; \tau] = 0$, $\hat{w}[\xi = 0; \tau] = 0$ and $\frac{\partial \hat{w}}{\partial \xi}[\xi = 0; \tau] = 0$ are satisfied.

Results

Through a process of linearization of the corresponding nonlinear ODEs around the static equilibrium configuration - using v as a control parameter - root loci diagrams can be obtained and the stability of the system evaluated with the determination of the critical velocity v_{crit} by assessing the real part of the eigenvalues, following Lyapunov's indirect method. Numerical integration is utilized to verify the dynamic behavior observed in the Argand's type diagrams. The nonlinear equations of motion of the inextensible pipe conveying fluid obtained by Semler, Li & Païdoussis [9] are also discretized with Equation (14) and analyzed. These results are compared with the proposed extensible model, which is consistent with the continuity equation, and the extensible system found in Ghayesh, Païdoussis & Amabili [8]. Two distinct scenarios of Table 3 are investigated with $N = 8$. The values are commonly used in the technical literature.

Table 2: Chosen scenarios.

Scenarios	β	α	ν	b	γ
S1	0.2	1000	0.5	0	0
S2	0.2	1000	0.5	0	100

It is important to note that the static equilibrium configuration for the transversal displacement is equal to zero because no external forces are assumed. For the extensible models, the axial static displacement is a function of γ and v , and is depicted with a graphic of $u \times v$ for some cross sections of the pipe; while the static displacement is identically zero in the inextensible case.

Root loci of the linearized models

The root loci diagrams show how each period T_i evolves with v , also displaying a color scale related to the value of the real part of the corresponding eigenvalue λ_i , i.e., characterizing the stability of the system in the neighborhood of the static equilibrium points. The eigenvalues and periods related to the transversal modes are shown in the inextensible diagrams. In the extensible ones, the associated axial quantities are perceived.

Figures 2 and 3 illustrate the stability analysis of **S1**. According to Figures 2, 3b and 3d, a Hopf bifurcation in the second transversal mode occurs at approximately the same value, defining the critical velocity $v_{crit} \approx 5.6$. The curves associated with the transversal modes are similar, with discrepancies for higher values of v in the post-critical interval, related to the order of the terms utilized in the derivation of each set of equations of motion and their linearizations. The axial periods present in the extensible diagrams remain almost constant. The main difference between the extensible models can be found in the axial static equilibrium configuration of Figures 3a and 3c: with the increase of v , a contraction is present in all the cross sections of the proposed extensible model, while in the results from Ghayesh, Païdoussis & Amabili [8], there is no static displacement.

Figure 2: Root locus of the inextensible model for Scenario **S1**.

The stability analysis of Scenario **S2** is presented in Figures 4 and 5. The gravitational effects associated to $\gamma \neq 0$ are well documented in the literature, thus, a higher critical velocity is expected and noticed. In all the models, a Hopf bifurcation happens in the third transversal mode. For the inextensible model and the extensible model formulated in [8], Figures 4 and 5d, $v_{crit} \approx 10.5$, whereas in the proposed extensible model, Figure 5b, $v_{crit} \approx 11.3$, a significantly different value. The periods related to the axial modes are still relatively constant with v .

The behavior of the axial static configurations of Figures 5a and 5c are remarkably distinct: as $\gamma > 0$, there is a pipe elongation present in both of the graphs at $v = 0$, but a contraction in all the cross sections exists for the proposed extensible model and the elongation becomes higher in the case of the model based on [8].

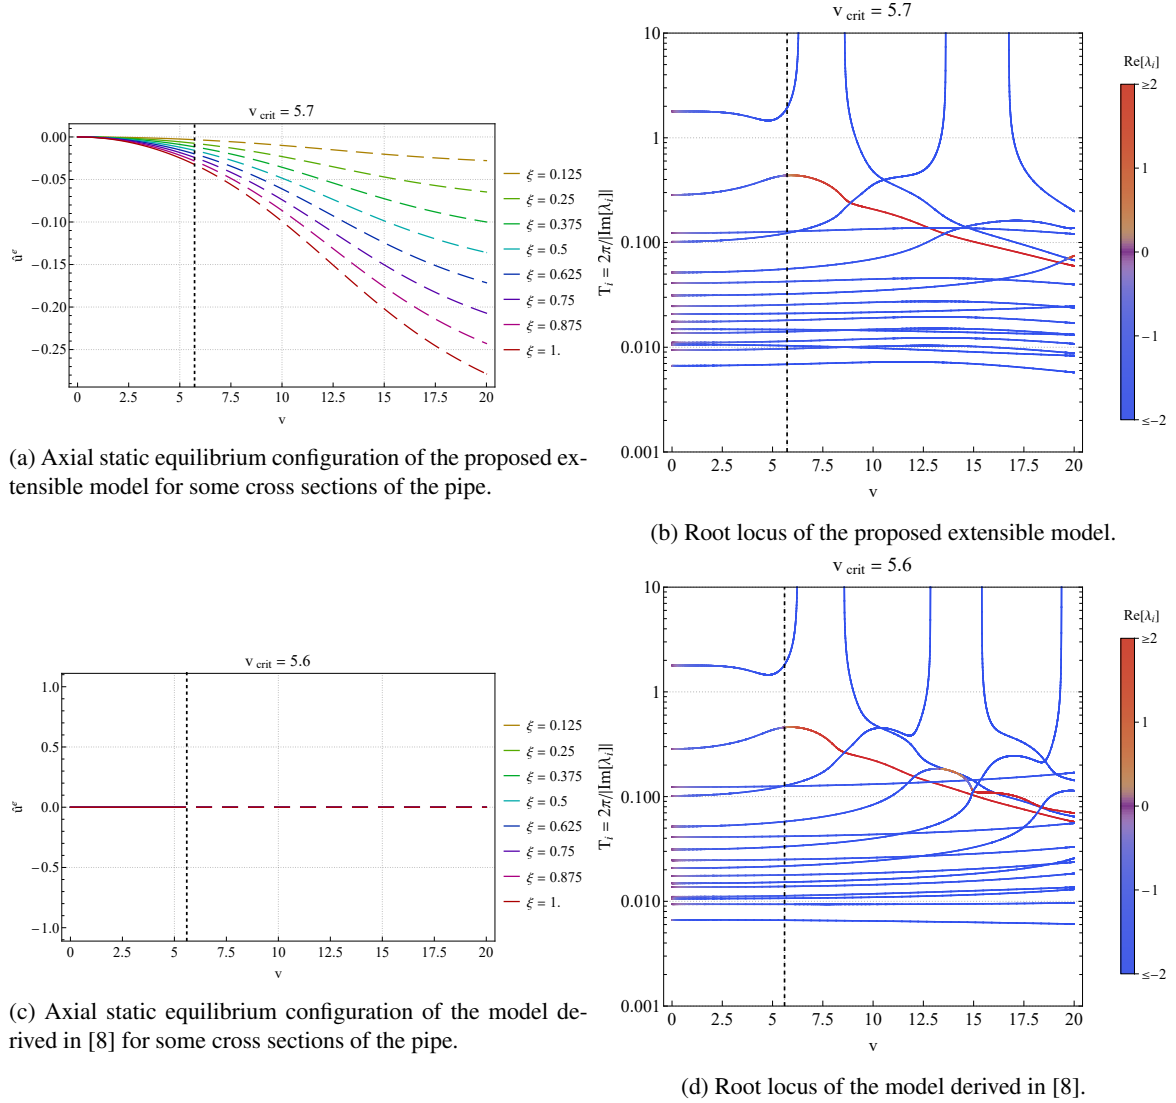

Figure 3: Stability analysis of the extensible models for Scenario S1.

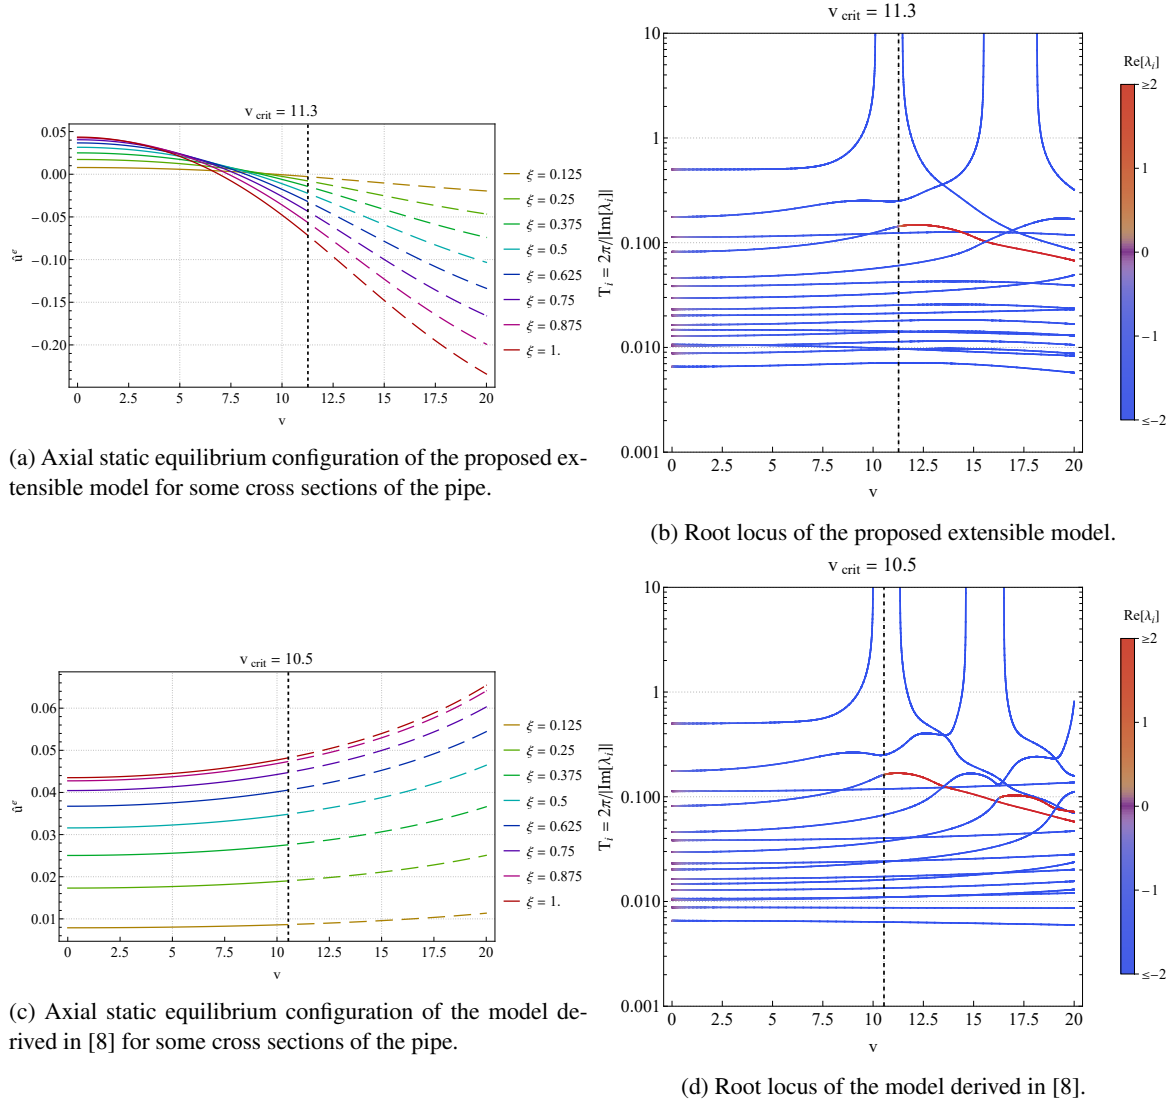

Figure 4: Root locus of the inextensible model for Scenario S2.

 Figure 5: Stability analysis of the extensible models for Scenario **S2**.

Numerical integration

Numerical integration of the nonlinear equations of motion of Scenario **S2** at $v = 11$ is done to verify the different behaviors foreseen from the root loci: for the ideally inextensible model and the extensible model of Ghayesh, Paidoussis & Amabili [8], there is a dynamic instability denoted by limit cycles; for the extensible model proposed in this work, the root loci indicate stability in the vicinity of the static equilibrium points. The free end ($\xi = 1$) axial and transversal displacements are shown in the Figures 6 and 7.

 Figure 6: Numerical integration of Scenario **S2** at $v = 11$ of the inextensible model shows dynamic oscillatory instability.

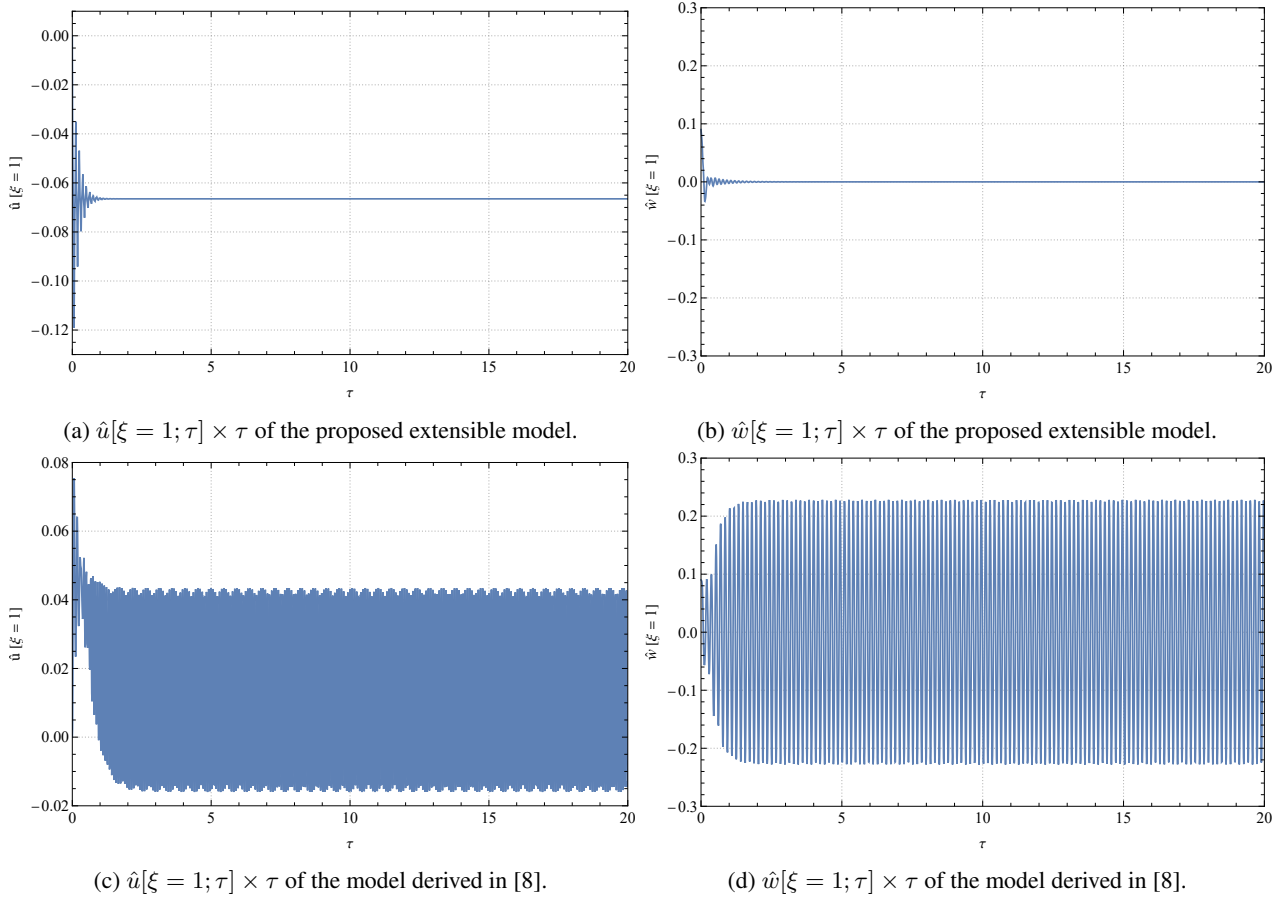

Figure 7: Numerical integration of Scenario **S2** at $v = 11$ of the proposed extensible model shows stability around the static equilibrium, while Ghayesh, Païdoussis & Amabili [8] extensible model displays a post-critical oscillatory regime.

The results obtained in time domain are consistent with those predicted by the linear analysis. Post-critical oscillatory regimes are noticed in the graphics of the inextensible and Ghayesh, Païdoussis & Amabili [8] models, whereas the proposed extensible model - which satisfies the conditions of the conservation of mass - shows stability.

Concluding Remarks

In this paper, a 2D reduced-order model for the cantilevered extensible pipe conveying fluid problem is proposed, in which the necessary conditions for conservation of mass (continuity equation) are satisfied. This model is obtained using the Extended Hamilton's Principle for nonmaterial volumes as formulated in Casetta & Pesce [4], with a cubic-order polynomial truncation and approximation followed by a discretization procedure based on Galerkin's method.

Although the formulation of the extensible model has similarities with nonlinear models of large displacements and small strains much discussed in the technical literature, the main difference is the consistent consideration of the conservation of mass in the internal flow. With such a hypothesis, a closed-form expression along the pipe length for the internal velocity U can be derived, which is a function of both the generalized coordinates and velocities of the problem (Eq. (8)). Previously, an extensible model discussed in Ghayesh, Païdoussis & Amabili [8] utilized Equation (7), in which the internal velocity U only depends on the generalized coordinates.

These distinct expressions for U have implications in the term related to flux of kinetic energy present in the Extended Hamilton's Principle, the fourth term of Equation (6). Under the assumption of an ideally inextensible pipe or Ghayesh, Païdoussis & Amabili [8] extensible model, this term is identically zero and the Hamilton's Principle for nonmaterial volumes is reduced to a form first obtained in McIver [2], Eq. (4). With the consideration of the proposed extensible model, the term associated with the transport of kinetic energy is nonzero and scenarios are investigated to study its influence on the dynamic response of the system.

Two tools are utilized for the comparison of the inextensible equations of motion of Semler, Li & Païdoussis [9], the extensible model described in this work and the extensible one obtained in Ghayesh, Païdoussis & Amabili [8]: (i) root loci diagrams calculated in the neighborhood of the static equilibrium configuration with v as control parameter and the characterization of the stability condition through Lyapunov's indirect method; (ii) numerical integration of the discretized nonlinear equations of motion to verify the dynamic behavior predicted by the root loci diagrams.

The analysis indicate a similar response for Scenario **S1** for all the models, with a Hopf bifurcation associated with the second transversal mode determining a critical velocity of $v_{crit} \approx 5.6$. The axial static equilibrium configuration of the

extensible models are distinct: for the proposed model, there is a contraction with the increasing of v , whereas for the extensible one derived in [8], the static displacement is zero.

For Scenario **S2**, a Hopf bifurcation occurs at the third transversal mode, but for the consistent extensible model $v_{crit} \approx 11.3$, and for the others, $v_{crit} \approx 10.5$. The root loci diagrams show a deviation of the present critical velocity with the numerical integration, confirming the expected response at $v = 11$ for the models. The axial static equilibrium remains different for the two extensible pipes.

Thus, extensibility effects may have substantial practical implications in the dynamics of this kind of system. The results obtained with the proposed extensible model reveal a higher critical velocity in a given scenario and different axial static configurations when compared to the cited previous models.

Acknowledgments

The São Paulo State Research Foundation (FAPESP) is gratefully acknowledged, for having supporting the whole development of the basic mathematical formalism, since 2012, through the Grants 2016/09730-0, 2013/02997-2 and 2012/10848-4, which set the fundamental grounds for this research to be successfully conducted, and for supporting the Conference attendance, Grant 2022/04072-5.

Summary. We develop two frameworks for “freezing” modulationally unstable wave packets of gravity waves over an uneven bottom modeled by a finite-depth third-order non-linear Schrödinger equation. We compare with experimental results in a 30 m wavetank featuring a sharp depth transition and propose a theoretical route for stabilizing of the modulated wave packets over an “adiabatic” depth variation.

Theoretical framework and experimental setup

We consider the stabilization of modulationally unstable wave packets within the framework of the nonlinear Schrödinger equation (NLS) in variable water depth [1].

$$i \frac{\partial U}{\partial \xi} + \alpha(kh) \frac{\partial^2 U}{\partial \tau^2} - \beta(kh) |U|^2 U = -i\mu_0 \frac{\partial(kh)}{\partial \xi} U \quad (1)$$

This is possible thanks to the simultaneous dependence of the parameters α and β in Eq. (1) on the adimensional depth (kh) , and has also been verified in an optical fiber experiment [4], where there is even more freedom to change the parameters.

We provide two frameworks for the understanding and development of the stabilization, or “freezing”, of highly modulated waves. The first theoretical framework is to connect a solution related to modulationally unstable waves, such as the Akhmediev breather (AB), to a solution like the dnoidal function which is related to a stable wavepacket. The second consists in reducing the phase space to that of a carrier wave of frequency ω_0 and the first two sidebands at $\omega_0 \pm \Omega$ (the so-called three wave picture). In this context, “freezing” the wave packet corresponds to an expansion of a homoclinic orbit and its transformation into an elliptic fixed point through the simultaneous variation of the NLS parameters α and β . We experimentally demonstrate this process in a $30 \times 1 \text{ m}^2$ water wave tank with a fake bottom floor as shown in figure 1 (a), and provide a rigorous theoretical description of this process for a sharp change in bathymetry [3]. We also provide a stabilization route when the bathymetry change is very slow [2]. The theoretical predictions in the three-wave picture and the measurements show that the relative phase among the side-bands locks to π and their relative amplitude oscillates around a finite value (fig 1, panels on the right). As shown in figure 1, apart from a 10% conversion to higher-order side-bands, this implies that the breathing stage of modulation instability (MI) is indeed frozen. We confirm that this complex wave dynamics is robust and such control of MI processes is feasible in a realistic experimental system. Our results highlight the influence of topography and how waveguide properties can influence and manipulate the lifetime of nonlinear and extreme waves.

Conclusions

We study the nonlinear stage of evolution of modulational instability in surface gravity waves over a water body of increasing depth. We show that this stage can be stabilized and results in a uniform train of pulses on a background. The initial condition does not need to be restricted to an exact NLS solution (as ABs), since we have shown that freezing occurs also in a three-wave system.

We have found a theoretical condition to dynamically stabilize unstable nonlinear waves. While the approach applies to any system described by the NLS equation, and could therefore be easily generalized to other dynamical models, we have experimentally confirmed our finding for the specific case of wave hydrodynamics. A sharp change in water depth simultaneously modifies the dispersion and nonlinearity experienced by surface gravity wave packets, thus dramatically modifying their dynamical behaviour. In the case of ABs, the separatrix expands and ends up enclosing the system trajectory, which is stabilized around an elliptic fixed point. This jump can be described as the optimal matching of an initial AB solution to a steady dnoidal solution of the universal NLS equation, illustrating the generality of this wave control process.

Although the flexibility available to vary parameters in the hydrodynamics of surface water-waves is much less than in other physical systems, such as optical fibers, our results help to clarify the possibility to dynamically control the breathing evolution of water wave-packets and to understand the impact of bathymetry on the persistence (or lifetime) of rogue waves.

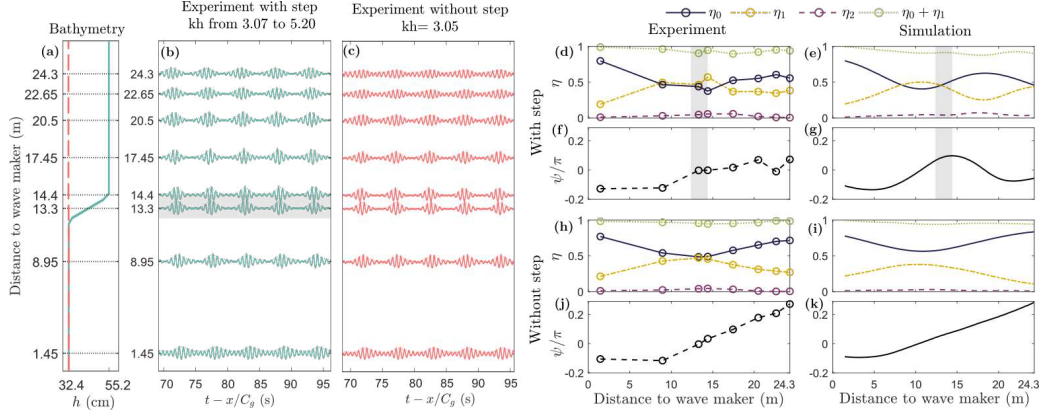

Figure 1: Left: (a) Water wave flume with artificial floor setup (cyan line), and the constant floor setup (dashed coral line). (b) Wave height at each recorded position for the experiment with variable bathymetry, multiplied by a factor 20; the gray stripe indicates the position of the step. (c) Wave height at each recorded position for the experiment with constant bathymetry, multiplied by a factor 20. (d)–(k) Sideband evolution of the AB-type surface water wave over the adopted bathymetry with the depth step (d),(e),(f),(g), and the constant flat bottom h_0 (h),(i),(j),(k). Here the initial condition for the envelope is of the form $U(\xi, \tau = 0) = u_0 e^{i\varphi_0} + u_1 e^{i\Omega\varphi_1} + u_{-1} e^{-i\Omega\varphi_{-1}}$, the sideband fraction $\eta_j = |u_j|^2 / (|u_0|^2 + |u_1|^2 + |u_{-1}|^2)$ and the relative phase $\psi = (\varphi_1 + \varphi_{-1})/2 - \varphi_0$. (d)–(h) Sideband dynamics as identified from the eight gauge measurements, connected by a linear interpolation; (g)–(i) corresponding NLS equation-simulated evolution. (d),(e),(h),(i) Sideband fractions η_0, η_1, η_2 of modes at detuning 0 (carrier), Ω , and 2Ω , respectively. (f),(g),(j),(k) Phase ψ of first-order sidebands (modes at $\pm\Omega$) relative to the carrier frequency.

Figure 2: Evolution of the envelope amplitude (shown in meters on the colorbar) from a perturbed plane wave initial condition to a stabilized modulated wave packet over a constant slope from 2 m to 5 m.

Experimental Investigation of Flexible Cantilevered Pipes Aspirating Water under VIV

Wagner Defensor, Celso Pesce, Guilherme Franzini, Guilherme Vernizzi, Vitor Maciel, Renato Orsino

Offshore Mechanics Laboratory, Escola Politécnica, University of São Paulo, Brazil

Summary. An innovative hydrodynamic campaign investigated three immersed flexible cantilevered aspirating pipes under VIV in a towing tank. Three experimental conditions have been considered: (i) aspirating flow; (ii) pure towing; (iii) combined aspirating and towing. Hopf bifurcations appeared in the aspirating case. Effects of supercritical internal flow on VIV were assessed and found small.

The experimental methodology and some results

The present extended abstract brings some experimental results concerning a hydrodynamic test campaign held at the Technological Research Institute (IPT) towing tank facility. The campaign showed ‘weak’ instabilities, of the Hopf bifurcation type, followed by fluttering of aspirating cantilevered flexible pipes, [1], [2], [3], and verified their small influence on VIV. Three flexible pipes, made of reinforced rubber hoses, with brass ballasts attached to the free end, were designed and built to respond, at the same towing speed, but each one at a distinct mode of vibration, the 1st, 2nd or 3rd (Figure 1, above, left). The motions of the pipes were tracked down by an underwater optical system. The *ballasted-hose* concept and the desired natural mode of vibration were identified by the acronyms BH- k ; $k = 1, 2, 3$. An in-house mathematical model [3] was specially derived and implemented to guide the design. Argand’s like diagrams predicted instabilities for all modes at very small internal aspirating flow velocities, (example for the BH-2 model in Figure 1, above-right). Aspirating flows up to $2v_{crit}$ were assessed, isolated and combined with towing (up to the modal reduced velocity $U_{ny}^* = U/f_{ny}D \approx 14$; $n = 1, 2, 3$). Data analysis employed Galerkin’s projection techniques in time domain, with modal functions obtained in the deformed configurations (also provided by the in-house model), followed by an innovative filtering procedure that uses the Empirical Mode Decomposition ([4], [5]), to remove very low frequency contents outside VIV’s range (Figure 2, charts below). Such slow motions occurred in the streamwise direction, as consequence of drag fluctuations due to the model deflection and the emission of tip vortices structures.

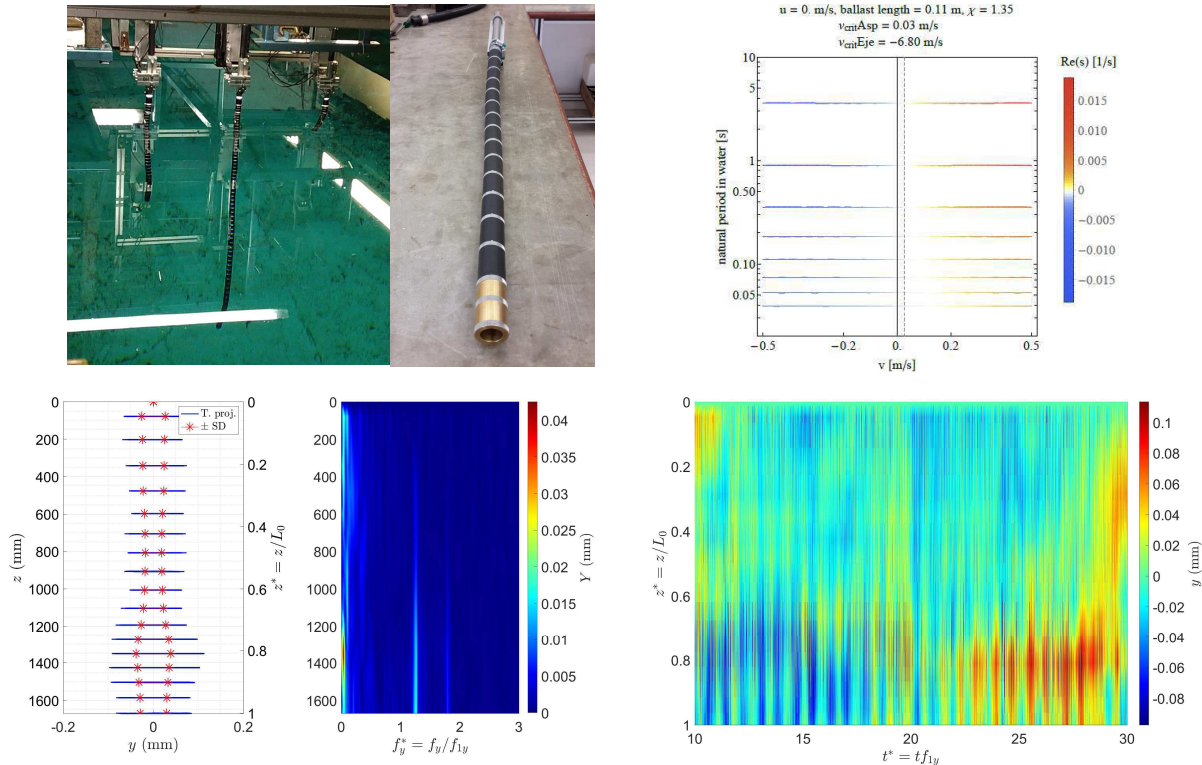

Figure 1: Above: left, ballasted-hose models; right, root-loci diagram, model BH-2. Below: aspirating case at $v = 2v_{crit}$; left to right: spanwise trajectories projections, amplitude spectra and coordinate scalogram, in the crosswise direction w.r.t. towing.

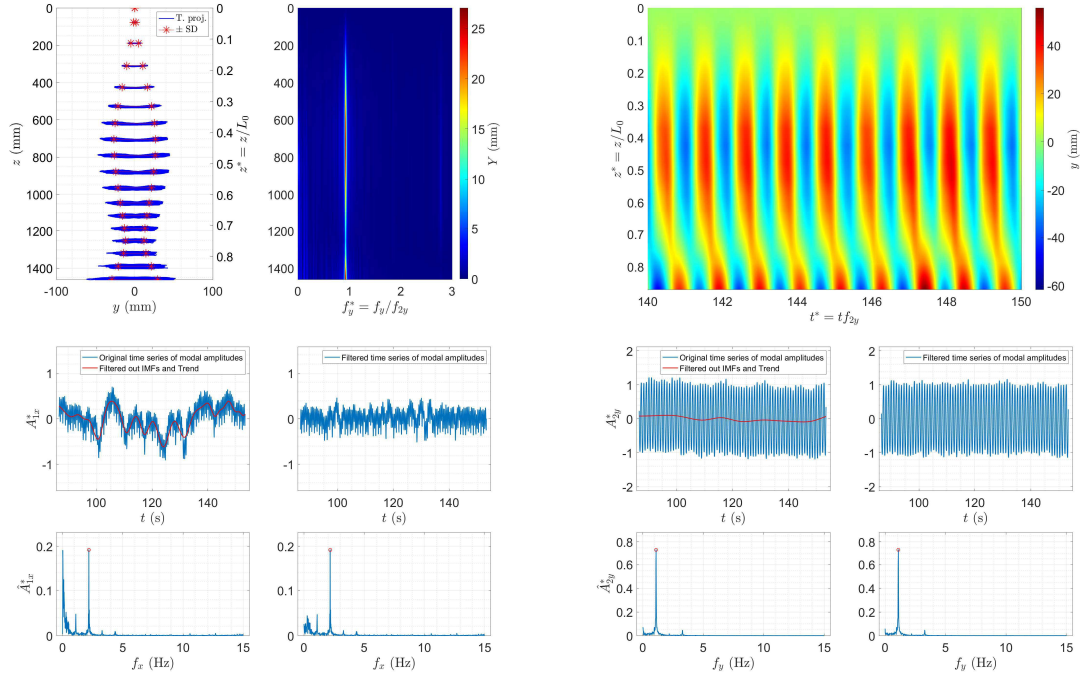

Figure 2: Model BH-2. Above, left to right: spanwise trajectories projections, amplitude spectra and coordinate scalogram, in crosswise direction. Below. EMD filtering of modal amplitude time series of the 1st and the 2nd mode shapes in streamwise (left) and crosswise (right) directions. Towing at modal reduced velocity $U_{2y}^* = 8.37$ ($U = 0.33$ m/s).

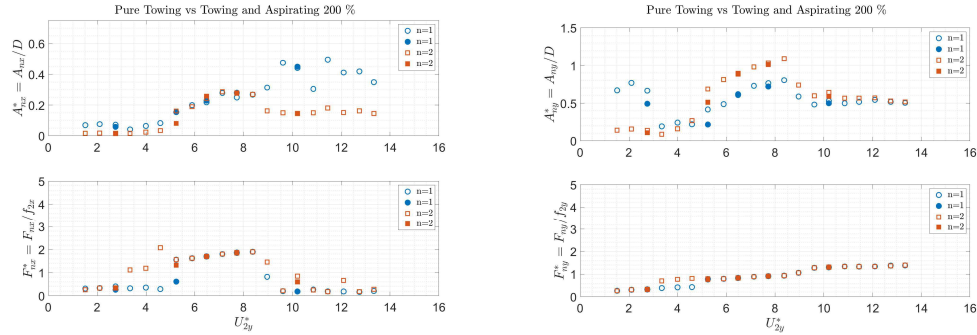

Figure 3: Model BH-2. Dimensionless modal amplitudes A_{nx}^* and A_{ny}^* and dimensionless dominant oscillation frequencies F_{nx}^* and F_{ny}^* of the n^{th} vibration mode contributions, as function of modal reduced velocity U_{2y}^* , in streamwise (left) and crosswise (right) directions. Empty markers: towing only. Filled markers: towing and aspirating at $v = 2v_{crit}$.

In pure aspirating conditions, at $v = 2v_{crit}$, a 1st natural mode instability is depicted in the spanwise amplitude spectra at $f_y^* \approx 1.25$ and in the scalogram, coordinate shifting between positive and negative values along time (Figure 1, below, left and right, respectively). An expected behavior showed up in the pure towing case, the 2nd natural mode shape dominating the dynamics (Figure 2, above). An example of the EMD filtering procedure is presented in Figure 2 (below). VIV is practically not altered by the aspirating flow, even at $v = 2v_{crit}$ (Figure 3). Aside a small decrease in amplitudes and in the respective dominant frequency values, no significant differences in modal responses were observed, compared to the pure towing case. Moreover, the aspirating flow mitigated the low frequency content in the streamwise oscillation, possibly by changing the tip vortex field structure. A more detailed analysis shall be presented in the full paper.

Summary. This study reports on the dynamic response of two elastically-mounted circular cylinders in tandem undergoing transverse flow-induced vibration (FIV) in a free-stream flow. The results show that the FIV responses of the two cylinders are affected significantly by the cylinder-cylinder spacing ratio. This study suggests that there exist a variety of FIV response regimes as a function of the flow reduced velocity and the spacing ratio.

Introduction

The dynamics in flow-induced vibration (FIV) of structures is of substantial continuing interest, due to its intrinsic nature in science and importance in a large variety of engineering applications, such as offshore structures in ocean currents, and high-rise buildings and bridges in winds. In the past six decades, numerous studies have been motivated to fundamentally characterise FIV of bluff bodies and to provide insights into mechanisms of the fluid-structure interaction. This has led to a large body of work with a focus on FIV problems of a single body, e.g. two typical body oscillator phenomena of FIV, *vortex-induced vibration (VIV)* of a circular cylinder and *galloping* of a non-circular cylinder that is susceptible to an aerodynamic instability induced by the body movement (see [1]). On the other hand, considerable studies have also been conducted on flow past two fixed cylinders in tandem (see [2]), and transverse *wake-induced vibration (WIV)* of a free cylinder in the downstream of a fixed cylinder (e.g. [3]). These studies have shown that the spacing between two cylinders in tandem is a key parameter affecting the flow pattern and thus the fluid forcing on the bodies, resulting in complex nonlinear dynamics and structural response. However, much less work has been conducted on the FIV responses of two freely-vibrating cylinders in tandem; this is particularly so for cylinders with low mass ratio (the ratio between the total oscillating mass to the displaced fluid mass) at moderate Reynolds numbers. Thus, this study aims to gain a better understanding of the influence of the cylinder spacing on the FIV responses of two freely-vibrating cylinders in tandem in a free-stream flow, and to analyse the nonlinear dynamics of the fluid-structure interactions and the interaction between the two cylinders, through an experimental investigation of the fluid-structure system with low mass ratio at moderate Reynolds numbers.

Experimental method

The present FIV problem was modelled on two low-friction air-bearing systems (see [4]) in conjunction with the free-surface recirculating water channel of the *Fluids Laboratory for Aeronautical and Industrial Research (FLAIR)*, Monash University. This water channel facility has a test section of 600 mm in width, 800 mm in depth and 4000 mm in length.

The cylinders were vertically mounted onto two separated air-bearing systems. These cylinders, which were precision made from aluminium tubes and anodised against water corrosion, had an outer diameter of $D = 40 \pm 0.010$ mm and an immersed length of $L = 614$ mm, giving an aspect ratio of $= L/D \approx 15.4$. For each cylinder, the total oscillating mass was $m = 1473.1$ g, and the displaced mass of the fluid was $m_d = 770.3$ g, giving a mass ratio of $m^* = m/m_d = 1.91$. The natural frequencies of the two hydro-elastic systems were measured by conducting free decay tests individually in air (f_{na}) and in quiescent water (f_{nw}). The structural damping ratio with consideration of the added mass (m_A) was determined by $\zeta = c/2\sqrt{k(m + m_A)}$, with $m_A = ((f_{na}/f_{nw})^2 - 1)m$. As shown in table 1, the natural frequencies were almost identical for the two circulars, while the difference in ζ was sufficiently small to have negligible effects. The FIV responses of the two cylinders were investigated for the spacing ratio (denoted by S^* as the streamwise spacing between the cylinder centres, S , normalised by the cylinder diameter, D , namely $S^* = S/D$) ranging from 1.25 to 15.0 over a wide reduced velocity range of $3 \leq U^* = U/(f_{nw}D) \leq 30$ and a corresponding Reynolds number range of $1570 \leq Re = UD/\nu \leq 15\,700$, where U is the free-stream velocity, f_{nw} is the natural frequency in water of the upstream cylinder and ν is the kinematic viscosity. More experimental details can be found in [4].

Results and discussion

Figure 1 shows the normalised amplitude responses as a function of the flow reduced velocity for the two cylinders with various spacing ratios. The amplitude response is denoted by A_{10}^* , which represents the mean of the top 10% amplitude

Cylinder	m [g]	m_d [g]	m^*	f_{na} [Hz]	f_{nw} [Hz]	ζ
upstream	1473.1	770.3	1.91	0.432	0.343	2.02×10^{-3}
downstream	1473.1	770.3	1.91	0.430	0.345	1.78×10^{-3}

Table 1: The present experimental parameters of the two (upstream and downstream) cylinders in tandem.

Figure 1: The normalised amplitude responses of the two cylinders in tandem as a function of the reduced velocity for various spacing ratios. The amplitude responses of the upstream and downstream cylinders (UC and DC) are plotted in (a) and (b), respectively.

peaks normalised by D .

As can be seen, the spacing ratio plays an important role affecting the amplitude responses of the two cylinders. For the cases of $S^* \leq 2.00$, the vibration of the upstream cylinder (UC) can be significantly enhanced in terms of the peak amplitude and also the U^* range exhibiting large body oscillation amplitude, as compared to that of a typical three-branch VIV response of a single circular cylinder (not shown here). For example, the A_{10}^* response of $S^* = 1.25$ displays an initial branch for low reduced velocities ($U^* < 5$), which is similar to that of the single cylinder case, but as U^* is further increased it exhibits a largely fluctuating variation to reach a peak value of $A_{10}^* \simeq 1.99$ at $U^* = 21.2$ (an increase of 234% against that observed in the VIV upper branch of the single cylinder case), prior to a gradual decrease trend to $A_{10}^* \approx 1.0$ for $U^* > 25$. As S^* is increased to 1.60, after reaching a peak value of $A_{10}^* \simeq 1.12$ at $U^* = 8.0$, the A_{10}^* response shows a gradual decrease trend with increasing U^* , distinctly different from those of the lower S^* cases. As S^* is further increase to 2.0, the A_{10}^* response exhibit a variation profile similar to the typical three-branch VIV response of a single cylinder, but with much larger vibration amplitudes. Furthermore, for the cases of $S^* \geq 5.00$, the A_{10}^* responses appear to be highly similar to the single cylinder case, indicating that the upper cylinder vibration is negligibly influenced by the perturbation of the downstream cylinder.

On the other hand, the A_{10}^* response of the downstream cylinder (DC) is also influenced significantly by S^* . As a result of the strong interaction between the two cylinders, the A_{10}^* response of the downstream cylinder tends to increase with U^* , but with large fluctuations at high reduced velocities ($U^* > 7$), for the cases of $S^* \leq 2.00$. As S^* is increased to 5.00, the A_{10}^* response sees a fairly stable increase trend for $U^* > 7$. However, for the cases of $S^* \geq 10.00$, the A_{10}^* response tends to decrease gradually with U^* increasing beyond 7.

Conclusions

The transverse FIVs of two circular cylinders in tandem have been investigated as a function of U^* for various spacing ratio of $1.25 \leq S^* \leq 15.00$. It was found that for $S^* \leq 2.00$ the FIV responses of the two cylinders exhibit complex variations due to their strong interaction, where their vibration could be largely enhanced as compared to VIV of a single cylinder. Enhancement of the A_{10}^* peak of the upstream cylinder diminished for $S^* \geq 5.00$, whereas the downstream cylinder displayed a decrease trend in A_{10}^* with increasing U^* beyond 7 for $S^* \geq 10.00$. The present results indicate that there exist a variety of FIV response regimes that would be of great interest for further investigations.

Fluid dynamics effect in large array

Ande Raghu, Mathieu Sellier and Stefanie Gutschmidt

Department of Mechanical Engineering, University of Canterbury, Christchurch, New Zealand

Summary. Fluid dynamics investigation of coupled oscillators and arrays of beams are important for several applications in biology, medicine, and especially and increasingly for MEMS and NEMS sensors. The most available literature on oscillators is either a single beam or small-sized arrays. Limited literature is available concerning the dynamics of large-sized arrays of beams. Our group has dedicated its research goals to understanding coupled MEMS oscillators and array dynamics to enhance technologies such as fast-scan AFM, nanometrology, and precision lithography. Some of these applications require knowledge of arrays in a fluidic environment. Before investigating fluid-structure interactions of such large-array a sound understanding of the fluid motion is required, which is the focus of this work. We investigate a large array of beams using the boundary integral technique, where the flow is governed by unsteady Stokes and Continuity equation. The analysis is performed for all beams that are equally excited in phase for different gap sizes between the beams at different Reynolds numbers, including the comparison of an increasing array size with the same and varying array lengths. Results include the onset of array effects, added mass, and viscous dissipation for a critical number of beams M , the gap between the beams and Reynolds numbers. The analysis suggests an increase in interactions between the neighbor and non-neighbor beams with an increase in array size at the same array length. The work guides for the design of arrays in fluids for different spacing and Reynolds numbers.

Background

Tuck [1] and Green [2] present an extensive work of dynamics for an individual beam, whereas Basak [3] and Manickavasagam [4] conducted investigations on small arrays of beams (number of beams less than five). Much lesser work can be found on a large array in general. No details are available for the large array of beams oscillating in fluids. In this work, we focus on the fluid dynamics of the large arrays [5].

Methodology

We base our analysis on the well established Boundary Integral Method (BIM) applied to unsteady Stokes and continuity equations. By applying the BIM, we have deduced the partial differential equations into integral form to calculate the fluid properties over the beams within the array using the analytical equation 1.

$$f(Re, x) = \frac{i}{Re} \left(\frac{1}{x} + (1i \cdot \sqrt{iRe} \cdot \text{sgn}(x) \cdot K_1(\sqrt{iRe} \cdot \text{abs}(x) \cdot (-1i))) \right) \quad (1)$$

The closed-form analytical equation is extended for M number of beams by following the technique used by Basak [3] and Manickavasagam [4]. We investigate the velocity configuration of all beams active in-phase, where $x = (\xi'_j - \xi_k)$, ξ'_j is a node on the beam surface, ξ_k is the midpoint between any two nodes, $\xi_k = \frac{1}{2}(\xi_{j'} + \xi_{j'+1})$, Re is the corresponding Reynolds number and K_1 is the modified bessel function of first kind.

$$\xi'_j = (2 + 2\bar{g})m - (3 + 3\bar{g}) - \cos\left(\frac{\pi j}{N}\right) \quad [m = 1, 2, 3, \dots, M], \quad (2)$$

To mitigate the singularities at the edges, the beam is discretized into unequal segments by using a generalized equation 2, which is applicable to all array of beams if the number of beams M in an array is greater than or equal to two as shown in Figure 1a and \bar{g} is the nondimensional gap.

Analysis and Results

The following investigations are considered for a velocity configuration of all beams active with a gap between the beams \bar{g} of 0.1 as shown in Figure 1a, which is below the critical gap theoretically [6] at Reynolds number 0.1. The input velocity of the beams and the matrix obtained from the analytical equation yields the hydrodynamic force over the array. Absolute, real, and imaginary hydrodynamic forces give us new insights into the large-array in fluids [5]. In Figures 1b to 1d horizontal axis presents the normalized beam number, the absolute A(F), imaginary I(F) (added mass), and real part R(F) (viscous dissipation) of the hydrodynamic force [7] are normalized corresponding to its respective width of the beam and plotted on the vertical axis.

From Figure 1b, it is observed that at the same array length and different array size there is an increment in the added mass and viscous dissipation which is due to the array effect which can be observed with an increase in the number of beams in an array, whereas with varying array length and increase in array size there is little effect on the dissipation as shown in the Figure 1c and drastic increment in the added mass due to increase in the array length as shown in the Figure 1d. The interaction between neighbor and non-neighbor increases with an increase in array size and at the same array length. If the distance between the beams is below a critical gap where the interaction of beams in an array is high due

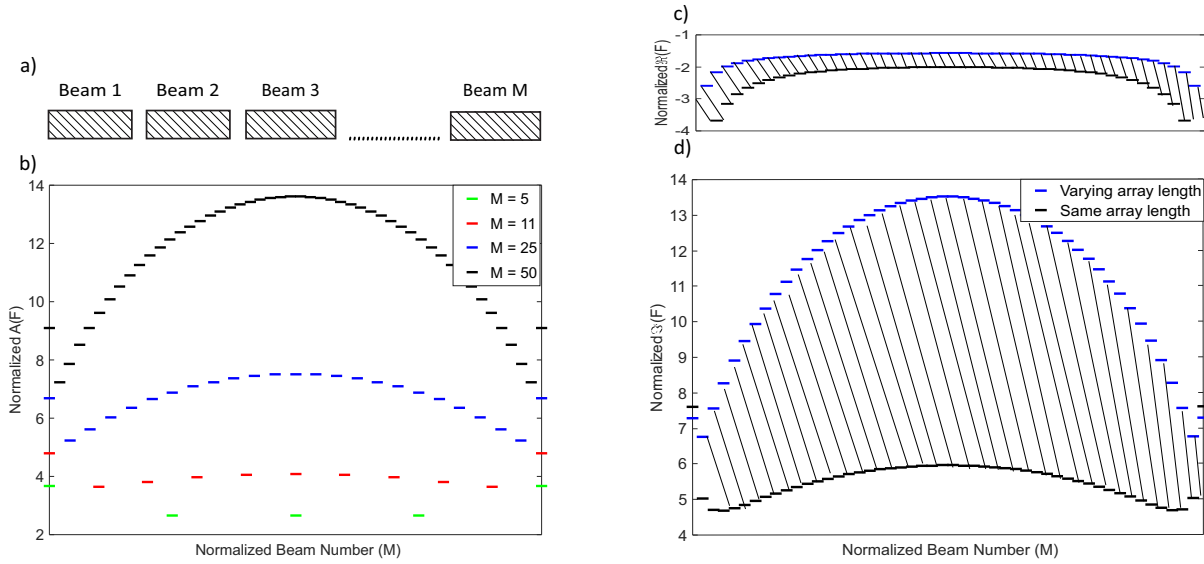

Figure 1: (a) Array of beams in non-viscous fluid (b) Absolute pressure for different array sizes (c) Real pressure and (d) Imaginary pressure for 50 beams array at $\bar{g} = 0.1$ and $Re = 0.1$.

to the overlapping of viscous layers, we can observe the array effect for varying the gaps between the beams for different Reynolds numbers. The hatched area in Figures 1c and 1d represents the increase in viscous dissipation and decrease in added mass with an increase in array size at the same array length.

Conclusions

It is important to understand the fluid dynamics of a large array of beams oscillating in the unbounded fluid environment to be able to accurately predict the full dynamics of such systems, and in turn to effectively develop future array technologies like AFM, lithography, and nano-metrology. In this work, we have extended the BIM of 2 beams by Basak [3] and small-sized arrays of beams by Manickavasagam [4] for any arbitrary number of beams to understand the associated array effects originating from the fluid environment. We have analyzed M equal to 5, 11, 25, 50 beams exciting in-phase in a non-viscous fluid to calculate the hydrodynamic forces of large arrays of beams for different gaps between the beams and Reynolds numbers. New insights from $A(F)$, $I(F)$, and $R(F)$ reveal critical design-relevant parameters for the development of future array technology. In addition, this work can be extended by oscillating the large array of beams close to a rigid surface and analyzing the influence of rigid surface on viscous damping and added mass.

Topology of exotic wakes

Morten Brøns*, Anne Ryelund Nielsen*, Puneet Matharu†, Matthias Heil†

**Department of Applied Mathematics and Computer Science, Technical University of Denmark, 2800 Lyngby, Denmark*

†*School of Mathematics, University of Manchester, Oxford Road, Manchester M13 9PL, UK*

Summary. The formation of vortices in the flow around an oscillating cylinder is shown to be a complex set of topological bifurcations as the amplitude of the cylinder oscillations is varied. We show that the transition from a wake where two vortices are shed per cycle, to a configuration with three vortices are shed, goes through intermediate stages, where secondary vortices are created but disappear again.

Introduction

The wake behind a transversely oscillating cylinder allows a remarkable richness of flow structures. Vorticity created at the cylinder surface is advected downstream and organizes into distinct vortices. For a stationary cylinder in the periodic regime, two vortices of opposite circulation are shed per cycle forming the famous von Kármán vortex street. This is also denoted a 2S wake, where S means the shedding of a single vortex [6]. When the cylinder oscillates, this pattern may be modified depending on the frequency and amplitude of the forced oscillation. Patterns such as 2P, P+S, 2P+2S have been observed – here P means the shedding of a pair of vortices from the same side of the cylinder. These configurations are known as exotic wakes [5]. Bifurcation diagrams in the frequency-amplitude parameter plane (f, A) have been established, both experimentally and computationally, by many researchers, e.g. [6, 3].

The purpose of the present paper is to study the bifurcations which lead from one pattern to another. We primarily consider the case where the oscillation frequency of the cylinder is chosen as the Strouhal frequency, that is, the frequency of the vortex shedding for a fixed cylinder. For low values of the amplitude of the oscillating cylinder the wake is of type 2S, but for the dimensionless amplitude A around 1, the pattern changes into P+S. In the entire parameter range we consider the flow is periodic. The Reynolds number is 100, where it is reasonable to assume the flow is two-dimensional. Simulations are performed using the `oomph-lib` finite-element library [1].

In this study we characterize a flow configuration by the topology of the vorticity field, and define a vortex as a local extremum of vorticity. An extremal point of vorticity can be created together with a saddle point in a forward cusp bifurcation [2]. Similarly, an extremum and a saddle may merge and annihilate in a backward cusp bifurcation. We note that there are alternative definitions of a vortex, for instance the Q -criterion, which has also been of use in identifying creation and destruction of vortices [4].

Results

The results are summarized in Fig. 1. We focus on the negative vortices formed at the top of the cylinder. For the dimensionless amplitude A less than about 0.85, a positive and a negative vortex on each side of the cylinder are formed in the shear layers a few diameters downstream. Once created, the vortices persist and are advected downstream. This is a classical 2S wake. See Fig. 1(a) for a typical example. Increasing A to 1 as in Fig. 1(b), the filaments of vorticity (shear layers) emanating from the vortices may turn into individual vortices through a forward cusp bifurcation. These secondary vortices disappear again after a few cycles in a backward cusp bifurcation. This intermediary pattern cannot simply be described by the symbols P and S. Increasing A the secondary vortices persist for longer and longer times. For $A = 1.08$, Fig. 1(c), the secondary vortices never disappear again, and a full P+S wake is formed.

Hence, the transition process from a 2S to a P+S wake does not occur at a specific value of A , but is a sequence of bifurcations, possibly infinitely many, over a quite large interval of the parameter.

Control optimization of digital hydraulic drive for knee exoskeleton

Rituraj Rituraj^{*}, Rudolf Scheidl^{*}

Summary. A successful knee exoskeleton device must follow the periodic motion of the gait cycle in an energy efficient manner. This work investigates an optimal control strategy that can allow the periodic behavior of such a device with minimum error while also consuming minimum energy. Using a multi-objective optimization technique, a trade-off between the periodicity error and energy consumption is demonstrated. From the pareto front, an optimal control variable set is determined which allows an acceptable periodic behavior of the knee exoskeleton with negligible energy consumption.

Introduction

Exoskeletons are wearable devices that provide additional strength to the wearer's limbs. These devices are commonly used in physical rehabilitation to assist in the recovery of a limb's motion and strength. Furthermore, they are used by factory workers, military personnel, and firefighters for carrying heavy equipment over long distances. Most of these devices currently use electromechanical drives for motion actuation. However, in recent years, hydraulically driven exoskeleton devices have gained interest among the researchers [1–3] due to their capabilities of high force density, easy energy recuperation, motion locking, and damping. The advent of digital hydraulic technology in the last decade has strengthened the case for hydraulically driven exoskeleton devices due the added advantages of high energy efficiency, power density, precision, and robustness.

Inspired by these benefits, the authors have recently developed a novel design of digital hydraulically driven knee exoskeleton [4]. A novel control strategy is also proposed in an upcoming work [5]. However, a key challenge with this exoskeleton device is its motion repeatability over multiple gait cycles. The device should track the desired knee motion in the same periodic manner as observed in typical gait cycles. Furthermore, to keep the power source light, the device should consume as little energy per gait cycle as possible. In this work, a control optimization study is conducted to determine the optimal sets of control variables that can allow the desired periodic behavior of the knee exoskeleton device with minimal energy consumption.

Knee exoskeleton design and control strategies

Figure 1 shows the knee exoskeleton design, its hydraulic drive, and the control strategies in different phases of the gait cycle. The comprehensive details are present in [4,5]. In brief, the exoskeleton device is actuated by two hydraulic cylinders. The hydraulic chambers of each of the cylinders are connected to the pressure source and tank via 2/2-way valves. The motion control is achieved via three different control strategies during different phases of the gait cycle. In the stance phase, where an inverse relation between the knee angle and knee torque exists, an elastic control is employed, which allows the hydraulic chambers to act as elastic elements. Next, a simplified form of the model predictive control (MPC) strategy is used to ensure proper tracking of the knee motion. Finally, a pressurization control strategy is employed for a brief period where hydraulic chambers are pressurized to the appropriate levels needed for the next gait cycle.

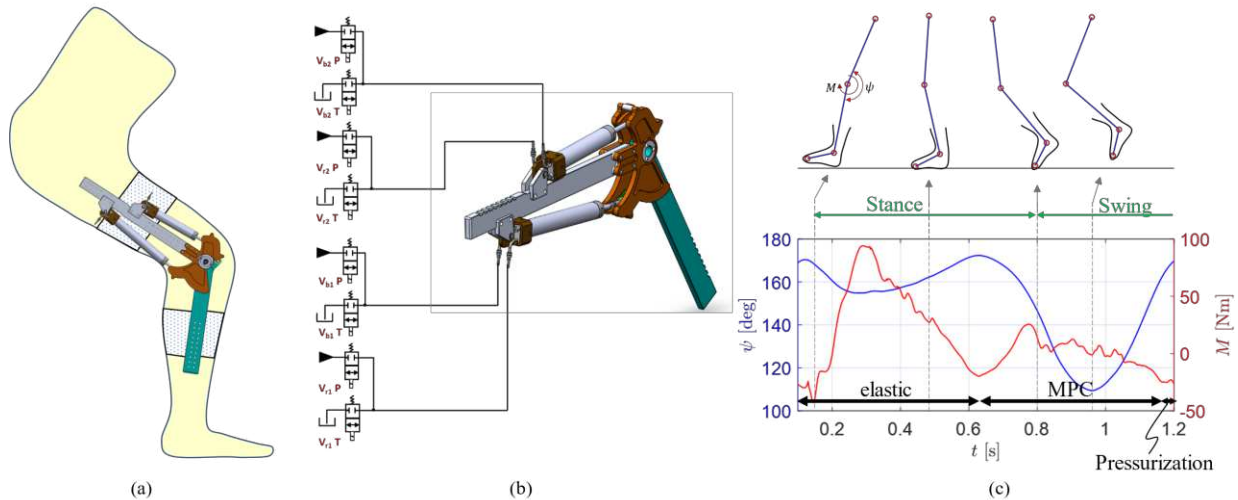

Figure 1: (a) Knee exoskeleton design, (b) hydraulic system, (c) phases in the gait cycle and control strategies used.

Control optimization study

The numerical simulations of the knee exoskeleton device show that the duration of each of the aforementioned control strategies and the time step involved in MPC significantly influence the accuracy of the periodic behavior of the device

motion over multiple gait cycles as well as the energy consumed per cycle. Thus, in the optimization study, the duration of the elastic control phase, the duration of the pressurization phase, and the time step in MPC algorithm are considered as the optimization variables.

The first optimization objective is to minimize the difference between the values of the state variables of the system at the beginning ($t = t_0$) and at the end of two gait cycles ($t = t_e$). The state variables are the knee angle (ψ), knee angle derivative ($\dot{\psi}$), and pressures in the four hydraulic chambers of the cylinders (p_i). Thus, the objective function is

$$\text{Minimize: } \epsilon = w_1 e_\psi + w_2 e_{\dot{\psi}} + w_3 \sum e_{p_i} \quad (1)$$

where, $e_\psi = |\psi_{t_0} - \psi_{t_e}|$, $e_{\dot{\psi}} = |\dot{\psi}_{t_0} - \dot{\psi}_{t_e}|$, $e_{p_i} = |p_{i,t_0} - p_{i,t_e}|$, and w_i are appropriately chosen weights.

The second objective is to minimize the energy consumed over two gait cycles. The energy consumption is determined as $E = V_p p_s$, where, V_p is the amount of fluid volume delivered by the pressure source and p_s is its pressure level.

This multi-objective optimization problem is solved using NSGA-II algorithm. The initial design space is populated with 1000 designs and the optimization algorithm is executed for 50 generations.

Results and discussion

Figure 2(a) shows the results obtained from the optimization study where the approximate pareto front is shown in red. Computational expensiveness limits the number of optimization generations and thus, the accuracy of the pareto front. Nevertheless, a trade-off between the periodicity error (ϵ) and the energy consumption (E) is observed. The negative energy consumption observed in the pareto front is the result of two factors. Firstly, the natural knee motion is inherently an energy delivering system over a complete gait cycle [6]. Secondly, several control variable sets save energy by supplying lower amount of high pressure fluid to the actuators. However, as observed in the figure, most of such sets exhibit high periodicity error.

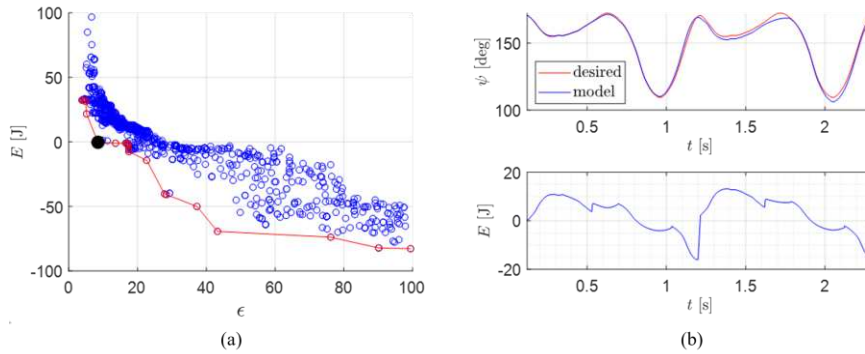

Figure 2: (a) Results from the optimization study with the pareto front shown in red, (b) Knee angle and energy consumption for a pareto optimal variable set (indicated as large black dot in Figure (a))

Figure 2(b) shows the simulation results obtained using a pareto optimal variable set (highlighted in large black dot in Figure 2(a)) for two gait cycles. The knee angle is tracked with reasonable accuracy and the energy consumption at the end of the gait cycle is almost zero. However, it is important to note that the losses due to internal friction were not considered in the energy calculation.

Conclusions

An investigation of the optimal control strategy for hydraulically driven knee exoskeleton is presented in this work. A multi-objective optimization study is conducted aimed at minimizing the error in the periodic behavior of the exoskeleton motion and the energy consumption per gait cycle. A trade-off between the two objectives is observed and using a pareto optimal variable set, it shown that a periodic behavior (with acceptable accuracy) could be achieved with theoretically zero energy consumption.

Non-linear Vibrations in a Coiling Process with Periodically Changing Radius

Helmut J. Holl

Institute of Technical Mechanics, Johannes Kepler University, Linz, Austria

Summary. The mechanical model of a winding process has to consider the coupling of the vibrations of the strip and the coiling drum due to non-steady state operation conditions. In the mechanical model of this variable mass system additionally variable parameters are present and result in non-linear equations of motion. The longitudinal and transversal motion of the axially moving strip and the bending deflection of the coiling drum are considered by Rayleigh-Ritz approximations which involve the application of the extended equation of Lagrange. A periodically changing radius is a potential source of vibration excitation. A time integration algorithm with small time steps has to guarantee a converged solution for the long computation time. Simulation results of steady state and non-steady state operation conditions are computed and show the coupling of the vibrations and the excitation due to the periodic radius function.

Introduction

A suitable mechanical model is necessary for the simulation of the vibrations in a coiling process. In the coiling process an axially moving strip moves continuously towards a rotating drum where it is coiled. Between two successive coiling processes the strip passes through a Steckel mill where the thickness is reduced. The mechanical model starts at the exit of the Steckel mill and considers the axial motion of the strip with the transversal oscillations. Then the strip is coiled where the strip is attached on the drum, contributes to the bending stiffness and increases the mass of the drum. The resulting mechanical model is a non-linear dynamic model with varying mass and system parameters, which are defined by the variable outer radius of the drum, the variable bending stiffness of the drum and a variable eccentricity of the rotating drum. Due to the coiled material the mass of the coiling drum increases or decreases continuously. For the outer radius of the coiling drum an Archimedian Spiral and a periodic step function is assumed, which gives an outer radius and bending stiffness depending on the coiled strip length. For the simulation of the coiling process with the long computation time a integration algorithm was implemented. For the derivation of the equations of motion Rayleigh-Ritz approximations are used to get only a few degrees of freedom in the mechanical model. The application of the extended equations of Lagrange, see [1], is necessary as the mass in the system is not constant, which is a restriction for the well-known equations of Lagrange, see [2]. In the extended equations of Lagrange the control volume concept with the surface integrals with partial derivatives as a kernel are present. In [3] additionally some literature with examples on dynamic systems with variable mass is discussed. In [4] an alternative approach for the influence of the variable mass is considered using reactive forces, where also some examples are shown. The coupled vibrations are analysed and numerical studies are performed in order to increase the knowledge about the complicated variable mass non-linear dynamic system of the coiling drum with an outer radius involving a periodic excitation and the axially moving strip. For the dynamic system the initial and boundary conditions are defined and with the given operation conditions a time-integration algorithm computes the solution.

Mechanical modelling of the coiling drum and the moving strip

Figure 1: Mechanical model of the rotating drum with the axially moving strip

The mechanical model includes the coiling drum on elastic bearings and the moving strip, see Fig. 1. Rayleigh-Ritz approximations and the extended equations of Lagrange have been used for the derivation of the mechanical model. For the derivation of the equations of motion it is important to distinguish between the material control volume and the spatial control volume. The mechanical model has five degrees of freedom, the horizontal and vertical deflection x, y and the rotation angle φ of the coiling drum, the transversal deflection of the moving strip q and the entrance speed of the strip s_L . The strip tension force F_B is given as a predefined time-dependent value at the entrance of the system and the torque at the coiling drum M_T is computed. The coiling drum is modeled as a beam with different stiffness in longitudinal direction. The outer radius of the drum increases and an Archimedian spiral $r = r_0 + \frac{h\varphi}{2\pi}$ as well as a step-function $r = r_0 + h \text{ floor}\left(\frac{\varphi}{2\pi}\right)$ have been analysed. For the computation of the actual stiffness it is assumed that the coiled strip is attached to the drum and contributes to the stiffness.

The model of the coiling drum and the moving strip is described and derived in [5]. The coupling between the coiling drum and the moving strip is modelled considering the strain in the strip $\varepsilon_S = \varepsilon_{xx} - zw'' + \frac{1}{2}w'^2$. The horizontal motion of the strip in longitudinal direction at the right position where it touches the coiling drum considers the shortening effect of second order, see [5]. φ ist the rotation angle and x is the horizontal deflection of the center of the rotating drum.

Computed Results

Figure 2: Amplitude and velocity of transversal motion of the strip

For the derived mechanical model the solution was computed and a parametric study has been performed. The parameters of the coiling drum based on the computations presented in this contribution are $L_0 = 5\text{m}$, $r_0 = 0.45\text{m}$, $h = 10\text{mm}$, $b = 0.5\text{m}$, $E = 105\text{kN/mm}^2$, $c_C = 10^7\text{kN/m}$, $\rho = 7800\text{kg/m}^3$, $m_0 = 1200\text{kg}$. For a strip tension force of $F_B = F_{B0} \left(1 + \frac{\sin(\pi t/2)}{2}\right)$ with $F_{B0} = 50\text{kN}$ the computation is carried out. From the results of the amplitude of the transversal strip vibrations in Fig. 2 the non-linear coupling effect with the varying frequency and amplitude is shown.

When a step-function of the outer radius of the coiling drum is used, the computed resulting vibrations are shown in Fig. 3 and Fig. 4 for a constant strip tension force at the entrance of the system in Fig. 1. It can be seen that the effect of the step function in the outer radius gives an impact-like excitation which occurs after every revolution. For successive rotations the vibration amplitudes are computed with a small time step to get a convergent result as the step-function of the radius gives a modification in the kinematics of the system.

Figure 3: Horizontal Position and speed of the Center of the Coiling Drum

Figure 4: Rotation angle and speed of the coiling drum

Conclusion

A mechanical model with a variable mass and varying parameters and a periodic function for the outer radius of a coiling process was derived. The simulation results show a production process for a constant axial speed. For a defined variation of the strip tension force at the entrance the vibration amplitudes of the coordinates show non-linear coupled vibrations and the frequency and amplitude for the transversal strip oscillation depend on the strip tension force. For the step-function of the outer radius the computation needs a higher effort and shows an excitation after every revolution of the coiling drum.

Summary. Mathematical models for wave energy converters (WECs) are naturally germinated from the models in classical offshore engineering applications, where the assumption of linear kinematics and dynamics is commonplace. However, while the assumption of linear, small amplitude, motion fits traditional offshore problems (it is desirable to stabilize ships, boats and offshore platforms), it is not representative of the expected (and desired) motions of a WEC, since the main objective is to enhance the response and maximize power extraction. The inadequacy of linear models for many wave energy applications has led to an increasing number of publications and codes implementing nonlinear hydrodynamics. However, nonlinear kinematics has received little attention, since few models yet consider six degrees of freedom (DoFs) and large rotations. This paper implements a nonlinear kinematic model for one of the most well established WEC concepts: an axisymmetric heaving point absorber with single taut line mooring. The influence of the nonlinear kinematics are demonstrated and potential sources of numerical instability in yaw are discussed. Finally, the model is also used to articulate parametric resonance in roll/pitch.

Introduction

The kinematics and dynamics of floating bodies is traditionally related to offshore engineering problems, such as: naval applications and the design of large oil and gas platforms [1]. For these applications, the main objective is usually to stabilize the motion of the floating objects, therefore the resulting small amplitude motions are within the limits of where linear theory is sufficiently accurate for modelling the system. However, contrary to these conventional offshore applications, wave energy converters (WECs) are designed and controlled with the objective of enhancing the wave induced motion to maximize power absorption [2]. Therefore, it is often the case that linear models become inapt to accurately predict the behaviour of a WEC. The fidelity of mathematical models is crucial for a reliable estimation of the cost of electricity and for the effectiveness of model-based control strategy [3], which are essential for achieving economic viability [4, 5]. Including nonlinearities in energy-maximising control strategies is both essential and possible [6].

As the wave energy field grows in experience and maturity, the necessity of nonlinear models, for a comprehensive design of most WEC types, becomes increasingly apparent [7, 8, 9]. While fully-nonlinear models, such as the ones solving Navier-Stokes equations, achieve high accuracy, they are not computationally viable for control or optimization applications. Considering the more computationally convenient partially-nonlinear models based on potential theory, most of the research is focusing on nonlinear hydrodynamics, namely on the modelling of nonlinear Froude-Krylov, radiation, or diffraction forces, or on viscous effects [10, 11, 12, 13]. However, little effort is found towards modelling nonlinear kinematics [14].

The consideration of nonlinear kinematics is usually necessary for systems with large amplitude motion and multiple, coupled degrees of freedom. The inclusion of nonlinear kinematics is shown to be important in applications such as biomechanics [15, 16], robotics [17, 18], transportation [19, 20], tracking control [21, 22] and design of manipulators [23, 24], to name a few. However, for wave energy applications, numerical models employed to simulate the dynamic behaviour of WECs generally assume the motion to be planar, in the direction of wave travel, with up to 3 DoFs considered (horizontal translation, vertical translation and rotation in the resulting plane: surge, heave and pitch, respectively) [25]. Moreover, the rotational displacement and velocity are normally assumed to be small. Few nonlinear studies are performed in 6-DoFs, especially considering roll/pitch parametric resonance or yaw instability [26, 27]. Parametric resonance is usually detrimental, but the ability to model it can enable more efficient harvesting instead [28, 29].

This paper presents a nonlinear model relevant for wave energy applications, including both nonlinear kinematics and nonlinear hydrodynamics. Typical WEC modelling approaches are challenged, discussing potential issues arising from employing the usual simplifying assumptions. In particular, potential numerical instability may arise from neglecting the mooring line torsional stiffness and viscous dissipation.

Mathematical model for a moored axisymmetric floater

The case study, schematically shown in Figure 1, is the archetype of the popular WEC concept known as a “point absorber” (since its dimensions are small compared to the wavelength such that it can be virtually approximated by a single point). Consequently, a natural choice is to design point absorbers to be independent of the incoming wave direction, so they are normally axisymmetric. The energy extraction results from the relative movement between the buoy and a fixed point on the sea floor. The buoy is attached to the sea floor by a single taut mooring line.

Figure 1: Cylindrical point absorber, with a single taut mooring line tethered to the sea floor (at depth h). Both the inertial frame (x, y, z) and the body-fixed frame $(\hat{x}, \hat{y}, \hat{z})$ have their origin at the still water level (SWL). The floater is shown at rest (in transparency) and displaced. The mooring line has axial stiffness K_{moor} , initial length L_0 and elongation ΔL . The device can rotate with respect to the mooring line.

Reference frames

Two right-handed frames of reference are defined, as schematically shown in Figure 1. The first one (x, y, z) is world-fixed, inertial, with the origin at the still water level (SWL) and on the centre of the buoy at rest, with the x -axis along and in the same positive direction of the wave propagation, and the z -axis pointing upwards. The inertial frame is used to describe the body displacements (ζ), divided into translations (\mathbf{p}) and rotations (Θ):

$$\zeta = \begin{bmatrix} \mathbf{p} \\ \Theta \end{bmatrix}, \quad \mathbf{p} = \begin{bmatrix} x \\ y \\ z \end{bmatrix}, \quad \Theta = \begin{bmatrix} \phi \\ \theta \\ \psi \end{bmatrix}, \quad (1)$$

The second right-handed frame of reference is $(\hat{x}, \hat{y}, \hat{z})$, body-fixed, hence non-inertial, with the origin at the center of gravity of the floater. This is used for writing the dynamic equation of the system, since the inertial matrix remains constant. Therefore, both forces and velocities are represented in the body-fixed frame, along the axis of the buoy. Velocities (ν), divided into translation (\mathbf{v}) and rotations (ω), are defined as:

$$\nu = \begin{bmatrix} \mathbf{v} \\ \omega \end{bmatrix}, \quad \mathbf{v} = \begin{bmatrix} u \\ v \\ w \end{bmatrix} = \begin{bmatrix} \dot{\hat{x}} \\ \dot{\hat{y}} \\ \dot{\hat{z}} \end{bmatrix}, \quad \omega = \begin{bmatrix} p \\ q \\ r \end{bmatrix}. \quad (2)$$

Kinematic mapping

It is worth remarking that forces and velocities are along time-varying axes, while displacements are along fixed axes. In linear hydrodynamic models there is no difference between such axes, based on the assumption of small displacements. However, in a nonlinear approach, a mapping from body- to world-frame velocities should be applied, at each time step, in order to obtain the correct displacements. One possible mapping is the following:

$$\dot{\zeta} = \begin{bmatrix} \dot{\mathbf{p}} \\ \dot{\Theta} \end{bmatrix} = \begin{bmatrix} \mathbf{R}_\Theta & \mathbf{0}_{3 \times 3} \\ \mathbf{0}_{3 \times 3} & \mathbf{T}_\Theta \end{bmatrix} \begin{bmatrix} \mathbf{v} \\ \omega \end{bmatrix} = \mathbf{J}_\Theta \nu, \quad (3)$$

where \mathbf{R}_Θ is the rotation matrix, depending on the Euler angles Θ , defined according to the 3-2-1 convention as:

$$\mathbf{R}_\Theta = \mathbf{R}_{\hat{z}, \psi} \mathbf{R}_{\hat{y}, \theta} \mathbf{R}_{\hat{x}, \phi} = \begin{bmatrix} c\psi & -s\psi & 0 \\ s\psi & c\psi & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} c\theta & 0 & s\theta \\ 0 & 1 & 0 \\ -s\theta & 0 & c\theta \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & c\phi & -s\phi \\ 0 & s\phi & c\phi \end{bmatrix}, \quad (4)$$

with c and s standing for $\cos()$ and $\sin()$ trigonometric operators, respectively. \mathbf{R}_Θ is applied to translational velocities. \mathbf{T}_Θ is applied to rotational ones, and is defined as follows:

$$\mathbf{T}_\Theta = \begin{bmatrix} 1 & s\phi t\theta & c\phi t\theta \\ 0 & c\phi & -s\phi \\ 0 & s\phi/c\theta & c\phi/c\theta \end{bmatrix}, \quad (5)$$

where t stands for the $\tan()$ trigonometric operator. Note that the singularity of \mathbf{T}_Θ in $\pm\pi/2$ is usually not an issue in wave energy applications, since the amplitude of the pitch angle is, by design, always expected to be smaller than $\pi/2$.

Coriolis and centripetal forces

Another consequence of using a body-fixed frame are Coriolis and centripetal forces, which are normally neglected under the assumption of small rotational velocities. Let us define, for convenience of notation, the skew-symmetric operator $\mathcal{S} : \mathbb{R}^3 \rightarrow \mathbb{R}^{3 \times 3}$ as

$$\mathcal{S} : \left\{ \boldsymbol{\lambda} \in \mathbb{R}^3 \mid \mathcal{S}(\boldsymbol{\lambda}) \triangleq \begin{bmatrix} 0 & -\lambda_3 & \lambda_2 \\ \lambda_3 & 0 & -\lambda_1 \\ -\lambda_2 & \lambda_1 & 0 \end{bmatrix} \right\}. \quad (6)$$

Using such a notation, it is possible to define Coriolis and centripetal forces as:

$$\mathbf{F}_{Cor} = -\mathbf{C}_{Cor}\boldsymbol{\nu} = - \begin{bmatrix} M\mathcal{S}(\boldsymbol{\omega}) & -M\mathcal{S}(\boldsymbol{\omega})\mathcal{S}(\mathbf{r}_g) \\ M\mathcal{S}(\mathbf{r}_g)\mathcal{S}(\boldsymbol{\omega}) & -\mathcal{S}(\mathbf{I}_r\boldsymbol{\omega}) \end{bmatrix} \begin{bmatrix} \mathbf{v} \\ \boldsymbol{\omega} \end{bmatrix}, \quad (7)$$

where M is the mass of the body, \mathbf{r}_g is the vector from the origin of the body-fixed frame (reference point) to the centre of gravity, and \mathbf{I}_r is the matrix of the moments of inertia with respect to the reference point. If the reference point is coincident with the center of gravity, then \mathbf{r}_g is the null vector and \mathbf{I}_r is a diagonal and minimal matrix, with I_x , I_y , and I_z on the diagonal. Consequently, the Coriolis and centripetal force in (7) becomes:

$$\mathbf{F}_{Cor} = - \begin{bmatrix} M(qw - rv) \\ M(ur - pw) \\ M(pv - qu) \\ qr(I_z - I_y) \\ rp(I_x - I_z) \\ pq(I_y - I_x) \end{bmatrix} \quad (8)$$

Hydrodynamic forces

The wave-structure interaction is modelled using the partially nonlinear hydrodynamic model detailed in [30]. This model decomposes the force from the fluid on the floater into several components: the Froude-Krylov (FK) force \mathbf{F}_{FK} , the diffraction force \mathbf{F}_d , the radiation force \mathbf{F}_r and the viscous force \mathbf{F}_v . The model is labelled "partially nonlinear" since the diffraction and radiation forces are modelled linearly, whereas the viscous and FK force terms are nonlinear. The viscous force is described by an integral quadratic representation, and the nonlinear FK force is calculated by integrating the undisturbed pressure field from the incident wave over the instantaneous (updated at each time step) wetted surface of the floater. Full details of the nonlinear FK force representation are given in [31] for axisymmetric floaters, and in [32] for prismatic floaters. An open-source toolbox for the implementation of the nonlinear FK method is provided in [33].

Mooring force

The mooring system applies a force, \mathbf{F}_m , to the attachment point at the bottom center of the floater. The mooring force is modelled here as a linear spring.

Equation of motion

Finally, the dynamical equation in 6 DoFs for the floater becomes:

$$\begin{cases} \dot{\boldsymbol{\zeta}} = \mathbf{J}_\Theta \boldsymbol{\nu} \\ \mathbf{M}\dot{\boldsymbol{\nu}} + \mathbf{F}_{Cor} = \mathbf{F}_{FK} + \mathbf{F}_d + \mathbf{F}_r + \mathbf{F}_v + \mathbf{F}_m \end{cases} \quad (9)$$

where \mathbf{M} is the inertial matrix,

Coupling between DoFs

For the case of linear hydrodynamics, incoming unidirectional waves induce a planar external excitation on axisymmetric floaters (surge, heave and pitch). However, when considering nonlinear FK forces, a coupling can manifest under certain conditions, due to an internal excitation of the sway and roll DoFs [31]. In particular, when the excitation frequency is about twice the natural frequency in roll, a Mathieu-type of instability induces parametric resonance [34].

In these regions of parametric instability, a nonlinear FK model can provide 5 DoFs of excitation. Note, there is no means of exciting the yaw DoF. Even when considering the mooring system, the single mooring line does not provide any coupling between the excited DoFs and yaw [35]. However, if nonlinear kinematics effects are introduced, the Coriolis and centripetal forces, as well as the kinematic mapping \mathbf{J}_Θ , have the mathematical structure to provide a coupling with yaw. The following sections will show that, if these forces and the kinematic mapping are not appropriately taken into account, then the model can exhibit numerical instability.

Kinematic mapping

The last row of equation (3) represents the mapping from the body-fixed rotational velocities, ω , to the rate of change of the yaw displacement, $\dot{\psi}$:

$$\dot{\psi} = q \frac{\sin \phi}{\cos \theta} + r \frac{\cos \phi}{\cos \theta} \quad (10)$$

If ϕ is not exactly zero, Equation (10) shows that, $\dot{\psi}$ will be greater than zero. For the case of 3-DoF excitation (linear FK model or nonlinear FK model away from the parametric instability region), ϕ is not excited and simply decays from a small initial value ϕ_0 ; consequently $\dot{\psi} \approx 0$. On the other hand, when 5-DoF excitation occurs (nonlinear FK model in the parametric instability region), roll is internally excited and eventually the term $q \frac{\sin \phi}{\cos \theta}$ is non negligible, nor $\dot{\psi}$ anymore either.

Therefore, it results that the yaw DoF is coupled with other rotational DoFs, either weakly (in the 3-DoF case) or strongly (in the 5-DoF case). However, if there is no excitation of the yaw DoF, the yaw displacement is bounded, since $\dot{\psi}$ is of the same order of magnitude of q : $\dot{\psi} = \mathcal{O}(q)$. Nevertheless, under certain conditions, yaw may also be weakly excited by Coriolis and centripetal forces, potentially inducing the system to be unstable and generate an unbounded yaw response.

Coriolis and centripetal forces

As shown in Equation (8), the surge component of \mathbf{F}_{Cor} is:

$$\mathbf{F}_{Cor}(1) = -M(qw - rv) \quad (11)$$

It is worth to notice that, in the simple 3-DoF case, the product $rv \approx 0$, so that $\mathbf{F}_{Cor}(1) \approx -Mqw$. Therefore, the mean of $\mathbf{F}_{Cor}(1)$ depends on the phase difference between pitch and heave, which are both externally excited. In particular, a zero mean is obtained if the phase difference is 90° , while strongly negative or positive means are obtained for phase differences of 0 or 180° , respectively. In a linear hydrodynamic model, the surge exciting force has zero mean, so that the resulting surge displacement is bounded to have the same sign of the mean of $\mathbf{F}_{Cor}(1)$, and magnitude depending on the mooring restoring force [35], since no hydrostatic force is present in surge. On the other hand, if a nonlinear hydrodynamic model is used, second order drift effects shift the mean of the surge exciting force to positive values, so that the resulting mean displacement is a combination of both the wave and the Coriolis and centripetal forces.

The yaw component of the \mathbf{F}_{Cor} around the center of gravity, as shown in (8), is the following:

$$\mathbf{F}_{Cor}(6) = -pq(I_y - I_x) \quad (12)$$

Since pitch is externally excited, q is never zero. Since roll is either internally excited (5-DoF case) or in a simple decay (3-DoF case), p is either significantly large or relatively small, respectively, but never exactly zero. It follows that $\mathbf{F}_{Cor}(6)$ is exactly zero if and only if $I_x = I_y$.

Numerical yaw instability

Generally, both intuition and experience teach that no significant yaw response is expected from an axisymmetric system. Physically, the only restoring force in yaw is provided by moorings. For the mooring system shown in Figure 1, the restoring is provided by the torsional stiffness of the mooring line, which is normally small and usually neglected [36]. Consequently, no yaw restoring term is usually implemented in the numerical model. In addition, no dissipative mechanism are usually implemented in yaw, because radiation damping is ideally zero and viscous losses are reasonably negligible, due to the smooth axisymmetric geometry. However, neglecting dissipative and restoring terms in the yaw DoF can lead to unexpected yaw responses, and potentially generating conditions for numerical instability.

Initial conditions

Let us assume that the initial conditions, (ζ_0) , are not exactly zero, but a small fraction of their expected steady state response, so that ζ_0 can be considered ‘almost’ zero. Such an assumption is consistent with the common application where, a mathematical model is coupled with a physical system, taking measured displacement and/or velocity signals as inputs (either in an experimental test-rig [37] or in real-sea deployment [38]). Furthermore, it is common practice to assume almost-zero initial conditions in nonlinear hydrodynamic models, in order to provide some initial energy to all DoFs and study the effect of instability [39, 40]. In absence of external-internal excitation or strong coupling, the small initial conditions rapidly decay. In the following discussion, the initial roll displacement, (ϕ_0) , is slightly greater than zero (say, 0.5°), so that ϕ , $\dot{\phi}$, and p are non-zero.

Furthermore, let us assume that the initial yaw displacement ψ_0 is zero. Although this is an unnecessary assumption, it will highlight that a response in yaw (with no external nor internal hydrodynamic excitation) can appear solely due to the nonlinear kinematics.

Transversal moments of inertia

Theoretically, the two transversal moments of inertia, I_x and I_y , should be identical. However, numerically, the geometrical properties of the buoy will be reproduced with finite accuracy, thus I_x and I_y may be not exactly the same as each other. In this study, as an example, I_y has been considered to be $99.9\%I_x$.

Excitations

Table 1 summarizes all possible conditions that can arise.

Table 1: Characteristic of the yaw oscillatory response, ψ . Considering no viscous nor restoring terms in yaw and a small perturbation of the initial condition in roll and pitch. Two transversal moment of inertia cases are considered: ideal ($I_x = I_y$) and almost-ideal ($I_x \approx I_y$), in combination with two hydrodynamic excitation conditions: 3-DoF (linear FK model or nonlinear FK model away from the parametric resonance region) and 5-DoF (nonlinear FK model close to the parametric resonance region).

	Hydrodynamic excitation	
	3-DoF	5-DoF
$I_x = I_y$	Decay	Sustained, $\mathcal{O}(\theta)$
$I_x \approx I_y$	Unstable	Unstable

Let us consider the two hydrodynamic excitation conditions:

- 3-DoF excitation, where the excitation is external only.
- 5-DoF excitation, where 3-DoF are external excitation and 2 DoF are internal excitations present in the nonlinear FK model close to the parametric resonance region.

In the ideal case ($I_x = I_y$), there is no forcing term in yaw, so that the yaw response will follow roll and pitch angles, according to equation (10). In particular, in the 3-DoF excitation condition, yaw will follow the decay of roll; in the 5-DoF excitation condition, the oscillatory part of yaw will follow the pitch sustained response, modulated by the sine of the roll response. A slowly increasing mean of yaw is also present, due to the absence of a restoring force.

However, in the almost-ideal case ($I_x \approx I_y$), equation (12) shows that there is a forcing term of the yaw DoF, much smaller in a 3-DoF scenario than a 5-DoF scenario, but never exactly zero. Consequently, due to the lack of viscous and restoring terms, the yaw DoF is not restrained and becomes unstable, so that its response diverges at a rate proportional to the difference between I_x and I_y . Therefore, when implementing Coriolis and centripetal forces in a 6-DoF model, it is important to include a yaw restoring term, which prevents the numerical instability from appearing.

6-DoF response

A nonlinear 6-DoF model has been implemented, including nonlinear kinematics, Coriolis and centripetal forces, nonlinear Froude-Krylov forces, and 6-DoF quadratic viscous forces, as in [2]. The nonlinear hydrodynamics of this model is able to articulate parametric resonance in roll and pitch, which is a Mathieu-type of instability, arising when the period of the excitation force is about half the natural period in roll and pitch ($T_{n,5}$). Such an instability is mainly induced by the heave displacement causing, among other effects, a time-varying metacentric height (GM), thus hydrodynamic stiffness in roll and pitch.

In order to highlight such a behaviour, the floater, whose schematics is shown in Figure 1, is inspired by the cylinder studied in [41, 42], which is a renown example of parametrically unstable floater, due to the 2:1 ratio between natural periods in pitch/roll and heave. However, a notional single mooring line has been included, in order to consider the full 6-DoF model. For simplicity, the mooring restoring force has been assumed to be linear and with no coupling between DoFs. Note that, in order to avoid numerical instability in yaw, a torsional stiffness of the mooring line has been included. Furthermore, a 0.1% perturbation of one of the two transverse moments of inertia has been considered, in order to highlight the lack of instability thanks to the torsional stiffness.

Finally, note that all parameters and results here presented are normalized, enabling application to structures of varying size, such as the large spars in [41, 42], and to smaller WEC-like structures, as in [43]. The relevant common feature is to realize a 2:1 ratio between pitch and heave natural periods. Table 2 shows the ratio between the natural period in each DoF and $T_{n,5}$.

Table 2: Natural periods normalized by the pitch and roll natural periods [-].

Surge & Sway	Heave	Roll & Pitch	Yaw
7.7	0.5	1	5.1

Figure 2 shows the amplitude of the response to regular waves, as a function of wave periods (T_w) and wave heights (H_w). Periods are normalized by $T_{n,5}$, while the wave height and linear displacements are normalized by the metacentric height (GM). The dashed and dash-dotted red lines correspond to $T_w = \frac{1}{2}T_{n,5}$ and $T_w = T_{n,5}$, respectively. As expected, a roll and sway response is localized around an excitation period equal to $\frac{1}{2}T_{n,5}$. At the same period, there is a clear reduction of heave response, due to an internal exchange of energy between DoFs. Finally, under the 5-DoF excitation condition, there is a small response in the yaw DoF, made possible by the nonlinear kinematics and the perturbation of the transverse moment of inertia. However, due to the restoring term in yaw, numerical instability is avoided and the yaw response is contained below 1 degree.

Figure 2: Amplitude of the response as a function of T_w and H_w . Periods are normalized by $T_{n,5}$, while the wave height and linear displacements are normalized by the metacentric height GM . The dashed and dash-dotted red lines correspond to $T_w = \frac{1}{2}T_{n,5}$ and $T_w = T_{n,5}$, respectively.

While Fig. 2 is obtained with a regular (monochromatic) waves, it is interesting to verify the development of parametric resonance and dynamic instability to more realistic irregular (panchromatic) waves. The most interesting condition is at the parametric resonance period, so that a peak period (T_p) of half $T_{n,5}$ is considered. Since the severity of the instability is proportional to the significant wave height (H_s) a medium-high value is considered, based on Fig.2, equal to GM . A typical Jonswap spectrum is considered, with the enhancing factor (γ) of 3.3. Figure 3 shows the dynamic response of the floater for a long realization of the resulting stochastic process. It is clear that the parametric resonance in roll is excited, but reaching a lower steady state amplitude than in the monochromatic condition, since the frequency-dependent instability is weaker.

Conclusions

This paper proposes a model in 6 degrees of freedom for axisymmetric floaters, including nonlinear kinematics, Coriolis and centripetal forces, and nonlinear Froude-Krylov forces. Although their physical impact is negligible, it is crucial to include damping and restoring terms in the yaw degree of freedom in the numerical model. In fact, if yaw is unrestrained, unstable and unbounded yaw responses may appear if there is a perturbation of the inertial properties of the system (likely

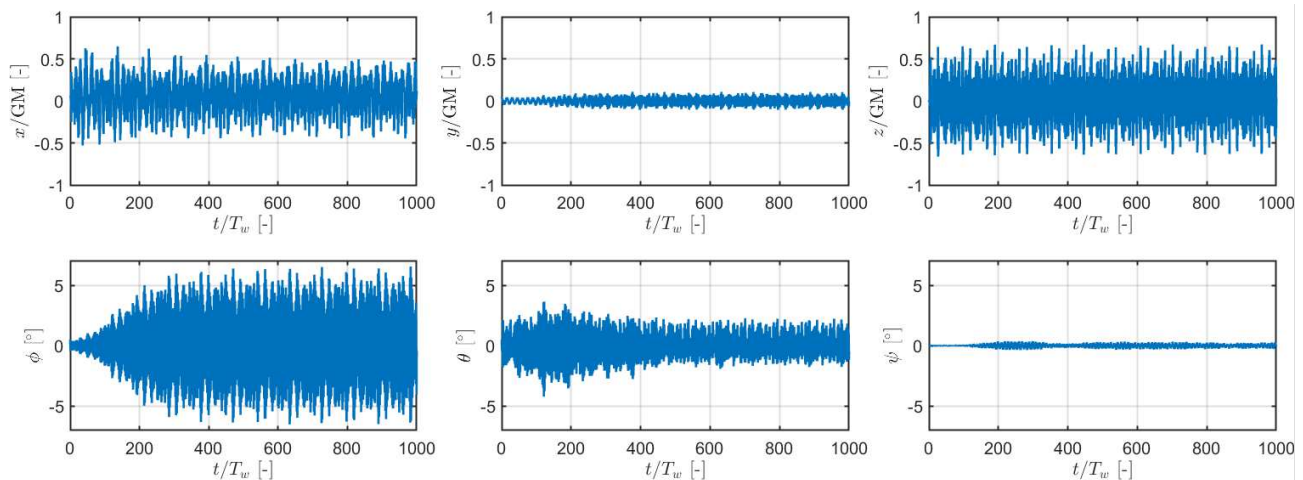

Figure 3: Dynamic response to a realization of a panchromatic wave with peak period $T_p = T_{n,5}/2$ and significant wave height $H_s = GM$.

if the mathematical model is coupled to a physical system). However, even with ideal inertial parameters, sustained bounded yaw response may be obtained if all other 5 DoFs are excited. This particular scenario arises due to parametric resonance conditions of the roll DoF, namely when the excitation force frequency is about twice the roll natural frequency. The proposed model, thanks to the nonlinear FK formulation, is also able to articulate parametric resonance.

On periodic solutions and modal energy transfer of mechanical systems with state-dependent impulsive stiffness excitation

Thomas Pumhössel

Institute of Mechatronic Design and Production, Johannes Kepler University Linz, Austria

Summary. In the present contribution, mechanical systems with impulsive stiffness excitation are investigated. It is shown that periodic solutions exist, which result in a repeated transfer of vibration energy from lower to higher modes and vice-versa. This allows that the structural damping of the mechanical system can be utilized more effectively, resulting in a faster decay of transient vibrations compared to the case where no impulsive excitation is present.

Introduction

The transfer of vibration energy, either in the modal space, or spatially to an attached system, allows to reduce transient vibrations after some initial disturbance. In the first case the enhanced damping properties of higher modes can be utilized more effectively, see. e.g. [1], whereas in the second case energy is transferred in a one-way, irreversible manner to a nonlinear coupled additional system, denoted as nonlinear energy sink (NES), see [2], for example.

In the present contribution, mechanical systems with state-dependent impulsive stiffness excitation are investigated. It is shown that, in the conservative case, periodic solutions exist which result in a periodic exchange of vibration energy across modes. By taking structural damping into account, the effect on the total energy content of mechanical systems is demonstrated.

Periodic solutions and energy transfer

In the following, mechanical systems with impulsive stiffness excitation described by equations of motion of the form

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + (\mathbf{K} + \sum_{k=1}^K \varepsilon_k(\mathbf{x}_k, \dot{\mathbf{x}}_k) \mathbf{G} \delta(t - t_k)) \mathbf{x}(t) = \mathbf{0}, \quad (1)$$

are investigated. Therein, \mathbf{M} , \mathbf{C} and \mathbf{K} represent the constant $(n \times n)$ -dimensional mass-, damping- and stiffness-matrix. Impulsive parametric excitation is introduced at equidistant instants of time t_k by using Dirac-delta functions $\delta(t - t_k)$, where the state-dependent strength of the impulses is denoted as $\varepsilon_k(\mathbf{x}_k, \dot{\mathbf{x}}_k)$. It was shown in [3], that the state of the system $\mathbf{r}(t) = [\mathbf{x}(t) \ \dot{\mathbf{x}}(t)]^T$ just after an impulse at t_k , i.e. at $t_{k,+}$, can be related to the state after the preceding impulse at $t_{k-1,+}$ by

$$\mathbf{r}(t_{k,+}) = \mathbf{J}_k(\varepsilon_k) e^{\mathbf{A} \Delta T} \mathbf{r}(t_{k-1,+}), \quad (2)$$

where

$$\mathbf{J}_k = \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ -\varepsilon_k \mathbf{M}^{-1} \mathbf{G} & \mathbf{I} \end{bmatrix}, \quad \mathbf{A} = \begin{bmatrix} \mathbf{0} & \mathbf{I} \\ -\mathbf{M}^{-1} \mathbf{K} & -\mathbf{M}^{-1} \mathbf{C} \end{bmatrix}, \quad (3)$$

and $\Delta T = t_k - t_{k-1}$ holds. The matrix \mathbf{J}_k was denoted as jump-transfer matrix by Hsu, see [3]. If the impulsive strength ε_k is selected to be state-dependent according to

$$\varepsilon_k = \left(\sum_{i=1}^n \mathbf{g}_i^T \mathbf{x}_{k-} \dot{x}_{i,k-} \right) / \left(\frac{1}{2} \sum_{i=1}^n (\mathbf{g}_i^T \mathbf{x}_{k-})^2 / m_i \right), \quad (4)$$

see [4], neither energy is extracted from, nor fed to the mechanical system by an impulse, i.e. the impulse is energy-neutral. In this case, \mathbf{J}_k becomes a constant matrix and Eqn. (2) can be written in the form

$$\mathbf{r}(t_{k,+}) = \underbrace{\mathbf{J} e^{\mathbf{A} \Delta T}}_{\mathbf{Q}(\Delta T)} \mathbf{r}(t_{k-1,+}) = \mathbf{Q}^k(\Delta T) \mathbf{r}_0 = \mathbf{\Psi} \mathbf{\Lambda}^k \mathbf{\Psi}^{-1} \mathbf{r}_0, \quad (5)$$

where $\mathbf{r}_0 = \mathbf{r}(t_0 = 0)$. The matrix $\mathbf{\Psi}$ is comprised of the eigenvectors of \mathbf{Q} , and $\mathbf{\Lambda} = \text{diag}(\lambda_i)$, $i = 1, 2, \dots, 2n$, of the corresponding eigenvalues. Following the notation in [5], a periodic solution with period R is given by a sequence of R distinct points \mathbf{r}^* in the state-space according to

$$\mathbf{r}^*(t_{m+r,+}) = \mathbf{Q}^r \mathbf{r}^*(t_{m,+}), \quad r = 1, 2, \dots, R-1, \quad (6)$$

$$\mathbf{r}^*(t_{m+R,+}) = \mathbf{Q}^R \mathbf{r}^*(t_{m,+}) = \mathbf{r}^*(t_{m,+}), \quad (7)$$

denoted as P - R solution. It can be seen from Eqn. (5), that the last condition (Eqn. (7)) is fulfilled if there exists a timespan ΔT between adjacent impulses, for which $\mathbf{\Lambda}^R = \mathbf{I}$ holds, where \mathbf{I} represents the identity matrix. With a simple example, the existence of such cases is demonstrated in the following.

The investigated mechanical system comprises two masses connected by stiffness and damping elements and is pinned on one end, see Fig. (1), where the stiffness $k_{01} = \bar{k}_{01} + \varepsilon_k g_{01} \delta(t - t_k)$, i.e. consists of a constant and an impulsive part. At equidistant instants of time t_k , stiffness impulses with a strength according to Eqn. (4) are applied. Hence, the equations of motion are of the form of Eqn. (1). As system parameters $m_1 = 1$, $m_2 = 0.5$, $\bar{k}_{01} = 1$, $k_{12} = 2$, and a stiffness-proportional damping $\mathbf{C} = \alpha \mathbf{K}$, $\alpha = 0.01$, were used for the numerical calculations.

Figure 1: Sketch of investigated mechanical system.

is investigated in more detail. Applying the mapping matrix \mathbf{Q} four times gives $\lambda_{1,2}^R = 1$ and $\lambda_{3,4}^R = 1$, i.e. the mechanical system attains the initial state again after applying four impulses. Hence, we have a P -4 solution with a period of $4\Delta T_{P-4}$. Figure (2b) depicts the corresponding 4-periodic timeseries of the impulsive strength ε_k . The effect of the impulsive excitation on the modal coordinates y_1 and y_2 is shown in Fig. (2c). As a first mode deflection according to $\mathbf{y}(t=0) = [1 \ 0]^T$ and $\dot{\mathbf{y}}(t=0) = [0 \ 0]^T$ was used as initial condition, the mechanical system does not show any second mode vibrations initially. This changes with the application of the first impulse, as energy is transferred from the first to the second mode. In the following, the system exhibits first and second mode vibrations simultaneously, until after one period the energy content of the second mode vanishes again. Thereafter, one observes a periodic exchange of energy from the first to the second mode and vice-versa. Including structural damping ($\alpha = 0.01$) allows to exploit the enhanced damping properties of the second mode, see Fig. (2d). During the phases where the second mode contains vibration energy, the total energy content E of the mechanical system decreases faster compared to the phases where only first mode vibrations occur. This results in a globally faster decay of the vibration energy E compared to E_0 (energy content where no impulsive excitation is present).

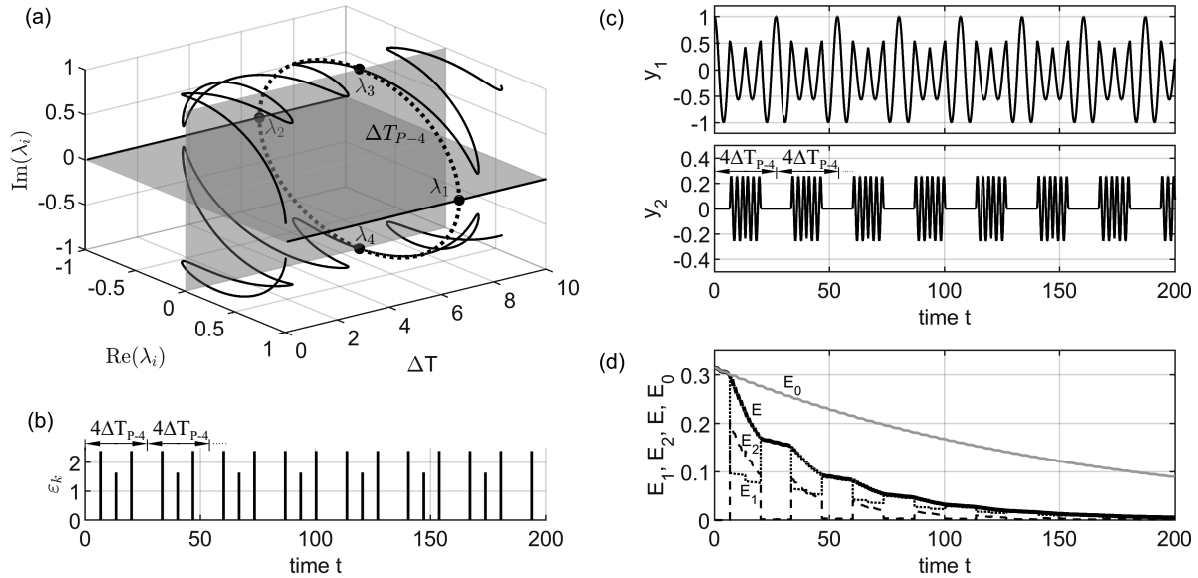

Figure 2: Eigenvalues λ_i , $i = 1, \dots, 4$, of mapping matrix \mathbf{Q} for different values of the timespan ΔT between adjacent impulses - undamped case $\alpha = 0$. (a). Impulsive strength (b), and modal displacements y_1 and y_2 (c) for the case $\Delta T = \Delta T_{P-4} = 6.68672$ and $\alpha = 0$. Modal energy contents E_1 (dotted) and E_2 (dashed), total energy content of the mechanical system E , and total energy content E_0 of system without impulsive excitation for the damped case (d).

Conclusions

It was demonstrated that conservative mechanical systems exhibited to impulsive stiffness excitation of energy-neutral kind can show a periodic behaviour, which can be utilized effectively to enhance the damping of transient vibrations.

Summary. This work focuses on the dynamics and stability of grinding operations. Surface regeneration, which is a well-known and widely accepted cause of regenerative chatter in machining, affects grinding in a unique way as it can occur not only on the workpiece but on the wheel as well. The vast majority of relevant publications consider only distributed radial wear or physical surface waves around the circumference of the grinding wheel in order to account for surface regeneration on the wheel. This research presents an alternative regenerative mechanism, namely the distributed dullness of the cutting edges captured by the specific energy, which is a fundamental quantity in grinding, similar to the cutting-force coefficient in conventional machining. The new chatter theory, which is validated experimentally, predicts stable grinding conditions with respect to wheel regeneration for a certain set of cutting parameters. This is atypical as far as the relevant literature is concerned, i.e., grinding is reported to be typically unstable with regard to wheel regeneration.

Introduction

Grinding is a widely used machining process with a significant 20-25% share of the manufacturing sector in developed countries [1]. The main difference between grinding and conventional machining lies in their respective cutting tools. While conventional processes (e.g. turning and milling) employ geometrically well-defined machine tools, grinding relies on a geometrically ill-defined wheel for material removal. Owing to its unique cutting tool, grinding has a number of advantages and disadvantages. Abrasive processes are known for producing excellent surface quality and dimensional accuracy, cutting difficult-to-machine materials with relative ease, and achieving high material removal rates. The downside of abrasive machining is excessive tool wear, significant heat generation, and – from a theoretical point of view – the complexity of process modelling and prediction due to the inherent randomness of the wheel geometry. This last disadvantage makes it especially complicated to accurately capture an already intricate phenomenon in grinding, which harmfully affects virtually all machining operations, namely regenerative machine tool vibration or chatter. The consequences of self-excited relative vibration between the workpiece and the cutting tool are serious: inadequate surface finish, inaccurate dimensions, reduced tool life, unpleasant noise, etc. Since machining under unstable conditions is highly unfavourable, chatter is to be avoided for the sake of product quality and manufacturing efficiency.

Literature review

Chatter modelling in conventional machining has been the topic of extensive research since Taylor published his famous work at the beginning of the 20th century, asserting that chatter is the most obscure of all machining problems, and there are probably no rules that can guide the machinist in maximising productivity and avoiding chatter at the same time [2]. Taylor's initial concerns have been allayed in the world of conventional processes by chatter theories that are capable of accurately predicting the onset of unstable vibrations [3,4]. However, grinding has been lagging behind the results of conventional theories, because the inherently random nature of its cutting tool makes regenerative chatter more difficult to model and predict. Nevertheless, grinding chatter has been the subject of active and diligent research since the middle of the 20th century [5,6].

Grinding is often a finishing operation responsible for the final surface quality and dimensional accuracy of the machined part. Therefore, in the case of grinding, unstable relative vibration between the wheel and the workpiece can be especially detrimental, because it can destroy a product on which a number of costly machining operations have already been performed. The uniqueness of grinding lies not only in its cutting tool but also in the fact that surface regeneration can occur not only on the workpiece but on the grinding wheel as well, introducing the possibility that the two phenomena happen simultaneously and influence one another in real time. This idea is often referred to as double regeneration in the literature, and has been meticulously studied ever since wheel-related instability was first measured in practice [7].

Surface regeneration on the grinding wheel has usually been modelled as distributed radial wear or physical surface waves around the circumference of the grinding wheel. While this is a perfectly reasonable approach to considering wheel-related instability, Li and Shin claimed that such a description is incomplete, as distributed radial wear alone cannot account for a number of experimental observations reported in the literature [8]. Therefore, they formulated a new theory based on a regenerative mechanism that combines distributed radial wear with distributed grit dullness (i.e. the distribution of the dullness of the cutting edges around the circumference of the grinding wheel). They characterised grit dullness by the specific energy, which quantifies the amount of grinding energy required to remove a unit volume of workpiece material, or equivalently, the amount of grinding power necessary to sustain a unit material removal rate. That is because a sharper/duller grain corresponds to a lower/higher specific energy, respectively. Therefore, Li and Shin considered not only physical surface waves but also specific energy waves on the grinding wheel.

Nevertheless, the current literature tends to model wheel regeneration as a result of uneven radial wear alone. The present study seeks to overcome this by investigating the approach taken by Li and Shin from an analytical and experimental perspective.

Model

A two-dimensional, single-degree-of-freedom model of single-pass surface grinding has been developed by the authors, where the distributed dullness of the cutting edges is quantified by the variation of the specific energy around the circumference of the wheel. The governing equation of motion of the system is linear in its primary variable, which is the specific energy (u), and contains two time delays – a point delay (T_g) and a distributed delay (τ , between 0 and $\tau_{c,0}$):

$$\ddot{u}(t) + 2\zeta\omega_n\dot{u}(t) + \omega_n^2u(t) = \ddot{u}(t - T_g) + 2\zeta\omega_n\dot{u}(t - T_g) + \omega_n^2u(t - T_g) - \frac{\mu_x\delta_0wC_d v_w^2\tau_g}{m\tau_{c,0}v_g} \int_0^{\tau_{c,0}} u(t - T_g + \tau_{c,0} - \tau) d\tau.$$

The point delay is equal to the rotation period of the grinding wheel, and the upper limit of the distributed delay describes the total time necessary for an individual grit to pass through the grinding zone. It can be seen that T_g is significantly larger than $\tau_{c,0}$ for practical values of the nominal depth of cut (δ_0). The mathematical complexities of the stability analysis introduced by these two time delays are dealt with in the frequency domain. Taking the Laplace transform of the equation of motion, the open-loop transfer function between the nominal depth of cut and the resulting wheel vibration reads

$$T_o(s) = \frac{\mu_x\delta_0wC_d v_w^2\tau_g e^{-T_g s} (e^{\tau_{c,0}s} - 1)}{m\tau_{c,0}v_g s(1 - e^{-T_g s})(s^2 + 2\zeta\omega_n s + \omega_n^2)}.$$

Having transformed the two time delays into a number of complex exponentials, it is possible to apply the Nyquist criterion to the open-loop transfer function above, in order to determine the stability properties of the system.

Results

The proposed theory predicts stable machining conditions for a certain, practically feasible set of grinding parameters (see black lines in Fig. 1). This is an unusual yet fascinating result, as grinding is reported to be typically unstable with respect to wheel regeneration in the literature [5,6]. Furthermore, a number of grinding trials have been performed by the authors as well, which present a strong case for the validity of the new model (see coloured circles in Fig. 1). The primary aspects of comparison were stability diagrams and, in the case of instability, chatter frequencies, which indicate a good correspondence between the theoretical predictions and the experimental data.

Figure 1: Comparison between theoretical and experimental stability boundaries with a good agreement between the two

Conclusions

The new chatter model proposed in this work is not only reliable in its own right, but also has a much broader area of application, calling for the alternative wheel regenerative mechanism of distributed grit dullness to be included in sophisticated grinding chatter models. Practically speaking, the new theory suggests that previously unknown regions of stability exist and can be utilised in the pursuit of avoiding chatter vibrations in grinding processes, which is the main and most promising outcome of this research.

Summary. In this paper, the problem of the active vibration control of a thin and flexible disc is addressed. The mechanical structure tackled here is equipped with two piezoelectric circular patches: one of them works as a sensor and the other is used as an actuator. Both are fixed on the disc, one on each side, and centered according to its axis of symmetry. The model of this system is obtained from a finite element analysis, leading to a linear state space model. The design of the proposed control scheme is based on delayed proportional actions. As a matter of fact, recent works emphasized the stabilizing effect of delayed feedback if a real multiple spectral occurs in the closed-loop called multiplicity-induced-dominancy (MID) property allowing to an assignment approach. The purpose of this work is to investigate the properties of the proposed MID-based output feedback controller in terms of vibration damping.

Introduction

This work focuses on the effect of multiplicity of spectral values on the exponential stability of a sixth-order retarded differential equation. An efficient way to study time-delay systems solution's stability is the frequency domain approach since in the Laplace domain, where a number of effective methods have been proposed, the stability analysis amounts to studying the distribution of the characteristic quasipolynomial function's roots, see for instance [10, 6, 7]. It is worth noting that the rightmost root for a quasipolynomial function corresponding to stable time-delay systems is actually the exponential decay rate of its time-domain solution, see for instance [9] for an estimate of the decay rate for stable linear delay systems. The dominance induced from a given multiple spectral value property called in the sequel *multiplicity-induced-dominancy* or MID for short is studied and analytically shown in scalar delay equations in [4], then in second-order systems controlled by a delayed proportional is proposed in [2] where its applicability in damping active vibrations for a piezo-actuated beam is proved. An extension to the delayed proportional-derivative controller case is studied in [3, 5] where the dominance property is parametrically characterized and proven using the argument principle. Further, in [1] some sufficient conditions are established showing that such MID property holds for arbitrary-order dynamical system.

Problem statement

System description

The system considered here is described in Fig. 1. It is a composite membrane composed by a brass disc with a clamped circular edge. This disc is embedded into a mobile support moving only along the z axis. The moving support is subjected to an unknown acceleration, noted $w(t)$ in the sequel. This flexible membrane is equipped with two PZT-based piezoelectric patches: one used as an actuator and the other used as a sensor. The sensor's thickness is $0.7mm$. It is greater than the actuator's thickness which is $0.4mm$. An explanation about why should the thickness of a piezoelectric sensor must be greater than the actuator's one can be found in [11]. These circular patches are supposed to be rigidly bounded on the disc, one on each side, and centered according to the axis of symmetry. All the physical parameters of the materials used here can be found in [8].

The main dimensions of the composite membrane are given in Fig. 1. The controlled input noted $u(t)$ is the voltage applied across the piezoelectric actuator. The measured output noted $y(t)$ is the electric voltage delivered by the piezoelectric sensor. The disturbance input $w(t)$ is the total acceleration applied to the clamped circular edge of the structure. The controlled output that we consider, noted $z(t)$, is the z component of the acceleration of a point located at the center of the disc and on the upper side of the sensor.

The input-to-output transfer functions of finite order are derived from a Finite Element modelling of the axisymmetric membrane, following the steps described in [12].

Control approach

An interesting control objective is to damp the peaks of resonance of the first three bending modes, by using an *output feedback controller*, without affecting the vibrating modes that are neglected in the model considered here.

Figure 1: Axisymmetric composite membrane (dimensions on the right) inserted in the device which is subjected to vibrations (Computer Aided Design figure on the left)

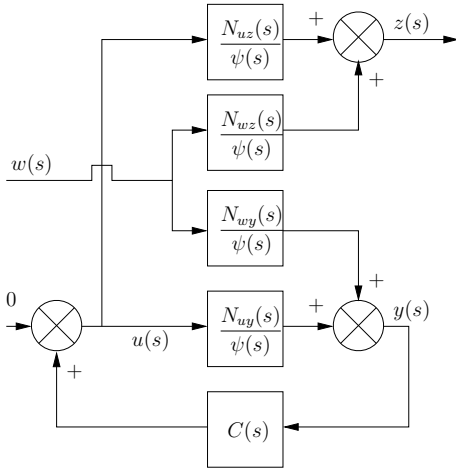

Figure 2: Feedback control structure.

By using the same notations as in [12], the piezo-actuated system is inserted in the output feedback control structure of Fig. 2, with a zero-reference signal and an input disturbance w corresponding to a rectangular impulse signal. The control problem consists in damping the vibrations due to the first three modes when the mobile support is subjected to a shock like disturbance. We define the output feedback control law $u(s) = C(s, \tau) y(s)$ involving the following Multiplicity-induced-dominancy (MID) controller given in Laplace domain by

$$C(s, \tau) := \frac{N(s, \tau)}{D(s, \tau)} \quad \text{where } N(s, \tau) := n_0 + n_{r_0} e^{-\tau s} \quad (1)$$

$$\text{and } D(s, \tau) := d_0 + d_{r_0} e^{-\tau s}.$$

By applying inverse Laplace transform, it can be easily shown that this control law is given in time domain by

$$u(t) = -\frac{d_{r_0}}{d_0} u(t - \tau) + \frac{n_0}{d_0} y(t) - \frac{n_{r_0}}{d_0} y(t - \tau) \quad (2)$$

which is an output feedback control law based on proportional actions plus delayed proportional actions.

Simulation results

The MID method gives the following numerical values for the parameters of the controller in (1) that assigns $\lambda_0 = -600$ as a rightmost root of multiplicity equal to 3: $n_0 \simeq 7.478025835$, $n_{r_0} \simeq 69.88393518$, $d_0 \simeq 1.626843813$, $d_{r_0} \simeq 5.858004955$ and $\tau \simeq 0.0001904171687$. To show the efficiency of the proposed MID-controller, we propose to compare, in Fig. 3, the time responses of both output signals in open-loop (blue) and in closed-loop (red) when the disturbance w is a rectangular impulse (black), say like a shock. We also put the time response of the control signal u that exhibits a peak of magnitude roughly equal to 12 V which is reasonable for this application.

 Figure 3: Time responses of the measured output y on the left, of the controlled output z on the middle and of the closed-loop control signal u on the right.

Conclusions

We have just shown a work dealing with the active vibration control of an axisymmetric membrane piezo-actuated, using closed-loop pole placement approach in order to design an efficient MID-based controller satisfying the control problem.

Analysis of Chatter Mechanisms in Cutting Process

Andrzej Weremczuk*, Rafał Rusinek* and Jerzy Warminski*

*Department of Applied Mechanics, Lublin University of Technology, Lublin, Poland

Summary. Analysis of a nonlinear two degree of freedom model of a cutting process is presented in the paper. Classical regenerative mechanism of chatter is enriched in an additional friction phenomenon which generates frictional chatter. A goal of the paper is to detect a mutual interaction between the regeneration and frictional effect. The nonlinear model is solved by means of the multiple time scale method. Stability of cutting process is checked in order to determine stability lobes diagrams and to find an influence of friction on the process. Nonlinear behaviour is also examined for different variants of stiffness ratio with the help of bifurcation diagrams where cutting velocity is chosen as the bifurcation parameters. Finally, the maps of chatter amplitudes are presented and new frictional stability lobe diagrams are proposed to analyse an influence of friction.

Introduction

Nowadays, cutting process is still one of the most popular manufacturing method. During machining operations, vibrations called chatter may occur between the workpiece and the tool. This phenomenon generates dimensional and geometrical inaccuracies, a poor surface finish, faster tool wear and reduction of spindle life. Therefore, it is necessary to understand and control chatter vibrations. The regenerative effect is related to the wavy workpiece surface generated by the previous cutting tooth pass. While, the frictional mechanism results from friction force occurring between the tool and the workpiece. Although, trace regeneration and friction are the most important in practical operations there are little papers which consider regenerative and frictional mechanisms together. Friction always exists in real cutting process therefore, excluding this phenomenon is rather a big simplification. Generally, chatter is a dynamic instability that can limit material removal rates, cause a poor surface finish and even damage the tool or the workpiece. Usually in the literature the problem of the regenerative and frictional chatter mechanisms are investigated separately, although friction phenomena exist always in case of a contact problem. Therefore, this approach describes the model of orthogonal cutting both with regenerative and frictional effect. The model of frictional chatter, presented in [3], is completed with regenerative effect. In order to get knowledge about an influence of frictional chatter on regenerative one and complete an mathematical approach, the mathematical model of cutting is developed and solved with the help of the method of the multiple time scales [1, 2]. An explanation of mutual interaction between frictional and regenerative mechanisms is the main purpose of the paper.

Mathematical model

To analyse regenerative and frictional mechanism of chatter, two degree of freedom model of orthogonal cutting is used (Fig.1a). Figure 1b presents the force distribution on the tool edge separately for the rake face and flank face. This is a quite new approach because classical analysis takes into account only the rake face forces or resultant force acting on the tool. Here, the resultant cutting force is distributed on the normal force on the rake N_1 and face N_2 force. The normal forces together with friction between the tool and the workpiece cause the friction force F_1 and F_2 on the rake and the flank face, respectively. This approach of cutting force distribution is presented more detailed in the paper [3]. The normal and the friction force are defined as follows:

$$\begin{aligned} N_1 &= Q_o a_p \left(c_1 (v_r - 1)^2 + 1 \right) H(a_p) H(v_r), \quad N_2 = K_{con} a_p H(a_p), \\ F_1 &= N_1 \mu_x \left(\operatorname{sgn}(v_f) - \alpha_x v_f + \beta_x v_f^3 \right), \quad F_2 = N_2 \mu_y \left(\operatorname{sgn}(v_r) - \alpha_y v_r + \beta_y v_r^3 \right), \end{aligned} \quad (1)$$

where, Q_o represents the specific cutting force modulus, a_p is the instantaneous penetration of the tool into the workpiece (depth of cut), c_1 is a constant controlling the dependence of the cutting force on the relative velocity between the tool and the workpiece v_r , K_{con} is the contact stiffness and H represents the Heaviside function. Note that the $H(v_r)$ models the loss of contact between the tool and the chip while $H(a_p)$ accounts for the tool coming out of the workpiece. In the friction forces μ_x , μ_y denote the static coefficient of friction between the tool and the workpiece, and the tool and the chip, respectively, α_x , α_y , β_x , β_y are constants which regulate the nonlinear characteristics of the friction forces between the respective surfaces in contact. v_r and v_f are the relative velocities between the tool and the workpiece, and the tool and the chip, respectively and sgn represents the sign function. The instantaneous penetration of the tool into the workpiece or the cutting depth a_p can be written in terms of the specified depth of cut a_{po} , the tool motion y and the tool motion one rotation before $y(t-\tau)$ as:

$$a_p = a_{po} - y + \delta y(t - \tau), \quad (2)$$

where, δ equals 0 or 1 when the regenerative effect is switched off or on. Time delay τ is connected with a spindle or a workpiece speed Ω by equation $\tau = 2\pi/\Omega$. The relative velocities between the tool and the workpiece v_r , and the tool and the chip v_f are related to the nominal cutting speed v_o , the shear angle of the workpiece material φ and the tool velocities by:

$$v_r = v_o - x', \quad v_f = v_r \tan \varphi - y'. \quad (3)$$

Figure 1: Two degrees of freedom model of orthogonal cutting (a), force distribution on tool edge (b) [3]

The non-dimensional equations of motion is defined in the form:

$$x'' + 2z_x x' + x = f_x, \quad y'' + 2z_y \sqrt{\alpha} y' + \alpha y = f_y, \quad (4)$$

where:

$$\alpha = \frac{k_y}{k_x}, \quad \omega_x^2 = \frac{k_x}{m}, \quad \omega_y^2 = \frac{k_y}{m} = \alpha \omega_x^2, \quad z_x = \frac{c_x}{2m\omega_x}, \quad z_y = \frac{c_y}{2m\omega_y}, \quad (5)$$

and the forces are given by:

$$\begin{aligned} f_x &= q_o a_p \left(c_1 (v_r - 1)^2 + 1 \right) H(a_p) H(v_r) + k_{con} a_p H(a_p) \mu_y \left(\text{sgn}(v_r) - \alpha_y v_r + \beta_y v_r^3 \right), \\ f_y &= k_{con} a_p H(a_p) + q_o a_p \left(c_1 (v_r - 1)^2 + 1 \right) H(a_p) H(v_r) \mu_x \left(\text{sgn}(v_f) - \alpha_x v_f + \beta_x v_f^3 \right). \end{aligned} \quad (6)$$

Analytical and numerical results

The nonlinear model described by Eq.4 is solved by means of the multiple time scale method. Next to verified analytical result the numerical simulation was performed by using Matlab-Simulink software. Both results are presented as stability lobes diagrams (Fig.2), where cutting velocity v_o , proportional to the spindle speed Ω , is on the horizontal axis and on the vertical axis is cutting resistance q_o . Unstable areas (gray color in Fig.2a) were obtained analytically, while the amplitude value (gray scale in Fig.2b) was also numerically determined. In both cases, a characteristic stable area was observed in the middle of the graph.

Figure 2: Stability lobes diagram obtained analytically (a) and numerically (b)

Conclusions

The paper presents the results of analytical and numerical analysis of a two degree of freedom nonlinear model. An analytical solution of the model near the primary resonances are obtained by using the method of multiple time scales. The frictional and regenerative mechanisms of chatter are important both acting together and separately. The regenerative effect is stronger for small velocities (rotational speeds) while the frictional one for higher velocities. However, it depends on the workpiece stiffness ratio as well. Friction causes a stabilising effect when regenerative chatter dominates. Regardless the chatter mechanisms the chatter free region can be found in the middle range of analysed velocities.

Bifurcation analysis at a degenerate parameter point of a non-collocated force control model

Li Zhang*, Huailei Wang* and Gabor Stepan**

*College of Aerospace Engineering, Nanjing University of Aeronautics and Astronautics, Nanjing, China

**Department of Applied Mechanics, Budapest University of Technology and Economics, Budapest, Hungary

Summary. Normal form analysis is carried out at a degenerate parameter point of the low degree-of-freedom non-collocated delayed force control model. It is shown that around the degenerate point where both the derivative of the real part of the eigenvalues and the first Lyapunov coefficient are zero, neutral stable periodic orbits arise and a specific transcritical bifurcation of limit cycles takes place.

Introduction

Force control is a relevant task of human motion control when an operator touches an object or the environment, and it is often studied as important part of the efforts for understanding human behavior. Due to the processing time of the sensory signals in the neural system, and also to the reaction time of the muscles, delay is one of the essential parameters in force control. This study will present bifurcation analysis at a degenerate parameter point of a non-collocated force control model in the presence of human reaction time delays.

Mechanical model

A basic model of delayed force control with non-collocated force sensor configuration is considered. A block of mass m is in contact with the rigid environment via a spring of stiffness k_1 along a horizontal axis as shown in Figure 1. The contact force can be obtained by a force sensor, which is a serially connected spring of large stiffness $k_2 (\gg k_1)$ located at the contact point to the rigid environment. The sensed signal is fed back to the control force Q of the human actuation. The governing equation takes the following form:

$$\begin{aligned} m\ddot{q}_1 &= Q - k_1(q_1 - q_2) \\ 0 &= k_1(q_1 - q_2) - k_2 q_2 \end{aligned} \quad (1)$$

where q_1 and q_2 are the absolute positions of the block and the end point of the spring that detects the force, respectively. With a simple control strategy and with saturation of the control force into consideration, the actual control force Q at time instant \tilde{t} is given by

$$Q(\tilde{t}) = -F_s \tanh\left(\frac{1}{F_s} P(k_2 q_2(\tilde{t} - \tau) - F_d)\right) + k_2 q_2(\tilde{t} - \tau) \quad (2)$$

where P is the feedback gain, τ is the reaction time of the actuator, and F_s can describe the level of the actuator force saturation. By shifting $q_1(t)$ by the equilibrium position q_{10} of the block m , i.e., by introducing the coordinate $\tilde{x}(t) = q_1(t) - q_{10}$, using the assumption $k_2 \gg k_1$, and introducing the dimensionless coordinates $x = \tilde{x} / (F_s / k_1)$ and $t = \tilde{t} / \tau$, the Newtonian equation (1) is transformed to:

$$\ddot{x}(t) + (\omega_n \tau)^2 x(t) = (\omega_n \tau)^2 x(t-1) - (\omega_n \tau)^2 \tanh(Px(t-1)) \quad (3)$$

Figure 1: A basic model of non-collocated delayed force control

Linear Analysis

By means of analyzing the characteristic equation of the linear part of Equation (3), the stability chart in the parameter plane $(P, \omega_n \tau)$ is obtained as shown in Figure 2. The stability boundaries and regions are determined according to the number of characteristic roots with positive real parts.

Figure 2: Stability chart in the parameter plane $(P, \omega_n \tau)$. Shaded regions refer to stability. Numbers indicate the number of characteristic roots with positive real parts. Black stability boundaries refer to supercritical Hopf bifurcations and red ones refer to subcritical Hopf bifurcations. The blue point at $(\pi, 1)$ is the degenerate parameter point.

The 5th order Normal Form at the degenerate parameter point

According to [1], the black stability boundaries refer to supercritical Hopf bifurcations and the red stability boundaries refer to subcritical Hopf bifurcations in Figure 2. At the blue point $(\pi, 1)$, the sense of Hopf bifurcations changes and the stability of the equilibrium swaps, which indicates that both the first Lyapunov coefficient and the derivative of the real part of the eigenvalues at the critical parameters are zero. To study this special degenerate parameter point, normal form up to the 5th order is carried out via symbolic calculation [2]. Let $P = 1 + \mu$, then the normal form reads

$$\dot{y}_1 = i\omega_c y + S_1 y \mu + S_2 y \mu^2 + \Delta_1 y^2 \bar{y} + S_3 y^2 \bar{y} \mu + \Delta_2 y^3 \bar{y}^2 \quad (4)$$

where $\text{Re}(S_1) = 0$, $\text{Re}(\Delta_1) = 0$, $\text{Re}(S_2) = \pi^2 / 4$, $\text{Re}(S_3) = -\pi^2 / 2$ and $\text{Re}(\Delta_2) = \pi^2 / 4$. Therefore, the neutral stable bifurcated periodic vibration has amplitude ρ

$$\rho = 2\sqrt{1 - \mu} \quad (5)$$

as shown in Figure 3.

Figure 3: Bifurcation diagram of periodic motions with respect to feedback gain P at $\omega_n \tau = \pi$. Red line refers to unstable equilibrium.

Conclusion

The normal form up to the fifth order is obtained at the degenerate parameter point where both the derivative of the real part of the critical eigenvalues and the first Lyapunov coefficient at the critical parameters are zero for the simple non-collocated force control model. The nonlinear analysis shows that neutral stable periodic orbits arise around this point. This is not a standard fold bifurcation, but transcritical bifurcation of limit cycles, which happens around this degenerate parameter point.

Stabilizability Limits for the Inverted Pendulum with a Multiple-Delay Fractional-Order Controller

Tamas Balogh, Tamas Insperger

*Department of Applied Mechanics, Budapest University of Technology and Economics and
MTA-BME Lendület Human Balancing Research Group, Budapest, Hungary*

Summary. In this study, we consider the PD^μ control of the inverted pendulum with different delays in the proportional and the fractional derivative terms. This concept gives a transition between several special cases already investigated in the literature. The main question is whether the critical delay can further be extended by employing fractional-order feedback combined with delay detuning.

Introduction

Time delay in state-feedback systems sets a strong limitation in the stabilization of unstable plants. If the feedback delay is larger than some critical value, then the system cannot be stabilized. This feature can well be demonstrated by the inverted pendulum paradigm [3, 4]. Stabilization of an inverted pendulum by proportional-derivative (PD) feedback is possible if and only if the feedback delay τ is smaller than a critical delay given by

$$\tau_{\text{crit}}^{\text{PD}} = \frac{T}{\pi\sqrt{2}}, \quad (1)$$

where T is the period of the oscillations of the pendulum hung downwards [4]. If $\tau > \tau_{\text{crit}}$, then one cannot find proportional and derivative gains that stabilizes the inverted position of the pendulum.

The critical delay can be increased by employing control laws other than PD feedback. For instance, if the feedback involves acceleration (PDA feedback), then the critical delay can be increased to $\tau_{\text{crit}}^{\text{PDA}} = \sqrt{2} \tau_{\text{crit,PD}}$ [3]. Alternatively, if the delay of the proportional and the derivative terms are detuned, then the critical delay increases to $\tau_{\text{crit}}^{\text{dPD}} \approx 1.47 \tau_{\text{crit}}^{\text{PD}}$ [3]. Another alternative way to increase the critical delay is the application of fractional-order control: in case of PD^μ feedback, $\tau_{\text{crit}}^{\text{PD}^\mu} \approx 1.12 \tau_{\text{crit}}^{\text{PD}}$ [1].

Introducing fractional-order derivative in the feedback loop allows us to exploit the time history starting from some initial time to the current time instant. This can be seen from the most frequently used definitions of fractional derivative: the Riemann-Liouville fractional derivative, the Caputo fractional derivative and the Grünvald-Letnikov fractional derivative. All of these definitions of the fractional derivative resembles a distributed delay term that converts into a point delay term if the order of the derivative is an integer [2].

Problem statement

The characteristic function of the system under investigation reads

$$D(s) = s^2 - a_0 + k_p e^{-s\tau_p} + k_d s^\mu e^{-s\tau_d}, \quad (2)$$

where $a_0 > 0$ is the open-loop system parameter, $\tau_p > 0$ and $\tau_d > 0$ are the feedback delays and $0 < \mu < 2$ is the order of the fractional derivative. This system can also be interpreted as a control system with a single latency τ with some additional delays (delay detunings) $\delta_p \geq 0$ and $\delta_d \geq 0$ in both terms such that $\tau_p = \tau + \delta_p$, $\tau_d = \tau + \delta_d$.

The D-subdivision method can also be applied to fractional-order systems. Substitution of $s = 0$ and $s = \pm i\omega$, $\omega > 0$ into $D(s) = 0$ gives the D-curves

$$s = 0 : \quad k_p = a_0, \quad k_d \in \mathbb{R}, \quad (3)$$

$$s = \pm i\omega, \omega > 0 : \quad \begin{cases} k_p = (a_0 + \omega^2) \frac{\sin(\frac{\mu\pi}{2} - \tau_d\omega)}{\sin(\frac{\mu\pi}{2} - (\tau_d - \tau_p)\omega)}, \\ k_d = (a_0 + \omega^2) \frac{\sin(\tau_p\omega)}{\omega^\mu \sin(\frac{\mu\pi}{2} - (\tau_d - \tau_p)\omega)}. \end{cases} \quad (4)$$

The D-curves bounds the parameter regions in the plane (k_p, k_d) where the number of unstable characteristic roots is constant. Stable regions (zero unstable characteristic roots) can be determined numerically using the argument principle. When the delays increase then the stable regions typically shrink and disappear. There is a critical delay $\tau_{\text{crit}}^{\text{dPD}^\mu}$: if $\min(\tau_p, \tau_d) > \tau_{\text{crit}}^{\text{dPD}^\mu}$ then the system cannot be stabilized by any triplet (k_p, k_d, μ) . The goal of this study is to determine the stabilizability boundaries in the plane (τ_p, τ_d) and to find $\tau_{\text{crit}}^{\text{dPD}^\mu}$.

Special case: PD^μ controller with a single delay

Stabilizability was already investigated if the delays in the proportional and fractional derivative terms are the same ($\tau_p = \tau_d = \tau$). In the case of a PD^μ controller with a single delay, the stabilizable region was derived in [1] in the plane of the dimensionless parameters $a = a_0\tau^2$ and μ (see the left panel in Figure 1).

Using the D-subdivision technique, we can observe four types of loss of stabilizability. These geometric conditions can be directly translated into the multiplicity conditions shown in the right panel of Figure 1. This gives a more uniform description of the stabilizability boundaries compared to that of [1]. Conditions $\det \mathbf{J} = 0$ corresponds to the singularity of the Jacobian matrix of the other three (four) equations with respect to k_p, k_d, ω_1 (and ω_2). The geometric interpretation of this condition is the tangency of D-curves at the limit of stabilizability.

Figure 1: Stabilizable region of (2) if $\tau_p = \tau_d = \tau$ with $a = a_0 \tau^2$ (left). The stabilizability boundaries and multiplicity conditions in the plane (μ, τ) if $a_0 = 2$ (right).

Main results: stabilizability diagrams in the plane (τ_p, τ_d)

Using a similar technique described in the previous section, we can construct stabilizability diagrams for the case $\tau_p \neq \tau_d$. First, we need to detect the geometric conditions at the limit of stabilizability using D-subdivision. These geometric conditions can be translated into multiplicity conditions. From the multiplicity conditions, we obtain a nonlinear system of equations, which can be reduced after solving for k_p and k_d . Finally, the reduced equations can be solved using pseudo-arclength continuation.

Figure 2 shows the stabilizability boundaries in the plane (τ_p, τ_d) for different values of μ . The stabilizable region can be extended compared to the detuned PD controller ($\mu = 1$) by choosing an appropriate value of the fractional order μ . The largest admissible delay is obtained for $\mu = 0.999637$. In this case the critical delay is $\tau_{crit}^{dPD\mu} = 1.00778 \tau_{crit}^{dPD}$ (see the right panel of Figure 2). Hence, an extremely small but still finite extension of the critical delay can be achieved by employing detuned fractional-order control.

Figure 2: The stabilizability boundaries in the plane (τ_p, τ_d) if $\mu \leq 1$ (left) and $\mu \geq 1$ (middle) with $a_0 = 2$ (stabilizable regions are to the left of the curves). The path of the critical point associated with the maximal allowed delay in the plane (τ_p, τ_d) if $\mu \leq 1$ (right).

A Reynolds' Limit Formula for the Shear Stress in Dorodnitzyn's Boundary Layer

Carla V. Valencia-Negrete*

* Department of Physics and Mathematics, Universidad Iberoamericana, A. C., Mexico City, Mexico

Summary. Shear Stress growth is an indicator of Boundary Layer separation. The main difficulty to obtain clear descriptions of its behavior lies in Navier-Stokes Equations' non-linearity. On the other hand, Dorodnitzyn stated a Gaseous Boundary Layer problem, valid in atmospheric conditions, and deduced a second-order quasi-linear problem for a transformation of the Shear Stress. This article presents a mathematical formalization of this last problem and a Reynolds' Limit Formula for it, deduced with Bayada and Chambat's change of variables. For general compressible Reynolds' equations, the problem was solved by Chupin and Sart in 2012. Undoubtedly, there is a mathematical formalization for Dorodnitzyn's model previous from the one that is given here, but the author has not been able to find it in the literature. In earlier work, the author verified his first step simplification. Now, the formalization is extended to Dorodnitzyn's second-order quasi-linear problem. Then, the small parameter problem is deduced, and a bound, independent of the parameter, is found in the corresponding Sobolev Space to prove the existence of a Reynolds' Limit Formula for Dorodnitzyn's Shear Stress problem.

Abstract

The Earth's Global Mean Temperature is going to increase by, at least, 1.5°C in the next 10 to 33 years [3, p. 6]. As a consequence, there will be an increment in the number of severe droughts and flooding [3, p. 9]. Its origin, atmospheric convection, could be studied as a boundary layer separation problem. To identify its sources and sinks, the suggestion is to study *shear stress* growth deduced from approximate gaseous boundary layer models in atmospheric conditions.

Figure 1: Dorodnitzyn's Rectangular Domain $\mathcal{R} = (0, L) \times (0, h) \in \mathbb{R}^2$

In 1942, Dorodnitzyn stated a Gaseous Boundary Layer problem [2] in a rectangle $R = (0, L) \times (0, h) \subset \mathbb{R}^2$, where $L \gg h > 0$ [2], of three simplified stationary Conservation of Mass, Conservation of Momentum, and Conservation of Energy laws, Eq. (1), (2) and (3),

$$\frac{\partial (\rho u)}{\partial x} + \frac{\partial (\rho v)}{\partial y} = 0; \quad (1)$$

$$\rho \left(u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} \right) = -\frac{\partial p}{\partial x} + \frac{\partial}{\partial y} \left(\mu \frac{\partial u}{\partial y} \right); \quad y \quad (2)$$

$$\rho \left[u \frac{\partial (c_p T)}{\partial x} + v \frac{\partial (c_p T)}{\partial y} \right] = \frac{\partial}{\partial y} \left[\kappa \frac{\partial T}{\partial y} \right] + \mu \left(\frac{\partial u}{\partial y} \right)^2 + \frac{\partial p}{\partial t}, \quad (3)$$

where one can assume that the *stationary density* $\rho \in L^2(R; (0, \infty))$; that the *horizontal velocity component* $u \in L^2(R)$ has *generalized derivatives* $\partial u / \partial x$, $\partial u / \partial y$, $\partial^2 u / \partial y^2 \in L^2(R)$; the *vertical velocity component* $v \in L^2(R)$; the *absolute temperature* $T \in L^2(R; (0, \infty))$ with $\partial T / \partial y$, $\partial^2 T / \partial y^2 \in L^2(R)$; the *dynamic viscosity* $\mu \in L^2(R)$, the *pressure* $p \in L^2(R)$, the *thermal conductivity* $\kappa \in L^2(R)$, all of them with first order generalized derivatives in $L^2(R)$; and both products ρu , $\rho v \in L^2(R)$. This is, assume ρ , u , v , T , μ , p and κ are elements of the space $W^{1,2}(R)$, so that a *Leibnitz Rule* for product differentiation is valid in the non-empty open domain $R \subset \mathbb{R}^2$ when both factors and all the *generalized derivatives* involved are elements of $L^2(R)$ [4, p. 11]. The value c_p is the *specific heat at constant pressure for dry air*, and we have four Ideal Gas Thermodynamic Laws, Eq. (4), (5), (6), (7): the *Prandtl number* $Pr = 1$,

$$Pr = \frac{c_p \mu}{\kappa} = 1; \quad (4)$$

the *Equation of State* for the *Universal Gas Constant* R^* , a volume $V = \iiint_B dx dy dz$ of a ball $B(r, \mathbf{x}_0) \subset \mathbb{R}^3$ of positive radius $r > 0$ and center $\mathbf{x}_0 = (x_0, y_0, z_0)$ such that $(x_0, y_0) \in R$ and $R \times \{0\} \subset B$, and the number of moles n of an ideal gas corresponding to the volume V ,

$$p V = n R^* T; \quad (5)$$

the *adiabatic polytropic atmosphere* [7, p. 35] where $b = 1.405$ and c are constants,

$$p V^b = c; \quad (6)$$

and the *Power Law* [6, p. 46]

$$\frac{\mu}{\mu_h} = \left(\frac{T}{T_h} \right)^{\frac{19}{25}}. \quad (7)$$

The boundary conditions, Eq. (8), (9), (10), (11), (12), (13), are given by the *free-stream velocity* $U > 0$, the *no slip condition*,

$$(u, v)|_{\{(x,h): 0 \leq x \leq L\}} = (-U, 0), \quad (8)$$

$$(u, v)|_{\{(x,0): 0 \leq x \leq L\}} = (0, 0), \quad (9)$$

the *free-stream temperature* $T_h > 0$, the *free-stream dynamic viscosity* $\mu_h > 0$,

$$T|_{\{(x,h): 0 \leq x \leq L\}} = T_h > 0, \quad (10)$$

$$\mu|_{\{(x,h): 0 \leq x \leq L\}} = \mu_h > 0. \quad (11)$$

periodic conditions for all $y \in [0, h]$:

$$(u(0, y), 0) = (u(L, y), 0); \quad (12)$$

and a Neumann condition:

$$\frac{\partial T}{\partial y} \Big|_{\{(x,0): 0 \leq x \leq L\}} = 0. \quad (13)$$

As Busemann previously did in 1935, Dorodnitsyn expressed T in terms of u , but considers the Conservation of Energy Law in terms of the *total energy per unit mass*, $E = c_p T + u^2/2$, in the form presented by Luigi Crocco in 1932. Additionally, he includes a pressure variation term, $\partial p / \partial x$, and so allows the possibility of a Boundary Layer separation. By a successive substitution of $T(u)$, this system of seven equations is reduced to a system of just two with inherited boundary conditions in terms of a *stream function* defined, in the formalisation, by means of a generalized *Green's Theorem* [5, p. 121] that is valid for elements of the Sobolev Spaces $W^{1,2}(R)$. Moreover, he defined a *diffeomorphism* $R \xrightarrow{s} \Pi$ that allows writing von Kármán's Integral Formula for a compressible fluid in an incompressible form in a polygonal domain $\Pi = s(R)$ where $(x, y) \xrightarrow{s} (\ell, s)$, $\ell(\hat{x}, \hat{y}) \xrightarrow{\hat{x}} \int_0^{\hat{y}} p(x, \hat{y}) dx$ and $s(\hat{x}, \hat{y}) \xrightarrow{\hat{y}} \int_0^{\hat{x}} \rho(\hat{x}, y) dy$. This way, he opens the road to adapt Blasius' method to state the *stream function* problem as an Ordinary Differential Equation.

In order to do this, he applies a subsequent *diffeomorphism* $\Pi \xrightarrow{z} S$ that takes the polygon Π into a strip band of infinite positive heights $S = z(\Pi)$ with $(\ell, s) \xrightarrow{z} (\ell, z)$ and $z(\ell, s) \xrightarrow{s} s/\sqrt{\ell}$. In terms of z , the *shear stress* $\tau = \mu \partial u / \partial y$ becomes $\tau_s(z) = (a x^{1/2} \tau) \circ s^{-1} \circ z^{-1}(z)$ for a constant a . If we denote $u_s(z) = u \circ s^{-1} \circ z^{-1}(z)$, $i_0 = c_p T_0$ and $\sigma_0 = 1 - (U^2/2i_0)$ where $T_0 = T_h + U^2/(2c_p)$ is the absolute temperature value at height $y = 0$ in R , then $(u, v, T, p, \rho, \mu, \kappa)$ is a *classical solution* of Eq. (1), (2), (3), (4), (5), (6), (7) with boundary conditions (8), (9), (10), (11), (12), (13) if and only if $\tau_s \in C^1(0, \infty)$ satisfies the second-order quasi-linear problem:

$$\tau_s \frac{\partial^2 \tau_s}{\partial u_s^2} = -A u_s \left(1 - \frac{u_s^2}{2i_0} \right)^{-6/25}, \quad (14)$$

with inherited boundary conditions and $A = 1/2 \cdot (n R^* T_0)/V \cdot T_0^{\frac{2b}{b-1}} \cdot \sigma_0^{1 - \frac{b}{(b-1)}}$. Bayada and Chambat's change of variables $R \xrightarrow{\phi^\epsilon} R^\epsilon$ for $\epsilon = h/L > 0$ with $(x, y) \xrightarrow{\phi^\epsilon} (x/L, y/(L\epsilon))$ provides a small parameter problem [8] for the sequence $(v^\epsilon)_\epsilon = (u^\epsilon, v^\epsilon)_\epsilon$ where $u^\epsilon = \frac{1}{L} u$ and $v^\epsilon = \frac{1}{L\epsilon} v$. This way, there is a inherent adimensional problem for the sequence (τ_s^ϵ) so that the existing bound found for (u^ϵ) in [8] is valid for (τ^ϵ) , and we can derive a Reynolds' Limit Formula for Dorodnitsyn's Shear Stress problem.

Summary Present study concerns the dynamics of special localized solutions emerging in the mass-in-mass anharmonic oscillatory chain in the state of acoustic vacuum. Each outer element of the chain incorporates an additional, purely nonlinear mass attachment. Analytical study of the later, revealed the distinct types of stationary discrete breather solutions. Along with the analytical description of their spatial wave profiles we also establish their zones of existence in the space of system parameters. Stability properties of these solutions are assessed through the linear analysis (Floquet). All analytical models are supported by the numerical simulations of the full model.

Introduction

Emergence of spatially localized, time-periodic solutions in the conservative nonlinear system, are known since the pioneering work by Ovchinnikov [1] at 1968. Special localized solutions which are usually referred to as discrete breathers (DBs) remain a subject of broad research interest in the various aspects of modern physics and mechanics. In fact DBs have a well-developed analytical methods when applied to the classical, nonlinear discrete models such as Discrete Klein-Gordon chains (DKGs), Fermi-Pasta Ulam (FPU) models, as well as the Discrete Nonlinear Schrodinger (DNLS) model [2]. Formation of spatially localized solutions in all these classical nonlinear models has quite a broad range of applications, including Josephson junctions, nano-mechanical systems, Bose-Einstein condensates, carbon nanotubes, (see for example [3]). Of late, formation of localized excitations as well as nonlinear normal modes in highly nonlinear discrete models admitting a state of acoustic vacuum e.g. purely cubic FPU chains [4], uncompressed granular crystals [5-6], has become a subject of intense research.

Some recent studies, have considered both analytically and numerically the formation of DBs in the two different configurations of locally resonant granular crystals i.e. weakly nonlinear, compressed granular chain [31] as well as the uncompressed ones [32]. Both configurations comprised the chain of granular elements incorporating the internal, linear oscillating inclusions. These numerical and analytical studies unveiled the stationary and mobile DBs and presented a detailed analysis of their stability properties as well as the corresponding bifurcation structures. The system under consideration in the present study qualitatively differs from the previously considered ones by its internal nonlinear, local substructure as well as the special dynamical state of acoustic vacuum. In this study, we focus on the analytic description of stationary discrete breather solutions as well as the prediction of zones of their existence in the space of system parameters.

Model

System under consideration is an infinite, locally resonant chain of elements inter-coupled by linear springs. The governing non-dimensional equations of motion read:

$$\begin{aligned}\varphi_n'' &= (\varphi_{n-1} - \varphi_n)^3 - (\varphi_n - \varphi_{n+1})^3 - \alpha(\varphi_n - \psi_n)^3 \\ \varepsilon \psi_n'' &= \alpha(\varphi_n - \psi_n)^3\end{aligned}\tag{1.1}$$

Analysis

Given the homogeneous structure of the system under consideration it is quite natural to study the dynamics and the bifurcation structure of the corresponding standing wave solutions by exploiting the well-known method of separation of variables $\varphi_n(\tau) = \hat{u}_n \eta(\tau)$, $\psi_n(\tau) = \hat{v}_n \eta(\tau)$. Where $u = \{\hat{u}_n\}_{n \in \mathbb{Z}}$, $v = \{\hat{v}_n\}_{n \in \mathbb{Z}}$ are real sequences and $\eta(\tau)$ is a time-dependent modal coordinate. Introducing this change of coordinates in (1.1) and applying some trivial algebraic manipulations, we obtain the following system of algebraic equations

$$\begin{aligned}(u_{n-1} + u_n)^3 + (u_n + u_{n+1})^3 &= u_n - \varepsilon v_n \\ \alpha(u_n + v_n)^3 &= \varepsilon v_n\end{aligned}\tag{1.2}$$

In the present study we construct the analytical description of the spatial profiles of DBs and derive the parametric zones of their existence. These solutions assume the out-of-phase oscillations between the adjacent outer as well as the outer and inner elements. Apparently, analysis of DBs may become extremely cumbersome, if one tries to tackle the system (1.2) as a whole. However, system (1.2) can be considerably simplified if one manages to reduce it from the system involving the amplitudes of vibrations of outer and inner masses $\{u_n\}_{n \in \mathbb{Z}}$, $\{v_n\}_{n \in \mathbb{Z}}$ into the one containing only

the motion of the outer elements $\{u_n\}_{n \in \mathbb{Z}}$). Fortunately, any solution of system (1.2) can be effectively represented by the following reduced system

$$\begin{aligned} (u_{n-1} + u_n)^3 + (u_n + u_{n+1})^3 &= u_n - \varepsilon (t^{[m]}(u_n))^3 \\ t^{[m]}(u_i) &= 2\sqrt{\frac{\beta}{3}} \cos\left(\frac{1}{3} \arccos\left(-\frac{3u_i}{2\beta}\sqrt{\frac{3}{\beta}}\right) - \frac{2\pi m}{3}\right), \quad m=0,1,2 \end{aligned} \quad (1.3)$$

where $m=0,1,2$ corresponds to a certain branch assigned to each one of the cells. In the present study we present the asymptotic description of DBs and establish analytically their zones of existence. Passing to the quasi-continuum limit we obtain the following essentially nonlinear ODEs for each one of the branches,

$$u[u^2]_{xx} + \frac{8}{3}u^3 + \frac{1}{6}\left\{\varepsilon(t^{[m]}(u))^3 - u\right\} = 0, \quad u \leq u_{\max} \quad (1.4)$$

It can be easily shown that the out-of-phase oscillations, can be obtained on the two branches only, namely ($m=0,1$). Comparison of exact spatial wave profiles of DBs computed from (1.3) with these obtained from QCA (1.4) are presented in Fig. 1 (a) and (b) panels accordingly. In Fig. 1 (c) and (d) we illustrate their zones of existence obtained analytically.

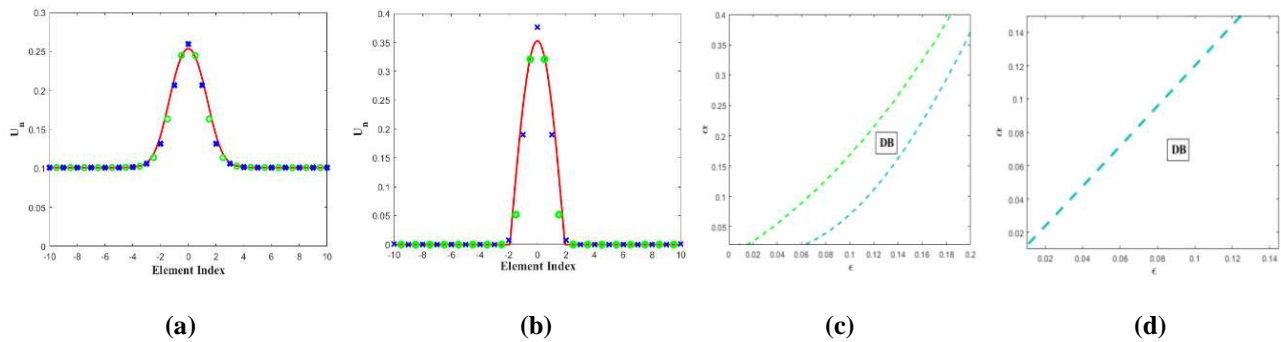

Figure 1 (a, b) Spatial wave profiles of DBs corresponding to the homogeneous configurations. QCA is denoted with the bold solid line while exact solutions are denoted with ‘cross’ markers for site-centered breathers and ‘o’ markers for the bond-centered breathers. (a) $m=0$ (b) $m=1$. System parameters: $\varepsilon=0.1, \alpha=0.1$. (c, d) Zones of existence of a discrete breather (DB) corresponding to the homogeneous configurations i.e. $m=0,1$. (c) ($m=0$) (d) ($m=1$).

Conclusions

In the present study we analyze the special family of discrete breather solutions. Results of analytical study enable to describe the spatial wave profiles and establish their zones of existence. Separate linear stability analysis of DBs performed in this study revealed their stability zones in the plane of system parameters.

Asymptotic analysis of transient behavior of two coupled exciters

Tunc Yüzbaşıoğlu*, Alexander Fidlin*

*Karlsruhe Institute of Technology (KIT), Institute of Engineering Mechanics, Karlsruhe, Germany

Summary. A model of two coupled exciters is considered to investigate transient behavior of self-synchronizing systems with non-negligible damping. An averaging method for partially strongly damped systems is used for asymptotic analysis. Stationary solutions of the system are derived. Attraction domains of different types of solutions are identified and depicted in phase space.

Introduction

Application of multiple exciters and utilization of self-synchronization in mechanical systems led to development of a new generation of vibratory machines including self-synchronous vibrating feeders, conveyors, screens, grinders and so on. Such systems replace kinematic connections like gears or chains with self-synchronization to generate required excitation forces. They also have the advantage of distributing and decreasing the load on bearings, if instead of just one big exciter, multiple smaller exciters are used.

The synchronization theory of mechanical exciters was first proposed by Blekhman [1]. Since then, many different synchronous systems are investigated. Previous works mostly just analyze synchronous solutions, their stability and existence with the assumption of negligible damping and that synchronization occurs far away from resonance. Goal of this work is to analyze transient behavior of synchronizing systems, examine different types of solutions in phase space and determine attraction domains of stable solutions.

Investigated model

Investigated model of two coupled exciters is shown in Fig. 1. It consists of a carrier of mass M , which is elastically suspended with a spring-damper element of stiffness c and damping d in horizontal direction. Two unbalanced rotors of mass m_i , moment of inertia J_i and eccentricity e_i , where $i = 1, 2$ is the index describing the number of rotors, are mounted on the carrier. They are driven in the same direction by induction or DC engines of limited power with a linearized torque characteristic given as $T_i = U_i(\omega_i^* - \dot{\varphi}_i)$. The parameter U_i describes the slope of motor characteristic and ω_i^* the nominal rotation speed. The equations of motion read

Figure 1: Investigated model

$$\xi'' + 2\sigma\xi' + \xi = \sum_{i=1}^2 \mu_i \nu_i (\varphi_i'' \sin \varphi_i + \varphi_i'^2 \cos \varphi_i), \quad \varphi_i'' = \varepsilon \left(\frac{s_i}{\nu_i} \xi'' \sin \varphi_i + u_i (\lambda_i - \varphi_i') \right) = \varepsilon f_{\varphi_i}, \quad i = 1, 2,$$

with the non-dimensional parameters and variables

$$\mu_i = \frac{m_i}{M^*}, \quad \nu_i = \frac{e_i}{e^*}, \quad \varepsilon s_i = \frac{1}{1 + J_i/m_i e_i^2}, \quad e^* = (e_1 + e_2)/2, \quad u_i = \frac{U_i s_i}{k m_i e_i^2}, \quad \lambda_i = \frac{\omega_i^*}{k},$$

$$\xi = \frac{x}{e^*}, \quad k^2 = \frac{c}{M^*}, \quad 2\sigma = \frac{d}{k M^*}, \quad M^* = M + m_1 + m_2, \quad \tau = kt.$$

The parameter ε is assumed to be small and the damping parameter σ is not small. The investigation is performed for a system with two identical rotors with different nominal speeds, which means that parameters of both rotors are identical except $\lambda_1 \neq \lambda_2$.

Asymptotic analysis

The averaging method for partially strongly damped systems is applied, see [2, 3]. Motion of the carrier can be replaced by its forced solution and the differential equation for ξ can be neglected in further analysis. Equations in standard form for a second order approximation with $\sqrt{\varepsilon}$ as the small parameter can then be acquired as

$$\frac{d\delta}{d\psi} = \frac{2\sqrt{\varepsilon}v}{p}, \quad \frac{dv}{d\psi} = \frac{2\sqrt{\varepsilon}(f_{\varphi_2} - f_{\varphi_1})}{p}, \quad \frac{dp}{d\psi} = \frac{2\varepsilon(f_{\varphi_2} + f_{\varphi_1})}{p}, \quad (1)$$

with the new variables $\omega_i = \varphi_i'$, $\psi = (\varphi_1 + \varphi_2)/2$, $\delta = \varphi_2 - \varphi_1$, $p = \omega_1 + \omega_2$, $v = (\omega_2 - \omega_1)/\sqrt{\varepsilon}$. By averaging these equations, a third-order system can be derived for the averaged variables $\bar{\delta}$, \bar{v} and \bar{p} .

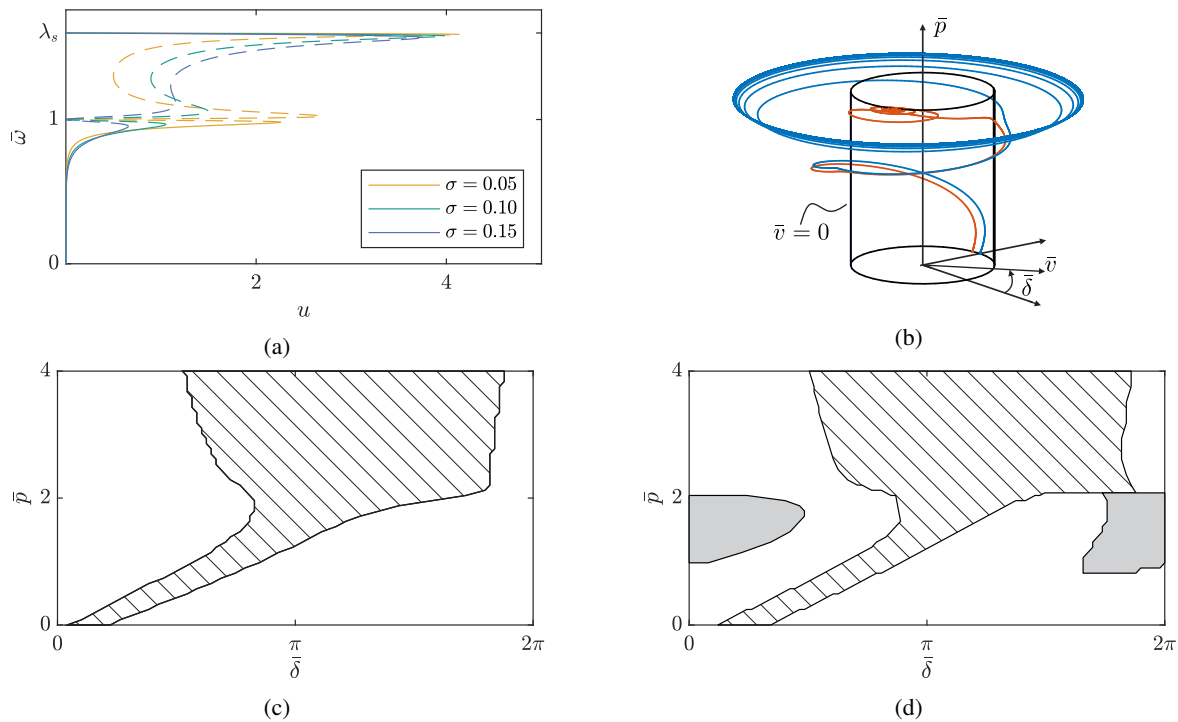

Figure 2: Results: (a) Stable (full) and unstable (dashed) stationary solutions of the averaged system for different values of damping, $\lambda_1 = 1.5$, $\lambda_2 = 1.7$, synchronization frequency $\lambda_S = 1.6$ derived according to [1]. (b) Two trajectories in cylindrical phase space. (c) A section of the phase space showing attraction domains of overcritical (white) and synchronous (hatched) solutions. (d) Same section of the phase space for smaller damping, where overcritical, synchronous and capture into resonance (grey) solutions all coexist.

Results

From the equation for $\bar{\delta}$ in Eq. (1) follows, that all stationary solutions of the system, which can be obtained under the assumptions made, are synchronous solutions ($\bar{v} = 0$, i.e. $\bar{\omega}_1 = \bar{\omega}_2 = \bar{\omega}$), including capture into resonance of both rotors. The stationary solutions as a function of parameter u ($u_1 = u_2 = u$) corresponding to the slope of motor characteristic and for different values of damping parameter σ are shown in Fig. 2a. First stable solution branch depicts capture into resonance, where both rotors cannot cross the resonance frequency of carrier ($\bar{\omega} = 1$). Second stable solution branch depicts synchronous solution at synchronization frequency λ_S . So Figure 2a can be interpreted as existence conditions of capture into resonance and self-synchronization as functions of engine power and damping. The overcritical solution, where both rotors reach their nominal speeds is not shown in Fig. 2a, because it is not a stationary solution.

To depict the phase space of the averaged system, cylinder coordinates are chosen, where \bar{p} is the vertical, \bar{v} is the radial and periodic variable $\bar{\delta}$ is the tangential coordinate. Since the variable \bar{v} can become negative an arbitrary radius is chosen for $\bar{v} = 0$, see Fig. 2b. In the same Figure, two trajectories are shown, which start at resting position with different initial phase differences. One trajectory ends with self-synchronization, which is a point at $\bar{v} = 0$ and the other one converges to the overcritical periodic solution, which is a limit cycle in phase space. Lastly, sections of attraction domains of different solutions at the surface $\bar{v} = 0$ are shown in Fig. 2c,d. The trajectories in Fig. 2b can be explained with the attraction domains in Fig 2c. There is a narrow region, where the system can directly run-up to the synchronous solution from resting position. If the damping is chosen smaller, the three solution types (capture, synchronous and overcritical) can also coexist, see Fig 2d.

Conclusion

A model of two coupled exciters is investigated using an averaging method for partially strongly damped systems. Averaged equations of second order approximation in $\sqrt{\varepsilon}$ are analyzed. Stationary solutions and their existence conditions are discussed. Phase space of averaged system is described. Attraction domains of different types of solutions are exemplary depicted.

Asymptotic formulation of bifurcation scenarios to post-buckling nonlinear vibrations in thermomechanically coupled plates

Valeria Settimi*, Giuseppe Rega*

*Dipartimento di Ingegneria Strutturale e Geotecnica, Sapienza University of Rome, Rome, Italy

Summary. The nonlinear dynamics of composite plates with thermomechanical coupling is analytically addressed in order to describe the main dynamical phenomena triggering the involved pre- and post-buckling response scenario. The static buckling occurrence, and two resonance conditions around the unbuckled and buckled equilibria are investigated by means of the asymptotic multiple scale method. The resulting modulation equations and the steady state mechanical and thermal responses are determined and compared with the numerical outcomes in order to verify the effectiveness of the adopted procedures.

Introduction

The nonlinear dynamical behavior of reduced order models of composite plates under different excitation conditions in a thermomechanical environment has been the subject of recent papers aimed at highlighting the role of multiphysics coupling and the main local and global features of the nonlinear response [1, 2]. The numerical analyses, carried out in strongly nonlinear regime and under different mechanical and thermal conditions, highlighted a rich and involved scenario characterized by multistability and possible chaos. Yet, the analytical treatment of the dynamical response can represent a useful tool to predict, describe and possibly modify the behavior of the coupled system. To this aim, three main response phenomena are detected in the weakly nonlinear regime, and the asymptotic multiple scale method [3] is applied in order to investigate existence and stability of the mechanical and thermal responses of the system.

Asymptotic analysis

With reference to a reduced model of rectangular laminated plate with von Kármán nonlinearities, third-order shear deformability and consistent cubic variation of the temperature along the thickness [4], the assumption of isothermal edges and free heat exchange on the upper and lower surfaces leads to obtain the following nondimensional equations of motion describing the plate dynamics around primary resonance:

$$\begin{aligned} \ddot{W}(t) + a_{12}\dot{W}(t) + (\Omega^2 - p)W(t) + a_{14}W(t)^3 + a_{15}T_{R1}(t) + a_{16}T_{R0}(t)W(t) - f \cos \Omega t &= 0 \\ \dot{T}_{R0}(t) + a_{22}T_{R0}(t) + a_{23}\alpha_1 T_\infty + a_{24}W(t)\dot{W}(t) &= 0 \\ \dot{T}_{R1}(t) + a_{32}T_{R0}(t) + a_{33}\dot{W}(t) &= 0 \end{aligned} \quad (1)$$

in terms of the nondimensional reduced variables $W(t)$ (deflection of the center of the plate), $T_{R0}(t)$ (membrane temperature) and $T_{R1}(t)$ (bending temperature). The mechanical excitations consist of a uniform compressive force p on the plate edges and a distributed harmonic transverse mechanical excitation of amplitude f and frequency Ω . The thermal excitation is represented by the constant thermal difference between plate and environment T_∞ , while a_{ij} are coefficients which incorporate the geometrical and physical properties of the model.

Local and global nonlinear dynamics of the presented model have been investigated by parametrically accounting for the single and combined presence of thermal and mechanical excitations. In particular, the transition to mechanically- or thermally-induced buckled responses has been analyzed, and a variety of rich multistable scenarios have been detected, as exemplarily shown in terms of numerical bifurcation diagrams as a function of the mechanical pretension in Fig. 1(a). With the aim to unveil the bifurcation phenomena triggering the development of such a rich scenario, identified in a strongly non-linear regime, a lower harmonic forcing amplitude has been applied to the system, with the relevant bifurcation diagram reported in Fig. 1(b). The results allow us to detect three main underlying dynamical features, i.e., a static pitchfork bifurcation inducing the mechanical buckling, and two resonance peaks occurring in the pre- and post-buckling branches. The first phenomenon occurs when the mechanical pretension p nullifies the linear mechanical stiffness, while the two peaks correspond to primary resonances of the pre- and post-buckling system frequencies with the external harmonic excitation.

The static buckling analysis is performed by obtaining the equilibria $\mathbf{e} = \{W_e, T_{R0e}, T_{R1e}\}$ of the coupled system (1), which have the following expressions:

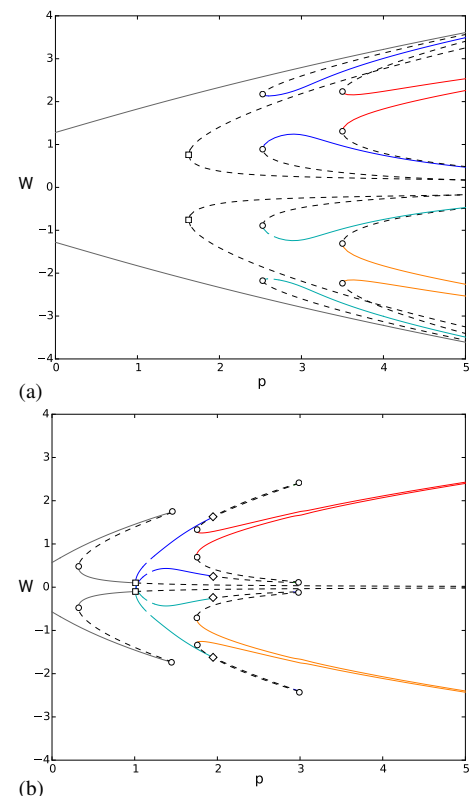

Figure 1: Bifurcation diagrams, with detection of the maximum and minimum values of the mechanical response as a function of p , at $\Omega = 1$, for $f = 1$ (a) and $f = 0.1$ (b).

Figure 2: Comparison between numerical (gray) and analytical (red) bifurcation diagrams for $\Omega = 1$ and $f = 0.05$.

$$\mathbf{e}_1 = \{0, -\frac{a_{23}\alpha_1 T_\infty}{a_{22}}, 0\}, \quad \mathbf{e}_{2,3} = \{\pm \frac{\sqrt{a_{22}(p - \Omega^2) + a_{16}a_{23}\alpha_1 T_\infty}}{\sqrt{a_{14}a_{22}}}, -\frac{a_{23}\alpha_1 T_\infty}{a_{22}}, 0\} \quad (2)$$

The \mathbf{e}_1 equilibrium corresponds to the pre-buckling configuration representing the mechanical rest position, while \mathbf{e}_2 and \mathbf{e}_3 represent the two stable buckled non-trivial solutions arising after the pitchfork bifurcation. As already highlighted in some previous works [1, 2], expressions (2) show that the thermal excitation T_∞ plays the same role as the mechanical pretension in governing the mechanical equilibria, so that it is possible to reproduce exactly the diagrams of Fig. 1 by alternatively applying a properly scaled thermal excitation. The two resonance conditions are analytically investigated by means of the asymptotic method of multiple scales, in order to study the system nonlinear dynamics around the previously obtained \mathbf{e}_1 and \mathbf{e}_2 equilibria: $W(t) = W_e + \tilde{W}$, $T_{R0}(t) = T_{R0e} + \tilde{T}_{R0}$, $T_{R1}(t) = T_{R1e} + \tilde{T}_{R1}$. The perturbation equations around the pre-buckling equilibrium have the same structure of Eqs. (1) (with suppression of a_{23} term in the membrane thermal equation), with the system frequency (i.e., the time-independent linear stiffness) being $\omega^2 = \Omega^2 - p - a_{16}a_{23}\alpha_1 T_\infty/a_{22}$. Conversely, the analysis around the buckled position implies the presence of additional terms in the mechanical and membrane thermal equations:

$$\begin{aligned} \ddot{\tilde{W}} + a_{12}\dot{\tilde{W}} + \omega^2\tilde{W} + a_{14}\tilde{W}^3 + \frac{3\sqrt{a_{14}}}{\sqrt{2}}\omega\tilde{W}^2 + a_{15}\tilde{T}_{R1} + a_{16}(\frac{\omega}{\sqrt{2a_{14}}} + \tilde{W})\tilde{T}_{R0} - f \cos(\Omega t) &= 0 \\ \dot{\tilde{T}}_{R0} + a_{22}\tilde{T}_{R0} + a_{24}\dot{\tilde{W}}(\frac{\omega}{\sqrt{2a_{14}}} + \tilde{W}) &= 0 \\ \dot{\tilde{T}}_{R1} + a_{32}\tilde{T}_{R0} + a_{33}\dot{\tilde{W}} &= 0 \end{aligned} \quad (3)$$

with $\omega^2 = 2(p + a_{16}a_{23}\alpha_1 T_\infty/a_{22} - \Omega^2)$. Consequently, the two asymptotic procedures require different choices in the scaling of variables and parameters, and different expansions to higher orders to account for the main effects (e.g., the occurrence of both quadratic and cubic nonlinearities, as in (3)). In both cases, anyway, they have been guided by the previous numerical analyses, which have pointed out the contemporary presence of slow (thermal) and fast (mechanical) dynamics, and have allowed to discuss the role of the coupling terms inside the three equations [5]. They result to be crucial into the thermal equations in order to determine the temperature response, while having a marginal effect on the mechanical equation, whose dynamics evolves much quicker than the coupled thermal one. The two procedures are developed separately, and the Amplitude Modulation Equations are obtained together with the reconstructed steady state mechanical and thermal responses. The outcomes reported in Fig. 2 show a good agreement between analytical (red) and numerical (gray) results, also in the post-buckling scenario where the mechanical response is moderately severe.

Conclusions

The analytical treatment through the multiple scale method is developed to describe the main dynamical phenomena underlying the rich multistable scenario characterizing the nonlinear behavior of thermomechanically coupled plates. The obtained modulation equations together with the reconstructed responses can be used to parametrically discuss the occurrence and stability of the main periodic unbuckled and buckled responses as a function of the main system parameters.

Axisymmetric, nonlinear capillary waves: dimple and jet formation

Lohit Kayal and Saswata Basak and Ratul Dasgupta

Department of Chemical Engineering, IIT Bombay, Mumbai, India

Summary. We study axisymmetric, nonlinear capillary waves in confined cylindrical geometry. Extending our recent analytically and computational studies [5, 2], we present a third order theory [6] which can describe dimple formation in nonlinear axisymmetric capillary waves for moderately large values of the wave steepness parameter ϵ . For $\epsilon > 1.8$, we show that the dimple produces a jet which evolves self-similarly in a window of time and space. Analytical predictions are compared to numerical solutions.

Jet formation from an axisymmetric capillary wave

Jet formation from bursting bubbles have attracted persistent attention from the scientific community for more than half a century [3]. In addition to scientific curiosity, the phenomena is also of significant meteorological interest as the bursting of bubbles on the open ocean surface (due to wave breaking) causes ejection of liquid droplets which are a source of sea-salt aerosols and can serve as cloud condensation nuclei. In a series of recent studies [5, 2] it was observed that similar jet ejection can also occur in apparently simpler conditions where the free-surface of quiescent liquid in a cylindrical container of radius R_0 is deformed as a an eigenmode of the linearised system viz. a Fourier-Bessel mode of the form $a_0 J_0(k_0 r)$. It was shown that [5, 2] that the resulting surface oscillation due to the restoring force of gravity and capillarity produces a trough whose subsequent evolution in time, closely resembles a collapsing cavity [4]. When the steepness parameter $\epsilon \equiv a_0 k$ is sufficiently large ($\mathcal{O}(1)$), a nonlinearity induced dimple like structure is produced at the base of the trough leading to the formation of a jet at the axis of symmetry [2, 5], much analogous to what is observed in the bursting of a bubble at a free-surface [8, 4]. While the $\mathcal{O}(\epsilon^2)$ non-linear theory presented in [2] was able to capture the inception of the dimple, it was unable to describe the same at later times. An important conclusion from [2] was that the lengthscale of the dimple rendered it completely dominated by capillary effects with the gravitational acceleration being insignificant. In this study, we lend further insight into this dimple formation focusing our attention on pure capillary waves (no gravity) [6]. A novel $\mathcal{O}(\epsilon^3)$ solution to the initial-value problem has been calculated [6] which significantly improves upon the second order calculation presented earlier in [2]. Fig. 1a depicts the initial axisymmetric, surface perturbation of the form $\eta(r, 0) = \epsilon J_0(k_0 r)$ and fig. 1b shows the formation of the dimple for a moderately large $\epsilon = 0.8$, and is described quite accurately by our $\mathcal{O}(\epsilon^3)$ calculation. This is the solution to the initial-value problem using ϵ as a perturbation parameter and the Lindstedt-Poincaré technique. It has the form

$$\eta(r, \tau) = \epsilon \cos(\tau) J_0(r) + \epsilon^2 \sum_{j=1}^{\infty} f^{(j)}(\tau) J_0(\alpha_{j,p} r) + \epsilon^3 \left[\sum_{m=1}^{\infty} g^{(m)}(\tau) J_0(r) + \sum_{j=1, j \neq p}^{\infty} h^{(j)}(\tau) J_0(\alpha_{j,p} r) \right]$$

Figure 1: Comparison of the surface evolution of the interface at steepness $\epsilon = 0.8$. Numerical solution to the Euler's equation (\bullet) using Basilisk [9], $\mathcal{O}(\epsilon^3)$ (—), $\mathcal{O}(\epsilon^2)$ (—). Third order theory captures the dimple very accurately. Here η is non dimensional interface and r is non-dimensional radial distance.

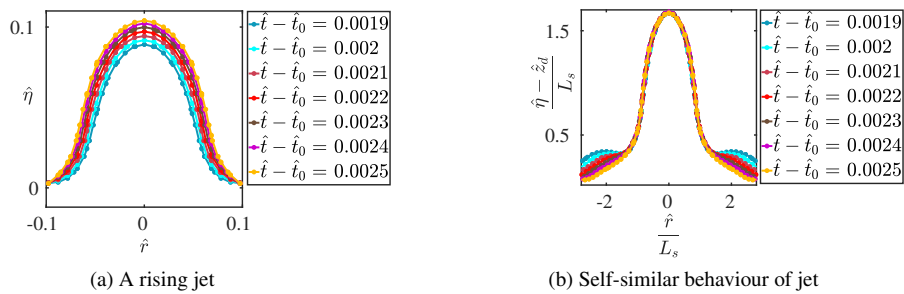

Figure 2: Panel (a), (b): Self similar behaviour of the jet at $\epsilon = 2.0$ and cylinder radius $R_0 = 2.936$ cm, where R_0 is the radius of the cylinder. Here \hat{t}_0 is the dimple formation time, $\hat{\eta}$ is dimensional interface and \hat{r} is dimensional radial distance, \hat{z}_d is the height of the jet base (all variables with hat are dimensional)

At larger values of $\epsilon = 2.0$, a clear jet emerges from the dimple as shown in fig. 2a. At large steepness ($\epsilon > 1.8$), we

find that the jet evolution in time becomes self-similar. This is shown in fig. 2b where the length scale $L_s = \frac{(\hat{t}-\hat{t}_0)^{2/3}}{(\frac{\rho}{T})^{1/3}}$ [7, 10] has been used to scale the vertical and radial coordinate. Note that ρ, T are density and surface tension and \hat{t}_0 is the dimple formation time.

Modal analysis

In fig. 3, we plot the surface energy of the system from modal analysis [2]. The figure shows the Fourier-Bessel modes which are excited at the chosen instant of time. For the case $\epsilon = 2.0$, the time instant has been chosen to lie within the self-similar window shown earlier in fig. 2b. Comparing $\epsilon = 2.0$ with $\epsilon = 1.0$, it is clearly seen that a large number of modes are excited in the case of $\epsilon = 2.0$ compared to $\epsilon = 1.0$. Note that we have plotted $|\hat{H}(l_j)|$ which comes from the coefficient of the Dini series and provides an instantaneous measure of the potential energy contained in various wavenumbers [1] (l_j is the j^{th} nontrivial root of the Bessel function $J_1(\cdot)$).

Figure 3: The potential energy between $\epsilon = 1.0$ (—) and $\epsilon = 2.0$ (—) are compared at the same time instant $\hat{t} = 0.0092$ s. At this instant the $\epsilon = 2.0$ simulation displays self similar collapse depicted earlier in fig. 2b. The simulation with $\epsilon = 1.0$ however does not show self similar behaviour at this instant or at later time.

Confinement and loss of self-similarity

We find that strong confinement (i.e. shrinking the radius of the container) leads to loss of self-similarity. This is shown in fig. 4(a) and (b) where both panels represent simulations with $\epsilon = 0.2$. In panel (a) the radius is small ($R_0 = 0.038$ cm) and the evolution of the jet is not self-similar in marked contrast to panel (b).

Figure 4: Panel (a), (b): Effect of container radius on the self similar evolution of jet

Conclusions

We investigate dimple and jet formation from nonlinear capillary waves in axisymmetric cylindrical confined geometry. The initial value problem has been solved to $\mathcal{O}(\epsilon^3)$ using the Lindstedt Poincaré perturbation technique and it is found that the weakly nonlinear solution can predict the formation of the dimple quite well for moderately large value of ϵ . Using simulations, we have shown that for $\epsilon > 2.0$, the evolution of the jet happens in a self similar manner in a narrow window of space and time. The physical reasons for this self-similarity as well as the eventual loss of the same will be discussed at the meeting. All simulations have been performed using the open source Basilisk [9].

Summary. Slack cables are pieces of conductors that are used in bretelles and Stockbridge dampers, to mitigate the wind-induced vibration of overhead transmission lines. Under cyclic and dynamic excitations, inter-strand friction in slack cables makes their behavior nonlinear and hysteretic. On the other hand, due to the low tension, their mechanical behavior is different from stretched cables. Thus, it is important to develop a model that can predict their nonlinear behaviors under vibration. The main purpose of this study is to reproduce this nonlinear behavior using a linear Euler-Bernoulli beam coupled with a Bouc-Wen hysteresis model. The parameters of the Bouc-Wen model are identified based on the results of a characterization test on the slack cable of a Stockbridge damper, available in the literature. Using this method, the local bending behavior of the slack cable is well-reproduced.

Introduction

When a system exhibits hysteresis behavior, it means the response of the system depends not only on its current state, but also on the history of the previous states. Under cyclic loads, friction between the sliding wires of a slack cable makes their mechanical behavior nonlinear and hysteretic. This characteristic is important since it governs the energy dissipation of the system. In contrast to taut cables, the power dissipation of slack cables is significant, and they are used in bretelles and Stockbridge dampers to mitigate the aeolian vibration of overhead transmission lines. Aeolian vibration represents the major cause of fretting fatigue failure in transmission lines [1].

Due to hysteretic characteristics, the bending stiffness of a cable varies according to the curvature. In the literature, there are several models for the study of the nonlinear bending stiffness of taut cables. These models allow for predicting hysteresis load-deflection curves and calculation of the system energy dissipation. The model of Papailiou [2] describes the secants bending stiffness as a function of curvature taking into account the inter-layer slippage and friction force between the layers of a conductor. This model is validated through the results of quasi-static tests for high level of tensions. The bending stiffness was shown to transmit smoothly from EI_{max} to EI_{min} , which corresponds to the full-stick state and full-slip state, by the propagation of the wire slippage layer by layer towards the core. Dastous [3] converted the model of papailiou based on the tangent bending stiffness method and implemented it in a finite-element formulation. Hong [4] improved the model of Papailiou by reconsidering some simplifying assumptions, and introducing new criteria for wire slippage regarding the radial pressure transmission between the layers. Paradis [5] used the criteria of Hong [4], and developed a new model by considering the micro-slips in contact areas between the wires. Langlois [6] implemented the model of Paradis, and reproduced the variable bending stiffness of tensioned conductors through a finite element model.

To study specifically the hysteresis behavior of slack cables, Sauter [7] modeled the messenger cable of a Stockbridge damper as a linear beam coupled with the Masing hysteresis model to describe the local moment-curvature relationship. Parameters of the model were obtained locally, based on the results of quasi-static tests. It was shown that the behavior of the slack cable during the bending process, varies spatially along the cable and during the bending cycle based on the deformation history (loading-unloading). Foti et al. [8] reproduced the hysteresis moment-curvature of a damper cable using a bilinear elastic-plastic model coupled with the classic Bouc-Wen model. Langlois [9], developed a finite-element model of the messenger cable of a Stockbridge damper with variable bending stiffness by superimposing beam elements with material nonlinearity. The constitutive parameters of the model were identified from the characterization test on Stockbridge dampers such that the overall behavior was best reproduced. The model of damper later was added to a span of conductor to study the aeolian vibration amplitude of a system of conductor-damper.

Low tension in slack cables makes their behavior different from tensioned cables, and very few researches are available to study the nonlinear mechanical bending behavior of the slack cables. The main objective of this study is to develop a nonlinear model that predicts the hysteresis behavior of a slack cable under different amplitudes and frequencies. For this purpose, an analytical model of the slack cable by using a linear Euler-Bernoulli beam coupled with a nonlinear Bouc-Wen model is developed. Bouc-Wen model is a hysteresis model that is based on the continuous change of the stiffness with varying displacement, proposed by Bouc [10] and later improved by Wen [11]. The dynamic response of the system under a low-frequency sinusoidal load is obtained and the moment-curvature hysteresis loop at different locations along the slack-cable is calculated. The parameters of the Bouc-Wen model are obtained iteratively to reproduce the results of the characterization test performed by Sauter [7] on a rigidly clamped slack cable of a Stockbridge damper. This model can be coupled with a validated conductor model to predict the aeolian vibration amplitude of the system.

Figure 1: Stockbridge damper [12].

Figure 2: Sketch of the experimental test on the messenger cable.

Properties of the Slack Cable

Slack cables are used in Stockbridge dampers shown in Fig. 1. It consists of a clamp, a short messenger cable, and two inertial masses. This kind of damper is used to mitigate the aeolian vibration of transmission lines. The clamp of the damper is rigidly connected to the conductor, and as the vertical movement of the conductor happens, the masses vibrate and bend the messenger cable. This causes the relative movement of the wires of the messenger cable. Because of the friction between the wires, they exhibit hysteresis behavior. This phenomenon makes the relationship between the load and deflection rate dependent and hence, causes power dissipation in the system. This nonlinearity is shown in the load-deflection curves of messenger cable from experimental tests [13, 14]. Bending tests are usually done to characterize the dissipative behavior of the messenger cables. In these tests, a short length of messenger cable is clamped at one-end and free at the other end, and subjected to a transverse force at the tip monotonically or cyclically varying. The load-deflection curvature curves are usually obtained for different tip displacements.

In this study, the experimental validation of the models are done based on the characterization test of Sauter [7]. In this test, a short slack cable with the length of 0.3 m was rigidly clamp at one-end, and the free-end was subjected to a transverse cyclic displacement at a low frequency. The parameters measured are:

- The moment-curvature diagram at 25mm from the clamp end for cyclic transverse displacement of the free-end (5mm to 30mm peak-peak)
- The local moment-curvature diagram at different points along the cable under the transverse displacement of 25mm peak-peak.

The properties of the slack cable is presented in Table. 1. Figure 2 shows the setup of the test, and the locations for which the local hysteresis were measured.

Governing Equations of the System

In this study, the slack cable is modeled as a simple cantiliver beam (Fig. 2), coupled with a Bouc-wen model. The bending deflection $v(x, t)$ of a Euler-Bernoulli beam under a sinusoidal load $f(t)$ can be described by the following equation:

$$\frac{\partial^2}{\partial x^2} \left(EI(x) \frac{\partial^2 v(x, t)}{\partial x^2} \right) + f(t) = m \frac{\partial^2 v(x, t)}{\partial t^2} + c \frac{\partial v(x, t)}{\partial t} \quad (1)$$

where m is the mass per unit length, c is the damping, EI is the bending stiffness. The boundary conditions for the cantiliver beam are:

$$\begin{aligned} v(0, t) &= 0, \forall t \\ v'(0, t) &= 0, \forall t \\ v''(l, t) &= 0, \forall t \\ v'''(l, t) &= 0, \forall t \end{aligned} \quad (2)$$

Where the prime denotes the derivative with respect to the space variable x , and l is the length of the slack cable.

As we are interested in the behavior of the system around the deformation of its first mode, the solution of the Eq. (1) can be expressed in the form of:

$$v(x, t) = \Gamma_1(x) g_1(t) \quad (3)$$

where $\Gamma_1(x)$ is the first natural mode of the system and $g_1(t)$ is the corresponding generalized coordinate. By solving the eigenvalue problem related to the free response of Eq. (1), the first vibration mode of the beam $\Gamma_1(x)$ could be obtained such that it satisfies the geometrical boundary conditions of the beam presented in Eq. (2).

Table 1: Mechanical Properties of the Slack Cable [7]

Total diameter (mm)	10.15
Number of layers except core	2
Number of wires	19
Wire diameter (mm)	2
Young modulus (GPa)	210
Mass per unit length (kg/m)	0.498

Thanks to the orthogonality of modes, the equation of motion in temporal state after addition of nonlinear Bouc-Wen model could be expressed as [10, 15, 16]:

$$\ddot{g}_1(t) + 2\xi\omega_1\dot{g}_1(t) + \alpha\omega_1^2g_1(t) + (1 - \alpha)\omega_1^2z(t) = F(t) \quad (4)$$

$$\dot{z}(t) = \dot{g}_1(t)[1 - \left|\frac{z(t)}{g_y}\right|^n (\beta + \lambda \operatorname{sgn}(z\dot{g}_1))] \quad (5)$$

Where the dots denotes the derivative with respect to time and ξ is the modal damping ratio, ω_1 is the first angular frequency, $F(t)$ is the modal force and $z(t)$ is the hysteresis parameter. The Bouc-Wen model is coupled with the equation of the beam in temporal state through a superposition of a linear elastic force $\alpha\omega_1^2g_1(t)$ and a nonlinear hysteretic force $(1 - \alpha)\omega_1^2z(t)$. The Bouc-Wen parameters, α is the post-elastic to initial stiffness ratio, g_y is the generalized yield displacement and β, γ, n are model parameters. The response of the system is calculated by direct integration of Eq. (4) and Eq. (5) using "ode45" function in MATLAB. To be able to use this function, the Eq. (4) and Eq. (5) have to be transformed into a system of first order as below:

$$\begin{aligned} \dot{Y}(1) &= Y(2) \\ \dot{Y}(2) &= -2\xi\omega_1Y(2) - \alpha\omega_1^2Y(1) - (1 - \alpha)\omega_1^2Y(3) + F(t) \\ \dot{Y}(3) &= Y(2)[1 - \left|\frac{Y(3)}{g_y}\right|^n (\beta + \lambda \operatorname{sgn}(Y(3)Y(2)))] \end{aligned} \quad (6)$$

The following initial conditions are considered for this system:

$$t = 0 \rightarrow \begin{cases} Y(1) = 0, & \dot{Y}(1) = 0 \\ Y(2) = 0, & \dot{Y}(2) = 0 \end{cases} \quad (7)$$

After obtaining the response of the system numerically, the moment-curvature relationship at each point through the slack cable could be obtained as [17]:

$$M(t) = \alpha\omega_1^2\phi(t) + (1 - \alpha)\omega_1^2z(t) \quad (8)$$

Where $\phi(t)$ is the curvature, and it is calculated directly from the derivative of Eq. (3) with respect to displacement. The moment-curvature diagram is calculated for different excitation loads with a low frequency at the free-end of the slack cable. The force is adjusted to have the desired tip displacements. It has to be noted that this model allows us to predict the behaviour of the system for higher frequencies. The Bouc-Wen parameters of the model are adjusted through an iterative process such that the experimental results is best reproduced.

Model Parameter Identification

The parameters of a messenger cable modeled by the Bouc-Wen model are identified from the experimental data of Sauter [7]. The identification of the model was done iteratively using MATLAB. Five Bouc-Wen parameters, and the local bending stiffness of the system EI are identified. Table 2 shows the identified parameters of the system. Parameters λ and β control the shape and size of the hysteresis loops [11]. α is the post-elastic to initial elastic ratio, and g_y is generalized yield displacement, and the parameter n is a nondimensional number that controls the transition from the elastic to inelastic part of the loop. Increasing this parameter to higher values can sharpen the transition [16]. This value is considered as 1 for all points.

Another parameter that has to be controlled is EI . Bending stiffness of a cable varies significantly with curvature during the bending, however it changes between two limits of EI_{min} and EI_{max} that are related to the full-slip and full-stick states, respectively. These parameters can be calculated as [1]:

$$\begin{aligned} EI_{min} &= \sum_i E_i I_{0i} = 2.83 N.m \\ EI_{max} &= \sum_i E_i (I_{0i} + A_i r_n^2 \sin^2(\alpha_i)) = 67.1 N.m \end{aligned} \quad (9)$$

Table 2: Bouc-Wen parameters of the model

x (m)	α	β	λ	g_y	n
0.005	0.35	45	90	0.06	1
0.015	0.2	45	90	0.05	1
0.025	0.2	45	90	0.0045	1
0.035	0.2	45	90	0.0045	1
0.050	0.19	45	90	0.0045	1
0.070	0.19	45	90	0.0045	1
0.095	0.19	45	90	0.0048	1
0.12	0.19	45	90	0.0049	1
0.15	0.19	45	90	0.007	1
0.18	0.19	45	90	0.008	1
0.205	0.19	45	90	0.008	1
0.230	0.19	45	90	0.009	1
0.250	0.19	45	90	0.008	1

Where E_i is the modulus of elasticity, I_{0i} is the moment of inertia of each wire around its axis, A_i is the area of each wire, r_n is the distance of the center of each wire from the center of the cable, and α_i is the lay angle of each layer. Figure 3 demonstrates the local bending stiffness identified for the slack cable. In this model, the calculated value of EI for the points close to the clamp is more than EI_{max} . The reason could be due to the effect of the clamp on the cable. In the zones far from the clamp, EI decreases to EI_{min} , and from the middle to the tip it remains almost constant. All the wires of the cable far from the clamp slip so fast, however because of clamp effects most of the wires near the clamp stay in stick-state. This explains the variation of the local bending stiffness of the system.

Figures 4-7, show the results obtained from the Bouc-Wen model using the identified parameters (Table. 2) in comparison with experimental results. Figure 4 shows the moment-curvature results of a point 0.025m from the clamp under different tip displacements (5mm to 30mm, each 5mm). Figures 5-7, show the local moment-curvature loops for different points along the cable (Fig. 2) under a constant tip displacement of 25mm. Using the identified parameters, the experimental results are well reproduced in all cases.

As another validation, the displacement of the free end of the cable is measured under a given force. The results are compared to the experimental results in Fig. 8. It should be noted that to compare the global behavior of the slack cable, different sets of identified values are in the Table. 2 are tested, and the values for the point 35mm best reproduced the global behavior. The limitation of this method is that there is no possibility to use different sets of Bouc-Wen parameters at the same time for different points through the beam. However, by selecting a correct sets of values, correct global behavior can be obtained.

Conclusions

The mechanical behavior of a slack cable is modeled using a linear Euler-Bernoulli beam coupled with a hysteresis Bouc-Wen model. In this study, the response of the system is obtained based on the projection of the first mode. The validity of this model is shown by comparing the present results with the experimental results of the slack cable. At both local and global levels, this model reproduced the hysteresis behavior of the slack cable, adequately. The important advantage of this model is providity a fast tool that can describe and predict the nonlinear behavior of the slack cables, without systematic experimental tests. In addition, this model can be integrated into a conductor model, and it allows the assessment of the aeolian vibration amplitude of transmission lines.

Summary. A mechanical model is introduced in order to investigate the snaking/rocking motion of towed two-wheeled trailers. The sense of the Hopf bifurcations related to the linear stability boundaries of the rectilinear motion are investigated numerically. The center manifold reduction is also performed semi-analytically, by which the relevance of the pitch motion is identified.

Introduction

The instability of towed vehicles is a relevant safety risk on the roads. In case of a badly chosen towing velocity and/or a badly loaded trailer, the vehicle may start a so-called snaking motion [1, 2]. The trailer may even start rocking on its wheels, and the rollover of trailer can happen.

In-plane mechanical models of towed vehicles are deeply analyzed in the literature (see, for example, [3]) and it is established that the Hopf bifurcation is subcritical at the linear stability boundary located at small towing velocities. Here, the trailer is modeled with a spatial, 4 degrees-of-freedom (DoF) mechanical model given in [4], namely, the pitch and roll motions are also considered when the nonlinear vibrations (e.g. the rocking motion) are analyzed semi-analytically and numerically.

Mechanical Model

The mechanical model of the two-wheeled trailer can be seen in Fig. 1. The trailer is towed with constant velocity v in X direction at the king pin. The motion of the trailer is described with the yaw angle ψ , the pitch angle ϑ , the roll angle φ and the lateral displacement of the king pin u .

Figure 1: The mechanical model of the trailer with the generalized coordinates and the tyre forces.

Since there are only geometric constraints, the system is holonomic. Thus, the equations of motion can be derived from the Lagrange equation of the second kind (for details see [4]). The lateral tyre forces are considered as

$$F_{\text{tyre,lat}} = \mu(\alpha) F_{\text{tyre,z}}, \quad (1)$$

where $F_{\text{tyre,z}}$ is the vertical load on the tyre and $\mu(\alpha)$ involves Pacejka's Magic Formula [6]. The side slip angle α is calculated by means of the longitudinal and lateral components of the velocity of the contact point T of the wheel:

$$\alpha = -\arctan\left(\frac{v_{T,\text{lat}}}{v_{T,\text{long}}}\right). \quad (2)$$

Linear Stability Analysis and Bifurcation Analysis

Based on the linear stability analysis of the rectilinear motion, it can be concluded that the linearised system can be separated into two subsystems: the pitch motion can be decoupled as a 1 DoF subsystem, while remaining equations form a 3 DoF subsystem. Thus, the pitch motion does not affect the linear stability of the rectilinear motion. But, it has effect on the nonlinear vibrations.

Asymmetry is introduced into the system by the lateral tyre force characteristics formulated in (1). The vertical load $F_{\text{tyre,z}}$ on the tyres depends linearly on the pitch angle ϑ , as it can be seen in the left panel of Fig. 2. The coefficient $\mu(\alpha)$ is an even function (see the right panel of Fig. 2), thus, the lateral tyre force contains mixed second degree terms with respect to the generalized coordinates and velocities. When the bifurcation analysis is carried out with center manifold (CM) reduction, it can be identified that the pitch motion influences the sense of the Hopf bifurcation through these second degree terms.

Figure 2: The characteristics of the vertical tyre forces and characteristics of the lateral force defined by the Magic Formula in $\mu(\alpha)$ [6].

The stability of the periodic orbits were also investigated by continuation in *DDE Biftool* [5]. It was confirmed that supercritical Hopf bifurcation exists at small velocities, while in-plane trailer models of the literature provides a subcritical one. To check our hypothesis on the effect of the pitch motion, a reduced model was also analyzed in which the pitch motion was blocked ($\vartheta \equiv 0$).

The nature of the periodic solutions, namely, the sense of the Hopf bifurcations can be seen in Fig. 3 for the spatial, 4 DoF model and for the reduced model. In the stability charts, the blue continuous and red dashed lines correspond to supercritical and subcritical bifurcations, respectively. In the figures, parameter f describes the vertical position of the center of mass. As it can be observed in the left panel, the periodic solution is stable at smaller critical speed in case of the 4 DoF model, thus, the bifurcation is supercritical. On the contrary, in the right panel, the periodic solution is unstable (subcritical Hopf bifurcation occurs) for the same critical speed when the reduced model is considered.

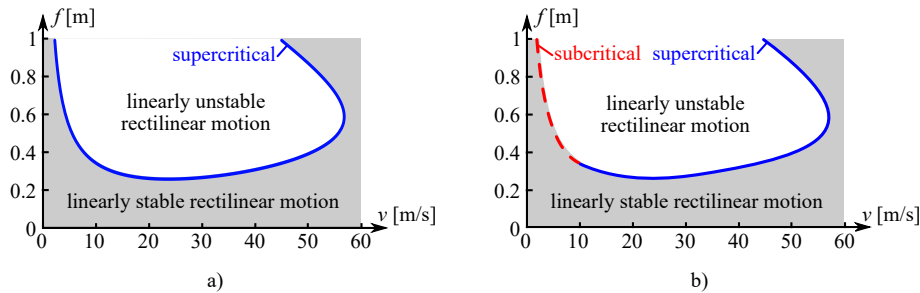

Figure 3: The stability of the periodic solutions a) for the spatial, b) for the reduced model.

Conclusions

Based on the semi-analytical bifurcation analysis, the effect of the pitch motion on the stability of the emerging periodic solutions is verified. It is shown that the in-plane trailer models of the literature can provide different results with respect to the sense of the Hopf bifurcation at small velocities.

Speed effects on vibration and collapse of slender structures under moving loads

G.H.M. van der Heijden*, X.W. Zhao*

**Department of Civil, Environmental and Geomatic Engineering
University College London, Gower Street, London WC1E 6BT, UK*

Summary. We study the nonlinear dynamics of one-dimensional slender structures such as beams and arches carrying a moving load. At resonant speeds the vibrations of curved beams are significantly suppressed, but large deformations are found to have a detuning effect. Arches are found to have different buckling (failure) modes depending on the depth of the arch and the speed of the traversing load.

Modelling

We study the nonlinear dynamics of one-dimensional slender structures such as beams and arches carrying a moving load. Geometrically-exact rod theory is used to model the structure, which is allowed to undergo arbitrary three-dimensional flexural and twisting deformations.

Results and conclusions

The exact natural frequencies ω_n (for symmetric or anti-symmetric modes) of a hinged curved horizontal beam with subtended angle α are given by

$$\omega_n = \mu_n \sqrt{\frac{EI}{\rho AL^4}}, \quad \text{where} \quad \mu_n = \frac{n\pi |(n\pi)^2 - \alpha^2|}{\sqrt{(n\pi)^2 + (1 + \nu)\alpha^2}} \quad (n = 1, 2, \dots)$$

(ignoring rotational inertia). Here EI is the bending stiffness, A the cross-sectional area, ρ the density, ν Poisson's ratio and L the length of the beam. The critical resonance speed is defined as the speed at which the maximum midspan deflection occurs when the load leaves the beam. It is given by

$$v_{\text{crit}} = \frac{\omega_1 L}{\pi}$$

(i.e., the fundamental period is twice the passage time).

We find that nonlinearity due to large deformations has a detuning effect on resonances, as can be seen in midspan deflection plots for different values of α (see Figure 1).

At resonant speeds v we find cancellation of vibrations even at large deformations (see Figure 2).

Arches are found to have different buckling (failure) modes depending on the depth of the arch and the speed of the traversing load.

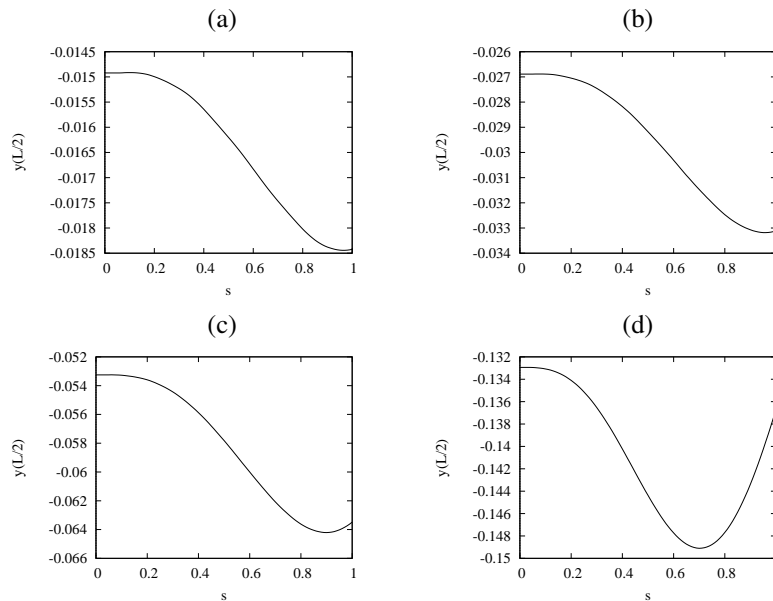

Figure 1: Detuning effect due to large deformations: (a) $\alpha = 50^\circ$, (b) $\alpha = 90^\circ$, (c) $\alpha = 120^\circ$, (d) $\alpha = 150^\circ$. The magnitude of the moving load is $F = 0.1$ (in units of EI/L^2). s is the instantaneous position of the load, normalised by L .

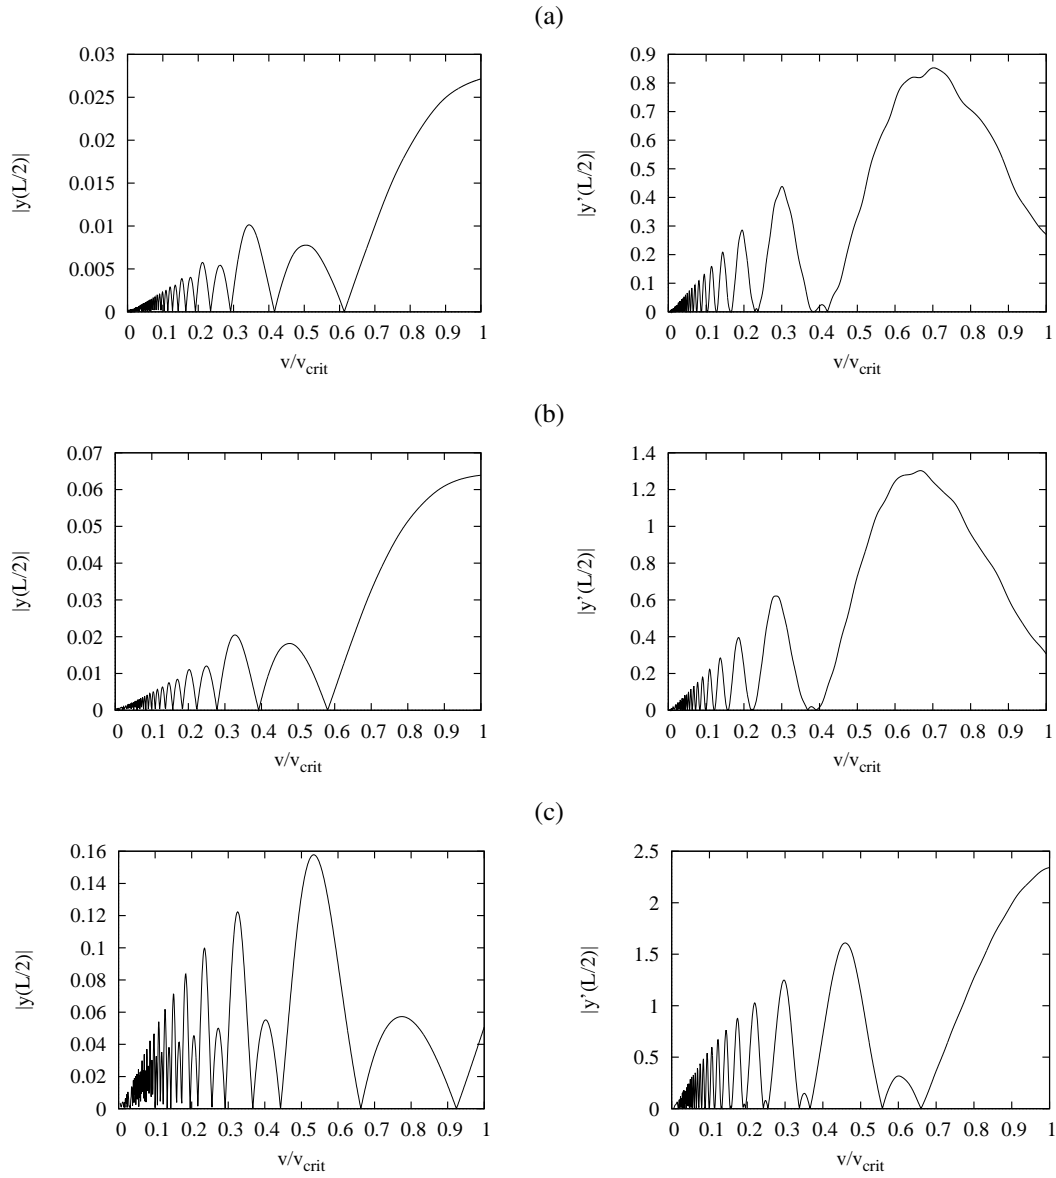

Figure 2: Cancellation of vertical midspan deflection (left) and velocity (right) of a horizontal curved beam with moving load $F = 1.0$ (in units of EI/L^2) at critical speeds v/v_{crit} . (a) $\alpha = 30^\circ$, (b) $\alpha = 90^\circ$, (c) $\alpha = 150^\circ$.

Nonlinear Dynamics of a Shearable-Extensible Beam with an Elastic Longitudinal Support: Analytical Derivation, Numerical Simulation and Experimental Validation

Lukasz Kloda^{*†}, Stefano Lenci[†] and Jerzy Warminski^{*}

^{*}Department of Applied Mechanics, Lublin University of Technology, Lublin, Poland

[†]Department of Civil and Buildings Engineering and Architecture, Polytechnic University of Marche, Ancona, Italy

Summary. Coupled axial-transversal nonlinear oscillations of a simply supported beam with an axial spring are studied in the paper. The exact model of a planar beam with associated boundary conditions is derived, and then to analyze free and forced-damped dynamics of the structure the perturbation method up to cubic nonlinearity is used. Next, a finite element model of the beam-spring system is considered and then outcomes are compared. Experimental tests on a slender beam confirmed quantitatively analytical and numerical models.

Introduction

In the *classical beam theory* for vibrations only transverse inertia forces and bending moment are considered [1], and the shearing effect together with longitudinal deformations are neglected. Those assumptions are relatively correct for slender structures with axially restrained ends. Large amplitudes of a thick beam require the Timoshenko's shearing theory, and for the beam unrestrained in axial direction longitudinal inertia terms can not be neglected [2]. The inertia changes the dynamics of the structure, and as a consequence the simply supported beam has no longer a hardening nature but a softening behaviour. An axial spring subjected to the unrestrained end allows to passively control hardening/softening dichotomy [3, 4]. The goal of this paper is to investigate nonlinear dynamics of the beam-spring system and its sensitivity on boundary conditions by considering nonlinear coupling between transversal and longitudinal modes. For model validation a laboratory test is prepared.

Beam models

Analytic

In the paper two beam models are used, both of them assume linear elastic material properties as Young (E) and shear (G) modules (Eqs. (1)). It means that nonlinearities arise only from geometrical and inertia coupling. In the reference (rest) configuration the beam has length L and rectangular cross-section A . Normal, shearing and bending forces are proportional to elongation \hat{e} , shear strain γ and curvature k_g , respectively:

$$N = EA\hat{e}, \quad V = GA\gamma, \quad M = EJk_g. \quad (1)$$

Note that the beam is *extensible*. W is the longitudinal displacement, and U is the transversal one. The *geometrical* definition of curvature [5] is adopted in our study, see Eq. (2). θ describes the rotation of the beam's cross-section (Fig. 1a) which contains the slope angle φ and γ . The deformations are given by

$$\hat{e} = S' - 1, \quad S' = \sqrt{(1 + W')^2 + U'^2}, \quad k_g = \frac{\theta'}{S'} = \frac{\theta'}{\sqrt{(1 + W')^2 + U'^2}}, \quad \theta = \varphi + \gamma. \quad (2)$$

Decomposing strain forces into horizontal, vertical and rotational coordinates and supplementing them by inertia ($\rho A \ddot{W}$, $\rho A \ddot{U}$ and $\rho J \ddot{\theta}$), damping ($C_W \dot{W}$, $C_U \dot{U}$, $C_\theta \dot{\theta}$) and external forces (P_W , P_U , P_θ) the following balance equations are obtained

$$(N \cos \varphi + V \sin \varphi)' = \rho A \ddot{W} + C_W \dot{W} + P_W(Z, T), \quad (3)$$

$$(N \sin \varphi - V \cos \varphi)' = \rho A \ddot{U} + C_U \dot{U} + P_U(Z, T), \quad (4)$$

$$M' - VS' = \rho J \ddot{\theta} + C_\theta \dot{\theta} + P_\theta(Z, T), \quad (5)$$

where dots ($\dot{}$) are time derivative and primes (') depict partial derivative with respect to the coordinate Z . The stiffness of the axial end spring k_s is responsible for change of boundary conditions only in the longitudinal direction:

$$U(0, T) = 0, \quad U(L, T) = 0, \quad M(0, T) = 0, \quad M(L, T) = 0, \quad W(0, T) = 0, \quad (6)$$

$$N(L, T) \cos \varphi + V(L, T) \sin \varphi + W(L, T)k_s = 0. \quad (7)$$

To solve the set of three equations (3)-(5) and associated boundary conditions (6)-(7) the multiple time scales method (MTSM) is applied, and after cumbersome computations, the frequency response curves are drawn for different $0 < k_s < \infty$ parameter [6].

Figure 1: Kinematics of the beam segment in analytical approach (a) and finite element model of the hinged-simply supported beam (b).

Finite element

Numerical computations are made with the commercial software Abacus_CAE. Dynamical analysis is performed in two modules: *linear perturbation-frequency* and transient in time *dynamic explicit*. The finite element model (FEM) presented in Fig. 1(b) is composed of 100 segments *B21*-type plus one linear spring connector k_s . Boundary conditions are consistent with (6)-(7). Four different computational methods are applied: (i) linear modal analysis, (ii) free nonlinear dynamics, (iii) following-path and (iv) shooting method. All four methods complement each other and allow a deep study of any dynamical system for selected parameters to discover unexpected phenomena. However the computations in time domain are very time consuming.

Results and conclusions

Comparison of backbone curves obtained by FEM and MTSM is presented in Fig. 2(a). After passing the transient vibrations the simulation for steady states are in excellent agreement. For Timoshenko beam with partial tip reinforcement, the structure has hardening behaviour. Due to technical limitations experimental tests have been simplified to a kinematically excited slender beam presented in Fig. 2(c) and, then overlapped with numerical counterpart. The axially unrestrained case represents softening phenomenon and again results shown in Fig. 2(b) are in very good agreement. We conclude that analytical and numerical results are confirmed by experiments with excellent compliance.

Optimal design of impact based non-linear energy dissipation mechanism in pipeline systems

Fabrizio Aloschi^{*,**}, Roberto Andreotti^{*}, Oreste S Bursi^{*} and Rosario Ceravolo^{***}

^{*}Department of Civil, Environmental and Mechanical Engineering, University of Trento, Trento, Italy

^{**}IGF - Ingenieurgesellschaft Dr.-Ing. Fischbach mbH, Erftstadt, Germany

^{***}Department of Structural and Geotechnical Engineering, Polytechnic of Turin, Turin, Italy

Summary. Numerous techniques exist to control vibrations and dissipate energy in pipes that are supported by rack structures. Impacts are often used as a means of dissipating energy. In this research, we optimize two design parameters, gap and coefficient of restitution (COR), of a pipeline supported in a rack that is allowed to hit bumpers. For a given loading characteristic, indeed, the energy dissipation from such a non-linear system is dependent on the gap and the COR. The ratio of the total energy dissipated through impacts to the energy dissipated by material and structural damping of the pipe-rack is used as a measure of the energy dissipation efficiency. However, excessive number of impacts of the pipe against the bumper can damage or produce dents in the pipeline. The objective functions are therefore conflicting because it is to be ensured that the optimized system provides the least number of impacts while dissipating the maximum amount of energy. A kriging metamodel is used to interpolate the experimental points that are calculated for the values of gap and COR that are chosen after application of the central composite design (CCD). Finally, the Pareto front of the two response surfaces is calculated.

Introduction and problem statement

There are various mechanisms to dissipate energy and control the response of pipeline systems. The use of tuned mass damper is probably the most commonly adopted approach. In this work, impact is used as an energy dissipation mechanism. As an example, this kind of systems were previously used in the Trans-Alaskan pipeline systems which passes through major seismic faults^[1]. During impact, a part of the input energy is dissipated in the form of heat, sound, plastic deformation of the material, etc. The COR is a measure of this dissipation.

Figure 1: Analytical model of a pipe in a rack

In this study, a typical pipe-rack structure is analyzed and analytically modeled as shown in Figure 1. The pipe is allowed to hit bumpers placed at the center of each span. The energy dissipation in this case is dependent on two design variables, gap and COR.

Let $x \in \mathbb{R}^{n \times 1}$ and $\dot{x} \in \mathbb{R}^{n \times 1}$ be the displacement and velocity respectively of the pipe-rack system where n is the total number of degrees of freedom. For a given seismic excitation of duration t_d , a given gap and COR, the net energy dissipated by virtue of the internal structural damping (non-conservative) at time t_d is given by,

$$E_{damping}(t_d) = \sum_{t=0}^{t=t_d} dx_t^T \cdot C \cdot \dot{x}_{t_d}$$

where $C \in \mathbb{R}^{n \times n}$ is the damping matrix of the system and $dx_t = x_t - x_{t-dt}$. The energy dissipated through impacts during this duration is given by,

$$E_{impact}(t_d) = \frac{1}{2} \sum_{i=1}^{N_d} (\dot{x}_{+i}^T M \dot{x}_{+i} - \dot{x}_{-i}^T M \dot{x}_{-i})$$

where \dot{x}_{+i} and \dot{x}_{-i} is the velocity after and before the i^{th} impact, which are related by the COR. M is the mass matrix of the system and N_d is the number of impacts in time t_d . At time t_d , two objective functions are defined for the design of the energy dissipation mechanism, as follows:

- i. Ratio of total energy dissipated through impact to the energy dissipated by the internal damping of the structure, given as,

$$O_1 = \frac{E_{impact}}{E_{damping}}$$

ii. The number of impacts required for dissipating unit amount of energy,

$$O_2 = \frac{N_d}{E_{impact}}$$

In this study it is aimed to dissipate the maximum energy through impacts. However, when the number of impacts increases, there are more chances for the pipeline to suffer damage or dents. Hence, it is also aimed to achieve a desired energy dissipation with a minimum number of impacts. Thus, for a given seismic input, the function O_1 is maximized, or equivalently, $-O_1$ is minimized, whereas O_2 is minimized.

Methodology and preliminary results

Non-linear time history analyses are used to evaluate the objective functions O_1 and O_2 for a given input motion characteristic, and for given values of gap and COR. A CCD^[2] provides the number of experiments that have to be carried out and also the corresponding values of gap and COR. The response surfaces, as shown in Figure 2, are subsequently evaluated by a surrogate kriging model that spatially interpolates the experimental outputs.

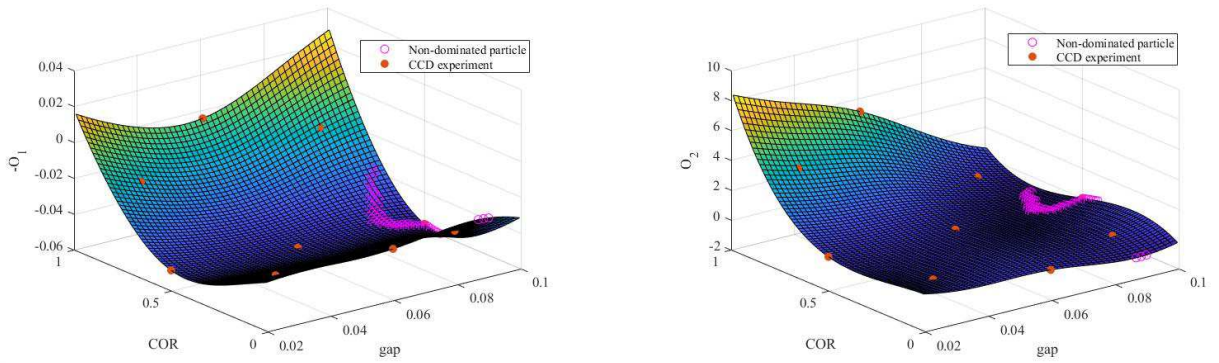

Figure 3: Response surfaces for (a) Objective function 1 and (b) Objective function 2

We finally find the Pareto front. The non-dominated particles, as shown in Figure 3, correspond to the solutions of this multi-objective optimization problem, for certain optimal values of gap and COR.

Figure 4: Representation of the Pareto frontier

Nonlinear vibrations of nanoplates based double mode model and the nonlocal elasticity theory

Jan Awrejcewicz*, Olga Mazur**

* *Department of Automation, Biomechanics and Mechatronics, Lodz University of Technology, Lodz, Poland*

** *Department of Applied Mathematics
National Technical University KhPI, Kharkiv, Ukraine*

Summary. Geometrically nonlinear vibrations of the rectangular simply supported nanoplates are investigated. The governing equations are employed in mixed form and used the nonlocal elasticity theory as well as Kirchhoff's hypotheses and the von Kármán theory. Application of the Bubnov-Galerkin method with a double mode model allows to reduce the governing system of partial differential equations (PDEs) to the system of the second-order ordinary differential equations (ODEs). Analysing obtained ODEs the small-scale effects and force influence are studied.

Particular interest in the study of nanostructures is associated with their wide application in high-tech industry due to excellent mechanical, thermal, electrical properties. Theoretical and experimental research has allowed to observe the small-scale effects that were not detected within the classical theory. This fact led to the development of non-classical continuum theories for study the objects with sizes in nanoscale. The presented work is aimed at the study of geometrically nonlinear vibrations of the small-scale plates. The formulation of the problem is performed based on Kirchhoff's hypotheses, the von Kármán theory. In order to take into account the appearance of the small-scale effects in nanoplates the nonlocal theory of elasticity [1] is applied. It is based on the fact that the stress at a given point is a function of strains at all other points in the body. According to this theory the constitutive relation in differential form [2] has the following form

$$(1 - \mu \nabla^2) \sigma = \sigma', \quad (1)$$

where σ' , σ are local and nonlocal stress tensors, μ is nonlocal parameter, and ∇^2 is the Laplacian operator. The nonlocal governing equations are taken in mixed form, introducing the Airy stress function F :

$$D \Delta^2 w = (1 - \mu \nabla^2) \left(-N_1 \frac{\partial^2 w}{\partial x^2} - N_2 \frac{\partial^2 w}{\partial y^2} + L(w, F) - \rho h \frac{\partial^2 w}{\partial t^2} - \delta_0 \frac{\partial w}{\partial t} + q \right), \quad (2)$$

$$(1 - \mu \nabla^2) \frac{1}{E} \Delta^2 F = -\frac{h}{2} L(w, w), \quad (3)$$

where differential operators are defined as

$$L(w, F) = \frac{\partial^2 w}{\partial x^2} \frac{\partial^2 F}{\partial y^2} + \frac{\partial^2 F}{\partial x^2} \frac{\partial^2 w}{\partial y^2} - 2 \frac{\partial^2 w}{\partial x \partial y} \frac{\partial^2 F}{\partial x \partial y}, \quad L(w, w) = 2 \left(\frac{\partial^2 w}{\partial x^2} \frac{\partial^2 w}{\partial y^2} - \left(\frac{\partial^2 w}{\partial x \partial y} \right)^2 \right), \quad (4)$$

and $\Delta^2 = \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right)^2$, $D = \frac{Eh^3}{12(1-\nu^2)}$ is flexural nanoplate rigidity, E is Young's modulus, ν is Poisson's ratio, w is deflection of the plate, N_1, N_2 are in-plane uniform forces, q is transverse force, ρ is density, h stands for thickness of the plate, whereas δ_0 is damping coefficient. It is assumed that the plate satisfies the simply supposed boundary conditions. The proposed approach is based on two mode presentation of the deflection $w(x, y, t)$ of rectangular small-scale plate with sides a and b as follows [3]:

$$w(x, y, t) = w_1(t) \sin \frac{\pi x}{a} \sin \frac{\pi y}{b} + w_2(t) \sin \frac{2\pi x}{a} \sin \frac{2\pi y}{b}, \quad (5)$$

where w_1, w_2 are bi-modal amplitudes, $\sin \frac{\pi x}{a} \sin \frac{\pi y}{b}$ and $\sin \frac{2\pi x}{a} \sin \frac{2\pi y}{b}$ are shape functions, that satisfy the chosen boundary conditions. Substitution (5) into the equation (3) allows to obtain the stress function presentation:

$$F = f_1 \cos \frac{2\pi x}{a} + f_2 \cos \frac{2\pi y}{b} + f_3 \cos \frac{4\pi x}{a} + f_4 \cos \frac{4\pi y}{b} + f_5 \cos \frac{3\pi x}{a} \cos \frac{\pi y}{b} + f_6 \cos \frac{\pi x}{a} \cos \frac{3\pi y}{b} + p_1 x^2 + p_2 y^2, \quad (6)$$

where coefficients depend on the small-scale parameter μ . Applying the Bubnov-Galerkin method, one can get the nonlocal system of ordinary differential equations. Size-dependent analysis of such system allows to study nonlinear vibrations regimes of the considered system. The numerical calculations are performed for graphene nanoplate with various excitation parameters.

Summary. Nanomechanical resonators are prone to nonlinear dynamic behavior at forces that are only a few nN. In this work, we introduce a novel design that allows us to engineer the dynamic range of a Si₃N₄ nonlinear string resonator using a pair of compliant supports. The design comprises a suspended string and two support beams that act as the compliant supports and form an H-shaped structure. By changing the support beams' width and length, we are able to tune the state of stress in the string and thus control its quality factor Q and Duffing constant γ . Our novel design allows engineering novel high- Q nonlinear resonators with large dynamic range.

Introduction

Although the Duffing nonlinearity has been frequently observed in nanomechanical systems, the engineering of it by geometric design has received little attention [1]. For studying and utilizing the nonlinear response of nano resonators, it is essential to precisely predict or tune their dynamic range in a simple and robust design. In this work, we decouple the stress-length dependence of high-stress Si₃N₄ nano strings [2] by introducing a pair of support beams. Our H-shaped structure offers new knobs for engineering nonlinearity in string resonators while maintaining dynamic similarity with doubly clamped strings. By changing the widths of support beams, we engineer the pre-stress of the string and thus control its Q factor and Duffing constant γ in a large frequency range.

Experimental procedure

Our samples are fabricated from 340nm thick high-stress Si₃N₄ with initial stress around 1.1GPa, which is deposited by low pressure chemical vapor deposition (LPCVD) on a silicon substrate. The scanning electron microscope (SEM) image of our H-shape structure is shown in Figure 1(a) and our measurement set-up is shown in Figure 1(b). A piezo actuator is used to drive the samples into resonance while a Polytec Laser Doppler Vibrometer is used to measure their out-of-plane deflection, as shown in Figure 1(c). The measurement is performed at room temperature and to minimize the air damping, the air pressure is pumped below 2×10^{-6} mbar.

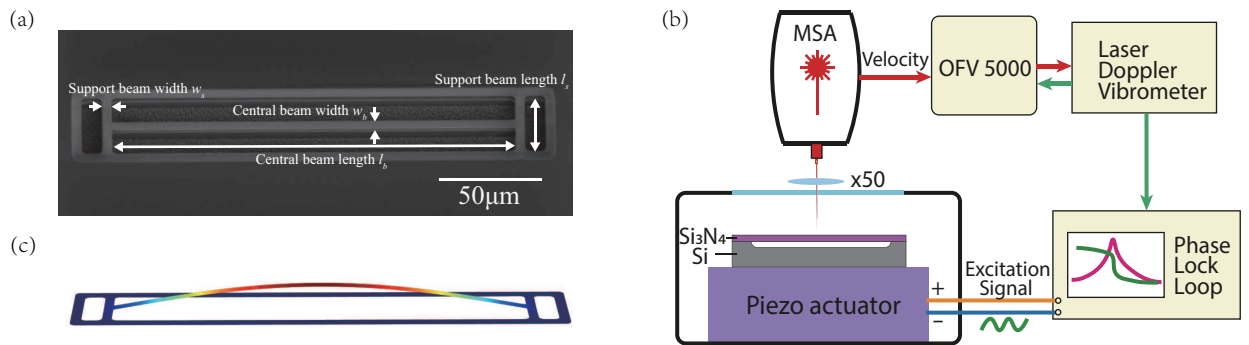

Figure 1: Experimental characterization of the H-shaped resonators. (a) Scanning electron microscope images of an H-beam with $l_b=200\mu\text{m}$, $w_b=4\mu\text{m}$, $l_s=31\mu\text{m}$, $w_s=4.5\mu\text{m}$. (b) Schematics of measurement set-up. (c) Fundamental mode shape of the H-beam in (a).

Modelling and the governing equation

Motion-induced tension modulation is the dominant source of nonlinearity in nanomechanical systems that gives rise to a cubic spring constant (Duffing term in the equation of motion) as follows [3]:

$$\ddot{x} + Q^{-1}\omega_0\dot{x} + \omega_0^2(x + \gamma x^3) = f \cos \omega t \quad (1)$$

Here, x is the generalized coordinate associated with the fundamental mode which is shown in Figure 1(c), Q is the mechanical quality factor, ω_0 is the fundamental eigenfrequency, γ is the Duffing coefficient, f is the force per unit mass acting on the nanoresonator of modal mass m and ω is the excitation frequency.

The critical vibration amplitude of the resonator associated with the onset of nonlinearity can be obtained as follows:

$$a_c = \left(\frac{64}{27} \right)^{0.25} \frac{1}{\sqrt{Q\gamma}} \quad (2)$$

We note that Q and γ in nanoresonators are functions of the pre-stress σ . Therefore, by controlling geometrical parameters of the support beams in our design, we can engineer the pre-stress σ in the central string resonator, tune Q and γ , and thus a_c of the resonator.

Control of quality factor Q and Duffing coefficient γ

Quality factor Q

For each resonator, we perform frequency sweeps in linear regime and record the resonant frequency of the fundamental out-of-plane mode by Lorentzian fits, as shown in Figure 2(a). After obtaining the fundamental resonant frequency, we perform ring-down measurements and obtain Q factors, also shown in Figure 2(a). In Figure 2(b), the simulated Q factors and the measurements on the H-beams with the same configuration are plotted against pre-stress σ in the string, which is tuned by the widths of the support beams.

Duffing coefficient γ

In this work, we extract γ by driving the string resonator in the nonlinear regime and sweeping the frequency in the spectral neighborhood of the fundamental resonance as shown in Figure 2c. By performing the experiments for multiple drive levels we find the "backbone" curve of the resonator and extract the Duffing constant γ using the following simple formula:

$$\omega_{backbone}^2 = \omega_0^2 (1 + 0.75\gamma x_{max}^2) \quad (3)$$

For the design with $l_b=200\mu\text{m}$ and $w_b=4\mu\text{m}$, we are able to tune Q factor down by 49% and tune γ down by 75% by varying w_s from $6\mu\text{m}$ to $1\mu\text{m}$. With this combined effort, we can tune the critical vibration amplitude a_c of the resonator up to nearly 300% compared to simple doubly clamped string resonators. This shows the potential of the new design in enhancing the dynamic range of high- Q resonators, which is essential for sensing applications.

Figure 2: (a) The Lorentzian response of the H-beam showed in the Figure 1(a) excited in its fundamental mode under 1.25×10^{-5} mbar air pressure and the ring-down measurement of it. The y axis is the normalized to the maximum amplitude. (b) Variation of Q factor according to σ for H-beams with $w_b=2\mu\text{m}$ and different l_b . Hollow circles and hollow diamonds with error bars are simulations and experimental results of Q factor respectively. (c) The Duffing effect of a doubly clamped beam with $l_b=200\mu\text{m}$ and $w_b=4\mu\text{m}$ excited by larger forces. The red line is the "backbone" curve.

Conclusions

We propose a new design for enhancing the dynamic range of high- Q Si_3N_4 string resonators by means of compliant supports. By tuning geometrical parameters at the boundaries, we are able to engineer the state of stress in the string from 0.1GPa to 1.0GPa. As a result, we can engineer the Q factor and Duffing constant γ of the resonator, and thus control its dynamic range.

Summary. In this work, we consider a MEMS device made of mechanically-coupled microbeams under electric actuation. We conduct an experimental study to identify the occurrence of veering and then investigate its dynamic response for different electric actuations. A slight change in the DC voltage bias from the veering point is observed to affect significantly the frequency response. Indeed, jump to large orbits occurred when perturbing the applied DC voltage while operating near the cyclic-fold bifurcation point. We also develop and validate a mathematical model to simulate the response of the device. The model showed similarities in the softening effect of the DC voltage bias and an added mass when matching their induced shift in the natural frequency. As such, one can exploit mode localization and the significant and abrupt jumps in the deflection of the coupled microbeams to enhance the sensitivity of mass sensors.

Introduction

The deployment of MEMS devices comprising electrically actuated vibrating micro-beams for mass sensing has gained significant interest in the last few years thanks to their outstanding dynamic features in response to small variations in their effective mass. MEMS mass sensor converts the presence of a tiny element (biological entities such as cells and viruses, gas molecules...) into a resolvable electrical signal via a transduction technique (capacitive, piezoelectric...). A new generation of MEMS mass sensors has been recently proposed based on adopting the concept of mode localization [1-4]. These devices have demonstrated significant improvement in terms of sensitivity by up to four orders of magnitude in comparison to their conventional counterparts. Yet, distinctive merits of mode localized mass sensors have been demonstrated over several research studies in the last decade [1]. However, there is still room for improvement of this kind of sensors, especially when exploiting and tuning their associated nonlinearities to increase further their sensitivity and extend their operating range. In this work, we consider a MEMS device made of mechanically-coupled microbeams subjected to electric actuation. We study unconventional nonlinear mass detection mechanisms and assessed their capabilities to enhance the performance of the mass sensors.

MEMS device description and experimental measurements

We consider a MEMS device comprising two mechanically coupled microbeams with slightly different lengths: $L_1 = 98 \mu\text{m}$ and $L_2 = 100 \mu\text{m}$ (see Figure 1). A coupling beam with a length of $L_c = 65 \mu\text{m}$ is placed at a distance $x_c = 4.9 \mu\text{m}$ from the clamped end of the microbeams. The electrostatic actuation of the device is made by the application of combined DC and AC voltages via a stationary electrode placed underneath the short beam. The device was fabricated by using the Multi-User MEMS Processes (MUMPS®). The microbeams are composed of a polysilicon layer Poly2 reinforced by a second polysilicon layer Poly1 at the fixed end. The measured gap between the cantilevers and the bottom electrode (Poly0) is around $g = 1.35 \mu\text{m}$. The MEMS device is placed in a vacuum chamber at a pressure around 0.3 mbar to minimize the damping effect and the actuation voltage is applied with a micro probe. The quality factor Q is found equal to 900. To measure the vibrations at the tip of each cantilever beam, a single point laser Doppler vibrometer is used in order to experimentally confirm the feasibility of the operating principle of the sensor.

Figure 1: MEMS device and cross sections showing the layers of the MUMPS® process.

Results and discussion

We plot in Figure 2(a) the experimental frequency response of the MEMS device obtained at two different DC voltages. The results are shown for the short beam. We note that the electrostatic force is applied only to the short beam while operating at veering and setting the AC voltage at 30 mV. The needed DC voltage to reach veering is found experimentally equal to 7.73 V. Adding a DC voltage bias of 200 mV induces a significant jump in the beam deflection when operating at a suitable and a fixed excitation frequency near the cyclic-fold bifurcation, as indicated by the arrow at $\omega = 166.140$ kHz in Figure 2(a). This jump is illustrated further in the time response shown in Figure 2(b). A DC voltage bias of 200 mV is introduced at $t = 1$ s. The softening effect induced by the DC voltage is equivalent to that of an added mass

deposited on one of the microbeams as will be demonstrated next. As such, the observed jump to large orbits can be exploited for mass sensing purposes.

Figure 2: Dynamic response of the MEMS device for different DC voltages (experimental results).

Following Euler-Bernoulli beam theory, we develop a nonlinear mathematical model governing the vibrations of the two mechanically coupled microbeams. The weak mechanical coupling is approximated by a torsional spring with rotational stiffness. We derive a reduced-order model using the Galerkin decomposition method [3]. In Figure 3(a), we compare the frequency response curves obtained using the developed nonlinear model (solid lines) against those measured experimentally (dotted lines). A good agreement between the numerical and experimental data is obtained. These simulation results demonstrate the capability of the nonlinear dynamic model to properly capture the dynamic response of the MEMS device. We show in Figure 3(b) the simulated frequency responses for different DC voltage biases (with respect to the veering DC voltage). We also plot the frequency response obtained when adding a mass of seven pg on the short beam. Of interest, the frequency response obtained for a DC voltage bias of 200 mV matches with that obtained for an added mass of seven pg. We note that increasing the applied DC voltage by 200 mV and adding a mass of seven pg lead to same shift in the natural frequency of the microsystem. As such, given these similarities, one can use the abrupt and significant jump to large orbits observed in mechanically coupled beams for mass sensing applications.

Summary. We study the frequency stabilization of a MEMS self-sustained oscillator operating in internal resonance. We show, both experimentally and theoretically, that coupling two vibrational modes with a frequency ratio of 1:3 through a nonlinear resonance makes it possible to stabilize the oscillation frequency of MEMS oscillators beyond any currently known frequency stabilization technique. Our analysis shows that this novel frequency stabilization stems from operation in a region of (nearly) zero frequency dispersion at large amplitudes. The large amplitude improves signal quality and the internal resonance provides both the zero dispersion as well as phase-locking between the modes, all of which are beneficial for noise reduction. Our findings provide a new strategy for engineering low-frequency noise oscillators capitalizing on the intrinsic nonlinear phenomena of micro- and nano-mechanical resonators.

Introduction

MEMS oscillators, which offer the potential for reduced power consumption, on-chip integration with CMOS, and a small footprint, are widely used for precision time keeping and as sensitive detectors. Therefore, their frequency stability is a key figure of merit. However, due to the small size of the mechanical vibrating structures in these MEMS oscillators, their vibrations are highly sensitive to noise and become nonlinear even for small amplitudes. Unlike linear vibrations, in nonlinear vibrations, the resonant frequency has a strong dependence on the oscillation amplitude (frequency dispersion), and therefore, amplitude fluctuations translate into frequency fluctuations. This amplitude-to-frequency (A-f) noise conversion considerably degrades the oscillator performance.

In this study, we show that a nonlinear resonance between a pair of modes that have a frequency ratio of 1:3 provides a zero-dispersion domain over which, local to the operating point, A-f effects are eliminated and the system regains some specific characteristics of linear vibrations, even though the operating point is well into the nonlinear regime. Moreover, the inter-modal phase locking of the nonlinear resonance produces a frequency stabilizing effect similar to that observed for pairs of synchronized oscillators. These effects both suppress frequency fluctuations in the primary mode, making the considered oscillator cleaner than its linear counterpart (which is ideally the cleanest oscillator).

Experimental method and observations

The resonator (i.e., the mechanical vibrating structure) of our MEMS oscillator is fabricated from single-crystal silicon and is composed of 3 beams connected at their centers to each other and to a pair of comb drives (see Refs. [1] for details). The resonantly interacting modes are the fundamental flexural mode (eigenfrequency ω_1) and the fundamental torsional mode (eigenfrequency $\omega_2 \approx 3\omega_1$); see the left panel of Fig. 1. The self-oscillation is achieved by a placing the resonator in a feedback loop with an amplifier and a phase shifter whose tuning both destabilizes the thermal vibrations and controls the amplitude and phase of the flexural mode. [4]

Figure 1: Device and experimental measurements. Left panel—the flexural (ω_1) and torsional (ω_2) modes from finite element models, which interact resonantly when $\omega_2/\omega_1 \approx 3$. Center panel—the operating frequency of the oscillator increases with the drive voltage, due to the Duffing nonlinearity, until it saturates with zero-dispersion in the vicinity of the 1:3 internal resonance. Right panel—at the internal resonance, the Allan deviation reduces dramatically, revealing the stabilizing effect of the nonlinear mode coupling.

The motion of the flexural (in-plane) mode is detected capacitively by one set of combs. The capacitance variation of the voltage-biased comb-drive electrode generates a current that is introduced into a current amplifier to produce a voltage output proportional to the oscillation amplitude of the flexural mode. This voltage is phase shifted and used to excite the beam through the other set of combs. The motion of the torsional (out-of-plane) mode is detected by an optical

interferometry method, with the laser spot focused on the outer-most position of the movable structure. The interference signal is then amplified to produce a voltage output proportional to the oscillation amplitude of the torsional mode. The frequency stability of the system was analyzed in terms of the Allan deviation from the signal of the flexural mode [2] $\sigma_y(\tau) = \sqrt{\frac{1}{2(N-1)} \sum_{i=1}^{N-1} (\langle y_{i+1}^T \rangle - \langle y_i^T \rangle)}$, where $\langle y_i^T \rangle$ are the relative frequency fluctuations averaged over the i^{th} discrete time interval of τ . The center panel of Fig. 1 shows the zero dispersion by the flattening of the operating frequency as a function of amplitude, and the right panel clearly shows the attendant frequency stabilization obtained in the internal resonance by the reduction of the Allan variance at these amplitudes.

Analytical model and results

We consider the following closed loop system with a 1:3 internal resonance

$$\ddot{x}_1 + 2\Gamma_1 \dot{x}_1 + \omega_1^2(1 + \eta_1)x_1 + \gamma x_1^3 + 3\alpha x_1^2 x_2 = S \cos(\omega_1 t + \phi_1 + \Delta) + \xi_1, \quad \ddot{x}_2 + 2\Gamma_2 \dot{x}_2 + \omega_2^2(1 + \eta_2)x_2 + \alpha x_1^3 = \xi_2,$$

where $\Gamma_{1,2}$ are the dissipation rates, $\omega_{1,2}$ are the modal eigenfrequencies ($\omega_2 \approx 3\omega_1$), S is the drive level (set by the amplifier), $\phi_1(t)$ represents the phase of the flexural mode, Δ is the imposed phase shift from the feedback loop, $\eta_{1,2}(t)$ are the frequency noises, and $\xi_{1,2}(t)$ are the additive thermal noises. We have assumed that the coupling stems from a single-term potential $U_{cpl} = \alpha x_1^3 x_2$, that the flexural mode nonlinearity is a simple Duffing type, γx_1^3 , and the torsional mode operates in its linear range. Using the method of stochastic averaging [3], we derive a pair of Langevin equations for the phase sum $\phi = \phi_1 + \phi_2$ and difference $\psi = 3\phi_1 - \phi_2$ (ϕ_2 is the phase of the torsional mode). Near a stable operating point, it can be shown that diffusion of the phase difference remains constant and small. In contrast, the diffusion of the phase sum is always strong and associated with a variance that increases linearly in time ($\langle \phi^2 \rangle - \langle \phi \rangle^2 = D_\phi t$). However, in the zero-dispersion domain, D_ϕ reduces drastically due to elimination of the A-f noise conversion. Moreover, we can neglect the diffusion of ψ , which is considerably smaller than the strong diffusion of ϕ , and then approximate, using the relations $\phi_1 = (\phi + \psi)/4$ and $\phi_2 = (3\phi - \psi)/4$, the diffusion constants of the individual phases ($\langle \phi_{1,2}^2 \rangle - \langle \phi_{1,2} \rangle^2 = D_{T_{1,2}} t$) as $D_{T_1} \approx (1/4)^2 D_\phi$, $D_{T_2} \approx (3/4)^2 D_\phi$. Therefore, the phase-locking mechanism ($\dot{\psi} = 0$) of the internal resonance leads to a further reduction in the phase noise of the first mode (D_{T_1}). We note that the flexural mode is subjected to the noises of the feedback circuitry while the torsional mode is largely isolated from such noise sources. Thus, if the second mode (nearly purely mechanical) is significantly cleaner than the first mode, i.e., $D_{\xi_2} \ll D_{\xi_1}$ and $D_{\eta_2} \ll D_{\eta_1}$, then the cleaner second mode, which has a threefold stronger influence, cleans the noisy first mode and its diffusion constant is reduced by a factor of 1/16, i.e., $D_{T_1}|_{\text{Inside IR}} = (D_{T_1}|_{\text{Outside IR}})/16$. This cleaning effect can be readily seen in Fig. 2, where in the zero-dispersion domain of the coupled-mode oscillator, the diffusion constant of the first mode is significantly lower than the diffusion constant of even the highly ideal single-mode linear oscillator. Note that without the phase cleaning effect, the diffusion constants would be (nearly) equal in the zero-dispersion domain.

Figure 2: Operating frequency Ω (left panel) and total diffusion constant of the phase of the first mode (right panel) as functions of drive level for single-mode linear (red), and coupled-mode (black) closed-loop oscillators, with $\omega_1 = 1$, $\omega_2 = 3.06$, $\gamma = 3$, $\alpha = 10$, $\Gamma_1 = 10^{-3}$, $\Gamma_2 = 10^{-4}$, $\Delta = \pi/2$, $D_{\eta_1} = 1$, $D_{\eta_2} = 0.1$, $D_{\xi_1} = 0.4$ and $D_{\xi_2} = 0.04$. Only the stable states in which $\Omega < \omega_2/3$ are shown. The diffusion constant of the linear oscillator decreases as S^{-2} , whereas the diffusion constant of the coupled-mode oscillator has a dual local minima (denoted by the dashed vertical lines), the lower of which is the usual operating point for a Duffing oscillator without zero dispersion. The cancellation of amplitude to frequency noise conversion at the zero-dispersion domain along with the phase constraint yield a diffusion constant for the coupled-mode oscillator that is even smaller than that of the linear oscillator.

Hopf Bifurcation in MEMS - (When) Do Such Exist?

Stefanie Gutschmidt* and Stefano Lenci†

*University of Canterbury, Christchurch, New Zealand

†Università Politecnica delle Marche, Ancona, Italy

Summary. When considering MEMS/NEMS not just as interesting dynamical systems theoretically, but also for technological applications, a Hopf bifurcation could be a desired property for e.g. increasing sensitivities of a sensor. However, MEMS/NEMS are not known to commonly experience a Hopf point. In this work we investigate a real MEMS system with integrated thermal actuation in passive and active operation modes and investigate this Hopf in MEMS/NEMS question. We show that when the system is operated actively, there are possible parameter ranges which include a Hopf bifurcation.

Background

MEMS are inherently nonlinear, which immediately provides additional properties to be exploited for technological implementation. These advantageous properties are associated with bifurcation points such as saddle-node, transcritical, pitch-fork and Hopf bifurcations. While the former three bifurcations are related to changes of fix-points (or real eigenvalue(s) of the Jacobian) of a system for a selected control parameter, the latter bifurcation is associated with a changing complex-conjugated pair of eigenvalues crossing the complex plane from negative to positive [1, 2]. Furthermore, the former bifurcations have been reported extensively in the literature (for example, the well-known pull-in phenomenon is associated with a saddle-node bifurcation) [3, 4], while the latter is less common, if not rare. For example, in the book by Younis [5] the occurrence of Hopf bifurcations in MEMS is not mentioned. The Hopf bifurcation is related to the damping properties of the system. A single degree-of-freedom (DOF) system (e.g. MEMS/NEMS in their first vibration mode) would therefore require negative damping properties. Furthermore, Gutschmidt and Gottlieb [6] and also Zehnder et al. [4] have observed Hopf (Neimark-Sacker) bifurcations in electrostatically coupled MEMS oscillators when operated near an internal resonance which is also known for parametrically excited systems in general [7] (for micro and macro-scale alike). From other macro-scale examples it is further known that other coupling can also introduce negative damping properties, especially when gyroscopic effects in addition to damping are present in a multi-DOF system. However, for more common MEMS geometries and configurations such scenario are rather rare or not existing.

Figure 1: SEM image of the self-actuation, self-sensing cantilever (JEOL JSM-IT300).

In this work we consider such an otherwise typical MEMS (Fig. 1), but with the ability to be operated passively and actively. Unlike other MEMS devices, the considered system has self-sensing and self-actuating capabilities [8] with which a feedback scheme can be introduced and damping properties are altered.

Passive & Active MEMS Model and Dynamics

The motion of the cantilever is generated by the top layer of the composite structure being thermally actuated (see Fig. 1). The deflection of the cantilever tip is monitored by an integrated piezo-resistive sensor located near the supported end (base). Our analysis is based on our previous work [9] in which we derive the governing equations for this composite MEMS system from basic principles. In this work we radically simplify these equations by considering only the first vibration mode of the cantilever and dominating terms are as follows

$$\ddot{q}_w + \delta \dot{q}_w + q_w - \alpha q_\theta = \kappa_{ext}, \quad (1a)$$

$$\dot{q}_\theta + \beta q_\theta = \gamma i^2. \quad (1b)$$

q_w and q_θ are the nondimensionalised mechanical and thermal variables of the system representing the modal deflection of the cantilever and the response of temperature difference, respectively. Parameters α , β , γ , δ are classic integration constants originating from a modified Ritz discretization [9], wherein δ is related to the damping. The coupling between the mechanical and thermal systems is determined by the strength of the coupling parameter α . κ_{ext} is an external periodic stimulus. The integrated thermal actuation is modelled as Joule heating, through which the feedback mechanism is introduced with

$$i = i_{DC} + a q_w, \quad (2)$$

where i_{DC} is an off-set current with which to control equilibrium states and a is the feedback strength.

Analysis & Results

The analysis emphasizes on the existence of a Hopf bifurcation for equilibrium solutions. However, Hopf (Neimark-Sacker) bifurcations in the presence of external excitation of the system are also of interest. We consider the three following systems: passive (decoupled from the thermal actuation, only Eq. (1a)), thermally coupled but passive Eq. (1), and the actively operated system Eqs. (1) and (2), [10], with their Jacobian matrices accordingly being

$$J_{passive} = \begin{bmatrix} 0 & 1 \\ -1 & -\delta \end{bmatrix}, \quad J_{coupled} = \begin{bmatrix} 0 & 1 & 0 \\ -1 & -\delta & \alpha \\ 0 & 0 & -\beta \end{bmatrix}, \quad J_{active} = \begin{bmatrix} 0 & 1 & 0 \\ -1 & -\delta & \alpha \\ \epsilon & 0 & -\beta \end{bmatrix},$$

with $\epsilon = 2\gamma a i_{DC}$ from substituting (2) into (1b). Investigating the roots λ_i for $i = 1, 2, 3$ of these systems (Fig. 2) reveals the absence and existence of Hopf bifurcations. Figure 2a) depicts the roots of systems $J_{passive}$ and $J_{coupled}$, respectively.

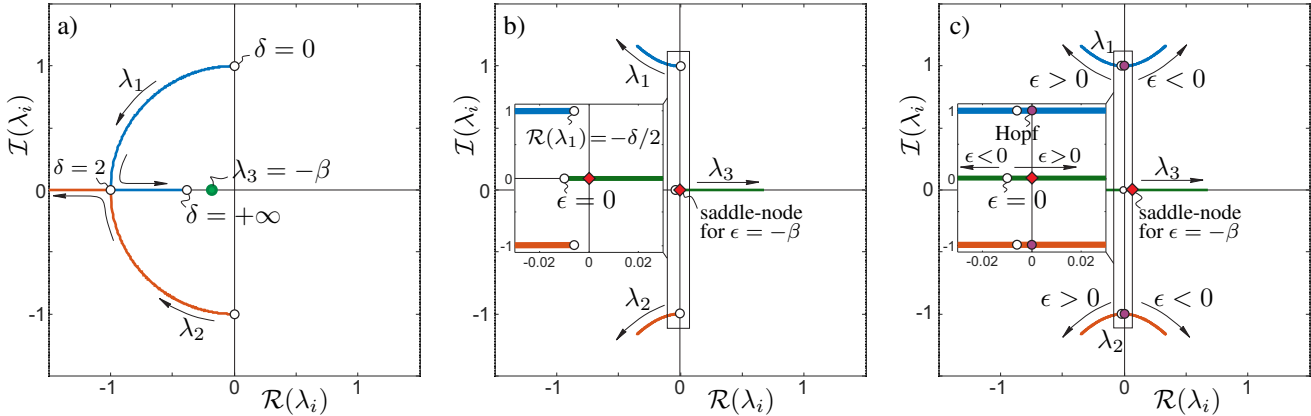

Figure 2: Roots of the MEMS for different operation modes; a) passive & passive coupled systems with all positive system parameters; b) active system with positive system and feedback parameters; c) active system with positive system and negative feedback parameters.

Note, the additional third root for system $J_{coupled}$ (green marker in Fig. 2a)). For positive values of δ (damping) there are no Hopf bifurcations present in either passive or coupled systems, as expected and observed in literature. Figure 2b) portrays the roots of the active system J_{active} (with feedback) for all system and feedback parameters having positive values. We observe a saddle-node bifurcation [10] but no Hopf! Only for negative values of the feedback parameter ϵ , a Hopf bifurcation is present which can be introduced by a negative off-set current i_{DC} or negative feedback strength a (see Eq. (2)).

Conclusions

In this work we investigate the existence of a Hopf bifurcation for equilibria of an ordinary MEMS structure as typically found in modern technological applications. The analysis includes passive and active operation modes, and reveals the existence of Hopf points for only the active operation mode and when feedback parameters include also the negative range. Although the emphasize is laid on Hopf bifurcations related to equilibria, the presentation will also include investigations of the system subject to external stimuli and the existence of Neimark-Sacker bifurcations.

Internal Resonances in Magnetic Resonance Force Microscopy

Evyatar Hacker and Oded Gottlieb

Department of Mechanical Engineering, Technion - Israel Institute of Technology, Haifa, Israel

Summary. We investigate the existence of internal resonances in magnetic resonance force microscopy asymptotically and numerically and demonstrate the possible existence of energy transfer from a directly excited mode to its out-of-plane counterpart. The reconstitution multiple-scales method reveals the existence of non-stationary dynamics that yields coexisting periodic and quasiperiodic dynamics for small damping that may enable multi-functional detection of both electron spin and the sample magnetic properties.

Magnetic resonance force microscopy (MRFM) is an imaging technique that enables acquisition of three-dimensional magnetic images at nanometer scales, and has been adapted for detection of magnetic spin of a single electron [1]. It is based on combining the technologies of magnetic resonance imaging (MRI) with atomic force microscopy (AFM). In conventional MRI devices the electronic spins are detected by measuring their magnetic induction using an inductive coil as an antenna. However, in MRFM the detection is implemented mechanically using a cantilever to directly detect a modulated spin gradient force between the sample spins and a ferromagnetic particle attached to the tip of the cantilever. While MRFM systems are receiving a growing amount of interest, to date, a comprehensive theoretical treatment is still lacking. Existing models are based on simplistic lumped-mass reductions that include linear estimates of cantilever stiffness and damping complemented by a nonlinear approximation of the magnetic force [2] and are unable to resolve the spatio-temporal complexity of the magneto-elastic sensor.

We thus consistently formulate a nonlinear initial-boundary-value problem (IBVP) combining the three-dimensional motion of a viscoelastic micro-cantilever and the dynamic interactions of the spin magnetic moments (see Figure 1-left). The MRFM cantilever IBVP incorporates the generalizes forces defined by the total magnetic field which are augmented by the time-dependent spin magnetic moment components in a rotating system of coordinates described by the Bloch equations [3]. We reduce the IBVP to a seventh-order nonlinear dynamical system and investigate the three-dimensional motion of the MRFM cantilever tip corresponding to adiabatic and non-adiabatic conditions. We emphasize that periodic base excitation of the vertical MRFM configuration here is not sensitive to a global homoclinic escape bifurcation threshold [4] typical of the traditional horizontal configuration of the cantilever sensor which is limited to operation below a jump-to-contact condition.

Figure 1 – MRFM model definition sketch (left), frequency response for the case of a 1:1 internal resonance (center) and for the case of a 2:1 internal resonance (right).

We use an asymptotic reconstitution multiple-scale analysis to accurately determine the MRFM system frequency response which enables estimation of the cantilever frequency shift corresponding to documented measurements. We investigate the stability of slowly varying evolutions for the conditions of both one-to-one (Figure 1-center) and two-to-one internal resonances (Figure 1 – right) which reveal the existence coexisting periodic solutions and secondary Hopf bifurcations [5].

Numerical integration of the dynamical system for different values of system parameters near its two-to-one internal resonance reveal symmetry breaking of a fundamental period-doubled solution (Figure 2) which evolves to an asymmetric period three ultra-sub-harmonic and culminates with non-stationary solutions depicted by a dense power spectra and corresponding poincare' map.

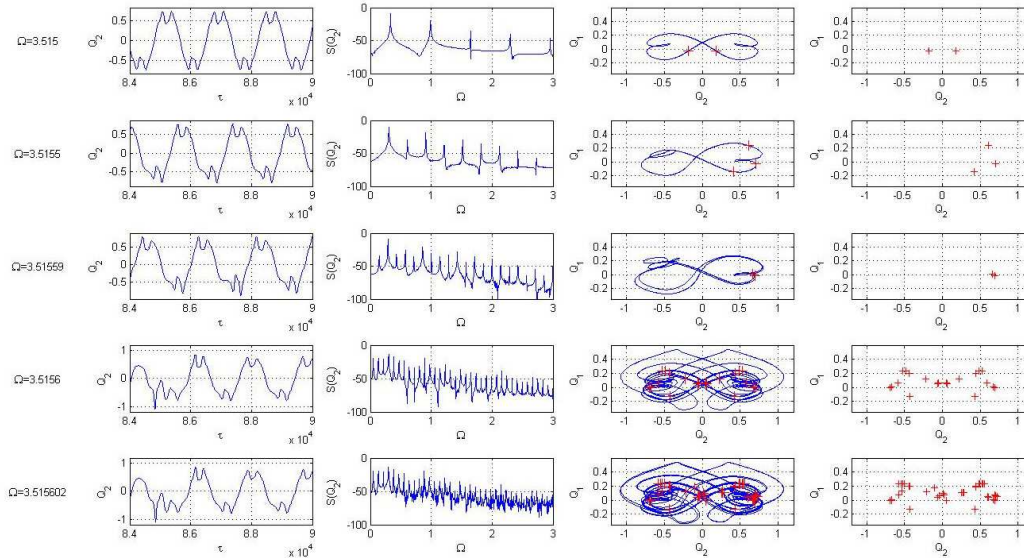

Figure 2 – Numerical response for a 2:1 internal resonance which exhibits complex periodic ultra-sub-harmonic solutions.

Numerical integration of the dynamical system for different values of system parameters near its one-to-one internal resonance (Figure 3) reveal quasiperiodic and chaotic like motion which in addition to identification of the spin gradient force may enable simultaneous multi-functional sensing of material properties of magnetized samples.

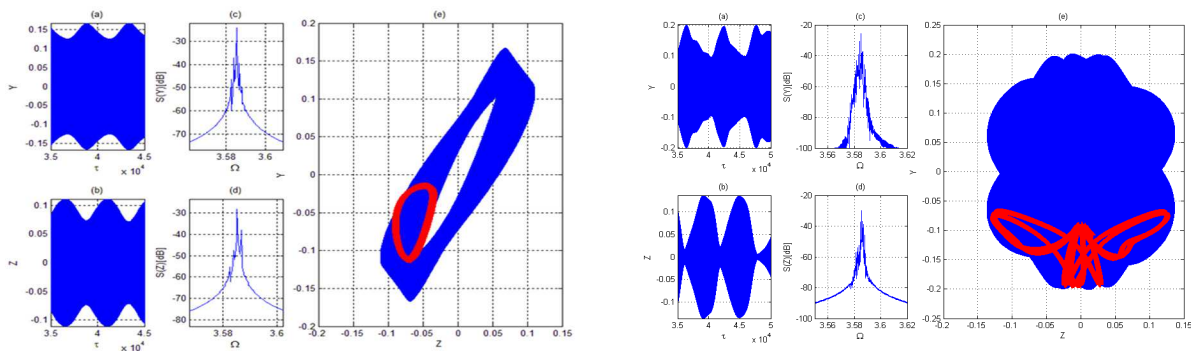

Figure 3 – Numerical response for a 1:1 internal resonance which exhibits a quasiperiodic torus (left) and a strange attractor (right).

Summary. This work presents an approach to chaos generation that both preserves and leverages the rotating frame approximation that is usually used to analyse nonlinear M/NEMS resonators. The approach relies on increasing the phase-space dimensions to meet the Poincaré-Bendixon condition. Chaos generation is further constrained within the parameter space by relying on arguments from Melnikov's method. Experimental validation is performed using a GaAs piezoelectric nonlinear MEMS resonator.

Introduction and Theory

The relatively low-loss and weakly nonlinear properties of M/NEMS resonators have made the use of perturbation based techniques to capture their dynamics a marking feature of this field of research. These perturbation techniques include multiple scale analysis and the rotating frame approximation, and assume that the dynamics take the form of a “slow-flow” envelope superimposed on an otherwise sinusoidal carrier. These same physical properties that make M/NEMS devices desirable and perturbations techniques possible are usually counterproductive when it comes to generating chaos, since this latter is not a perturbation phenomenon.

Mathematically this effect can be understood by looking at the governing Duffing equation, written in a non-dimensional form as:

$$\ddot{x} + \gamma\dot{x} + x + \alpha x^3 = F_1 \cos(\omega_1 t) + F_2 \cos(\omega_2 t) \quad (1)$$

where x is the displacement, γ and α correspond to the non-dimensional dissipation and nonlinearity terms, and F_1 , F_2 , ω_1 and ω_2 are the magnitudes and frequency of externally applied forcing terms. Note that for the rotating frame approximation to apply, the frequency difference between $(\omega_1 - \omega_2) \ll 1$

The application of the rotating frame approximation to equation (1) gives:

$$\begin{aligned} \dot{X} &= -\delta Y + \frac{3\alpha}{8}(X^2 + Y^2)Y - \frac{1}{2}(F_2 \sin(\Theta) + \gamma X) \\ \dot{Y} &= \delta X - \frac{3\alpha}{8}(X^2 + Y^2)X + \frac{1}{2}(F_1 + F_2 \cos(\Theta) - \gamma Y) \\ \dot{\Theta} &= \Omega = (\omega_2 - \omega_1)/\omega_0 \end{aligned} \quad (2)$$

where, $\delta = (\omega_1 - \omega_0)/\omega_0$, and X and Y are the rotating-frame quadratures.

Equation (2) explains why it is difficult to generate chaos within the range of applicability of the rotating frame approximation in the case of only one forcing term is applied, i.e. $F_2 = 0$. Since in such a case the system reduces to a two-dimensional system ($n = 2$), and does not possess the necessary dimensions, i.e. $n = 3$, for chaos generation.

The typical approach to chaos generation in nonlinear M/NEMS devices have been to operate the device beyond the regime where equation (2) is valid, usually by applying large driving amplitudes and using exotic nonlinearity [1, 2]. However, it is equally possible to generate chaos while remaining within the perturbation regime, by expanding the rotating frame dimensions from $n = 2$ to $n = 3$, which can be done by applying the second tone, i.e. $F_2 \neq 0$.

While increasing the rotating-frame dimensions from 2 to 3 is a necessary condition, it nevertheless does not define the area within the four-dimensional parameter-space (δ , Ω , F_1 , F_2) where chaos can exist. Fortunately, the system of equation (2) is typically described by Melnikov's method [3], which imposes the existence of a homoclinic bifurcation as a precondition for chaos generation. The existence of a homoclinic orbit implies operating within the bistable regime. Thus, it is an equally necessary condition to have at least one of the two applied tones within the bistable area of operation shown in Fig. 1(a)-(c) as a function of the non-dimensional parameters.

Experimental Validation

Experimental validation is performed using a GaAs piezoelectric MEMS clamped-clamped beam resonator. Under low drive amplitudes (70 mV), the single-tone frequency response of the device shows a resonance frequency and quality factor of $f_0 = 1.559$ MHz and $Q = 1000$ respectively, Fig. 1(d). For large amplitude sweeps (2.8 V), the device exhibits a hardening-type Duffing nonlinearity, which is fitted to give an $\alpha = 16$, Fig. 1(d).

Upon the application of two tones, with one tone having 1 V amplitude and $\delta = 4$ kHz, while the other tone (2 V) is swept over a $\Omega = 10$ kHz interval. The system exhibits a frequency doubling bifurcation route to chaos once the high amplitude tone is within its respective bistability region. This effect holds for a bidirectional frequency sweep, as shown in Fig. 1(e). The spectral response as well as the phase-space plots corresponding to a rotating frame periodic motion, period-doubling motion, and chaotic motion are shown in Fig. 1(f)-(h), and Fig. 1(i)-(k), respectively.

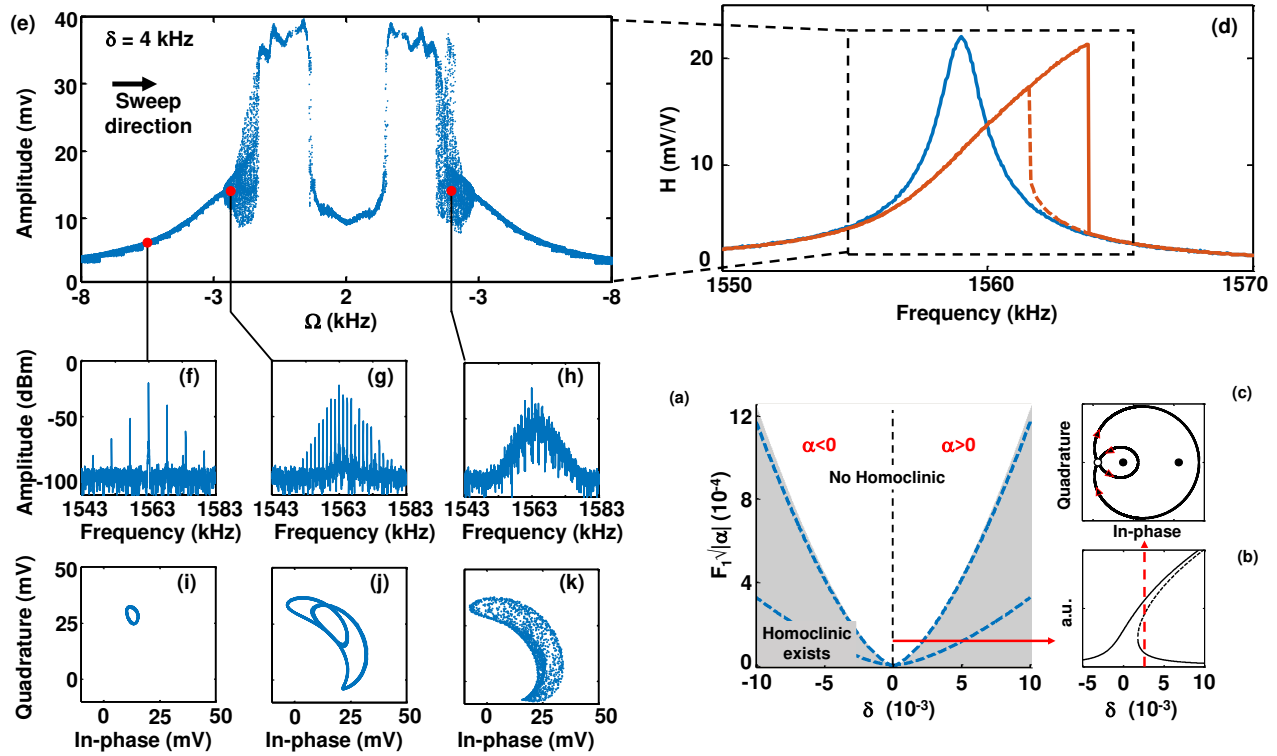

Figure 1: (a) Bistability map plotted as a function of non-dimensional force and detuning, showing the region of bistability for a lossless driven Duffing resonator (grey area), and for a low-loss ($Q=1000$) Duffing resonator (area within the dashed blue line). (b) Amplitude versus detuning response of a lossless Duffing taken for $F_1 \sqrt{\alpha} = 1$. The corresponding phase-space plots for a detuning of $\delta = 2.5 \times 10^{-3}$ is shown in (c). The stable fixed points and the saddle point are shown as black and white dots respectively, as well as the homoclinic orbit. (d) Experimentally obtained frequency response sweep showing the linear regime (blue trace) and the Duffing regime (red trace). (e) Amplitude of the rotating-frame oscillations under the effect of a two-tone excitation, with one fixed tone ($\delta = 4$ kHz), and Ω swept between $[-8, 2]$ kHz, the frequency is swept in both directions with the forward and backward sweeps plotted side by side. The oscillations show Period 1, Period 2, and chaos, the spectral density and phase space plots of which examples are shown in (f)-(h), and (i)-(k), respectively.

Conclusions

In conclusion, this work presents an approach that leverages our understanding of the rotating frame approximation in order to generate chaos in nonlinear M/NEMS resonators using low power actuation. The chaos generation area within the parameter space is constrained using arguments from Melnikov's method, and the technique presented here is independent of the exact device design and scale, and therefore is generally applicable to low-loss nonlinear M/NEMS resonators.

Summary. Emergence of *discrete breathers* (also known as Intrinsic Localized Modes) in nonlinear lattices, analogous to *solitons* in continuous media, is a uniquely nonlinear phenomenon wherein energy gets localized in specific nodes of the lattice. While extensively studied in various contexts including optical systems and MEMS arrays, the effects of random excitation on the formation and dynamics of breathers remains largely unexplored. In this talk, we will present our recent results which demonstrate that additive white noise excitation can aid the *controlled* formation and sustenance of discrete breathers in a nonlinear electrical lattice. In addition, we will present computational results that demonstrate that a temporary burst of random excitation of the white noise type can facilitate the change of location of a breather in a lattice. The results are expected to be of both theoretical interest as well as in several important applications involving discrete breathers, such as targeted energy transfer.

Overview and Analytical Framework

Discrete breathers (also known as Intrinsic Localized Modes) correspond to localization of energy at specific locations within perfectly periodic, nonlinear lattices. Manifest as sustained, stable oscillatory modes, the existence of breathers is predicated on the nonlinearity and discreteness of the lattice. Studies of discrete breathers may be traced back to investigations of the Fermi-Pasta-Ulam oscillator chain. Since then, the phenomenon has been observed in a broad spectrum of systems such as Josephson junctions, photonic crystals [2] and micro-cantilever (MEMS) arrays [3] thereby establishing its universality. In addition to being fundamentally important in theoretical studies of energy distribution in periodic nonlinear systems, breathers are of interest in applications such as targeted energy transfer and signal processing. The dynamical scale of several systems in which breathers emerge point to the importance of stochastic effects. Furthermore, it is known that phenomena such as stochastic resonance that arise due the interplay between randomness and nonlinearity can be exploited to advantage in applications. However, the influence of randomness on the formation and dynamics of breathers is yet to be understood and motivates the present effort. In recent work, we found that random excitation (characterized by additive white noise of appropriate intensity) of even an arbitrarily chosen cell of a lattice for a short period of time can induce breather formation in a nonlinear electrical lattice [1]. Here, we specifically ask whether random excitation of a node at which a breather has emerged can induce a change of location of the breather. In other words, we ask whether random excitation can be used as a technique to manipulate and move breathers to different locations in a lattice.

Analytical Framework

The non-dimensional dynamic model equations for a unit cell “ n ” in the considered electrical lattice are given in Equations (1) and (2) [4]:

$$\frac{dv_n}{d\tau} = \frac{1}{c(v_n)} \left[y_n - i_D(v_n) - \frac{1}{\omega_0 C_0} \left(\frac{1}{R_I} + \frac{1}{R} \right) v_n + \frac{\cos(\Omega\tau)}{RC_0\omega_0} \right] \quad (1)$$

$$\frac{dy_n}{d\tau} = \frac{L_2}{L_1} (v_{n+1} + v_{n-1} - 2v_n) - v_n \quad (2)$$

In these equations, $v_n = V_n/V_s$ is the non-dimensional node-voltage of cell n , $\tau = \omega_0 t$ is the non-dimensional time, $\Omega = \omega/\omega_0$ is the non-dimensional driving frequency with $\omega_0 = 1/\sqrt{L_2 C_0}$, $c(v_n) = C(V_n)/C_0$, and $i_D(v_n) = I_D(V_n)/\omega_0 C_0 V_s$. Note that the sinusoidal sources in each cell are identical in frequency Ω , amplitude V_s , and phase. R_I is an additional term added to account for the resistance of the inductors. It is considered to be parallel to L_2 and its value is dependent on the driving voltage amplitude V_s . In this case, where we have chosen $V_s = 4V$, R_I is equal to $5 \text{ k}\Omega$ [?].

To account for stochastic excitation, the modelling equations are recast as a vector-valued Ito stochastic differential equation given in Equation (3):

$$d\mathbf{x}(\tau) = f(\mathbf{x}(\tau), \tau) d\tau + \sigma \tilde{G} d\mathbf{W}(\tau) \quad (3)$$

where $d\mathbf{W}(t)$ is a Brownian motion increment that is drawn from the standard normal distribution and represents a white-noise Gaussian process. The noise intensity is represented by the scalar coefficient σ . The computational results are obtained by simulating the above equations using the standard Euler-Maruyama scheme for numerical solutions of stochastic differential equations.

Figure 1: Averaged Results for Noise Burst at Cell 12

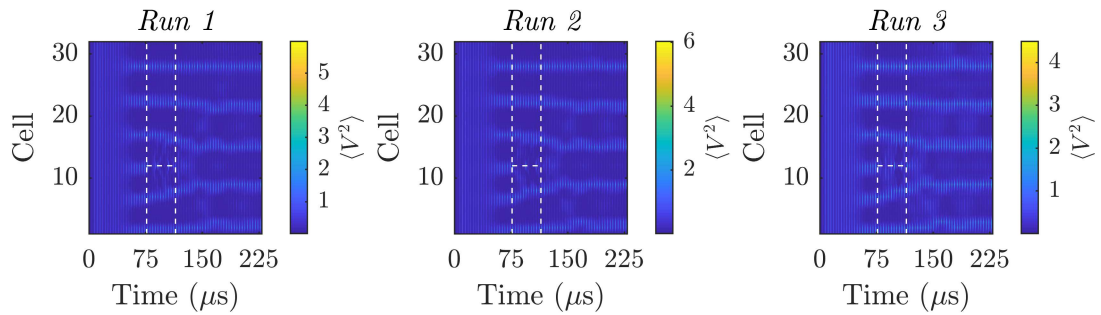

Figure 2: Individual Run Results for Noise Burst at Cell 12

Results

Breather formation spurred by small randomized initial voltage conditions at top node of cell in the range of 0 to 0.04 volts is observed. White noise is applied at cell 12 starting at 1/3 into the simulation, turned off again at the halfway point into the simulation. Figure 1 depicts the average of ten individual runs each using the same initial conditions but different noise profiles, with the dashed white lines indicating when and where noise is applied. As apparent, when $\sigma = 0.15$, the breather located at cell 12 is effectively eliminated. Individual run results pictured in Figure 2 further corroborate this. The ability to eliminate or shift breathers was found to depend on the initial condition profile used. For 2 of the 3 profiles used, including this one, it was possible to move or eliminate the breathers using a noise burst at its location. For the third profile tested, the breathers were too robust and reappeared after the noise burst in the same location. However, the effectiveness in the other two IC cases indicate that noise may be used to control the location of these breathers on average. The other cases suggest that appropriate choice of noise intensity is essential to successfully move the breathers.

Conclusions

The results indicate that random excitation characterized by additive white noise can induce a change of location of breathers in the lattice. This has not been reported in the literature and hence is a novel aspect with implications in applications where shepherding breathers across a lattice would be of interest. In addition, our recent results showing that discrete breather formation in a nonlinear electrical lattice may be controlled by random excitation will also be presented in the talk. Together, the results suggest that random excitation can be employed as a novel pathway towards controlling the emergence and dynamics of discrete breathers in nonlinear lattices.

SFI MaREI Centre, University College Dublin, Ireland

UCD Energy Institute, University College Dublin, Ireland

Summary. We consider a rotating Sinai Billiards system in this paper and consider a square wall boundary with a circular scatterer. We subsequently consider the effects of rotation on this system for a number of particles. The question of ergodicity is considered from the point of view of whether or not in long time the particle can explore the complete phase space. The system is numerically simulated and tested for a range of rotational speed, indicating non-ergodic responses.

Introduction

A two-dimensional billiard with reflective square boundary and a single circular disk obstacle at the center is considered in this paper. In absence of external force, a point mass in this standard classical Sinai billiard system would have straight line trajectory until it collides either with the outer wall or the inner wall. Upon elastic collision it will change the direction of the velocity in accordance with angle of incidence is equal to angle of reflection. In this paper, the billiard system is considered under rotating conditions without an external force. Subsequently, we intend to investigate how non-ergodicity is manifested in the system as a function of rotational speed and the radius of the disk at the centre, the two main parameters governing the outcome of the system.

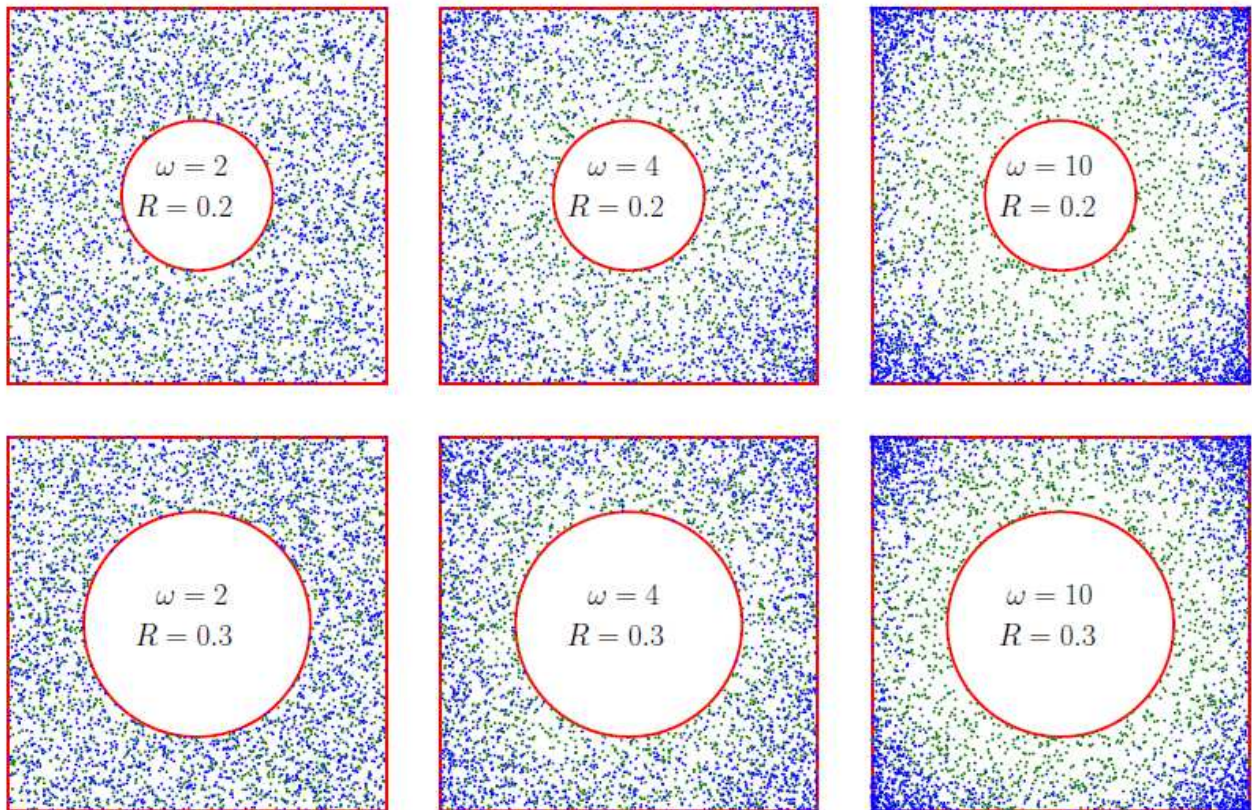

Fig.1. An ensemble of the initial and final positions of particles for different rotational speeds and disk radius. The green points indicate $N=2000$ initial positions of the mass point for N independent simulations. The blue points indicate their final positions after an equal amount of time has elapsed.

Results and discussions

Particle trajectories starting from different sets of initial conditions defined by position and velocity are simulated. The effect of increasing the rotational speed of the table for several cases of the radius of the circular disk on those trajectories are observed. For a certain set of rotational speed and radius of disk, 2000 initial conditions of location and velocity were considered drawing from uniformly distributed values between the inner and outer boundaries. After a sufficient time has elapsed ($t = 10$), the locations of the particles are noted for all of these independent runs, as observed in Fig 1.

From Fig.1, it is observed that as rotational speed increases, particles spend more time away from the disk and for high value of rotational speed the trajectories are trapped at the corners of the outer wall of the billiard making the system highly non-ergodic.

Summary. We explore the capabilities of feedback control to stabilise and manipulate propagating bubbles in the confined geometry of a rectangular Hele-Shaw channel. Several steadily-propagating solution branches exist in this system, but only one is linearly stable. Subsequent branches featuring increasingly deformed bubble shapes and increasing numbers of unstable eigenmodes. Our aim is to use feedback control and control-based continuation to detect and stabilise at least the first of these unstable branches. This system is an appealing prototype for control: the low Reynolds number and strongly confined geometry means the system state is essentially encapsulated in the interface shape as viewed from above, recent experimental realisations of this system are in good agreement with depth-averaged models, and the system responds well to actuation via fluid injection, but nonetheless practical implementation of feedback control presents significant challenges. Here we use a depth-averaged model to explore how control would work in this system, including the design of a suitable feedback gain, the impact of control on the bifurcation structure, the complexities of controlling a propagating bubble moving past a fixed array of injection points, and how our idealised simulations relates to experimental reality.

Introduction

The study of nonlinear dynamics in soft matter systems often leads to a myriad of steady states. Stable states can be studied via both experimental and computational methods but experimental investigations at best transiently observe unstable states. Control based continuation (CBC) is a methodology that applies feedback control to the physical system using a target state as the control parameter. By choosing an unstable state as the target state and carefully choosing a feedback strategy it is possible to detect and stabilize the unstable solution without otherwise modifying it. This methodology enables tracking of bifurcation structures as well as experimental investigations of unstable behaviour [1, 2, 3]. Our aim is to use the CBC to investigate free-surface problems in fluid dynamics, both to understand the rich range of dynamical behaviour and to widen the range of possible applications of CBC in the future.

We study the propagation of an air bubble through a fluid filled rectangular Hele-Shaw channel at low Reynolds number. This system is a classical problem in fluid dynamics with known rich dynamics, which we have previously explored both via a depth-averaged model and also via laboratory experiments [4]. For steady propagation, the bubble system supports one stable solution (figure 1(a)) and an infinite number of multi-tipped unstable solutions that assume an increasing number of interface tips and unstable eigenvalues (figure 1(b,c)). Our aim is to develop and test an experimentally viable protocol for the stabilization of unstable solutions, to detect and stabilise at least the first unstable solution branch.

Figure 1: Three steady modes for a bubble propagating from left to right in a Hele-Shaw channel, calculated using our model.

Model

We take advantage of the shallowness of Hele-Shaw channels by using a depth-averaged approximation of the system, thus avoiding the computational complexity of the full 3D problem for bubble propagation. The problem domain is then two-dimensional, with the interface shape corresponding to the top view seen in experiments. The numerical simulations are implemented in C++ using the open-source object-oriented multi-physics finite element library oomph-lib (www.oomph-lib.org).

Our model is inevitably an approximation of the full experimental system and does not capture all details of the bifurcation structure in the experiments. Nonetheless, the model is in good qualitative agreement with experiments and in quantitative agreement in appropriate regimes. As a result, we have reason to believe that control strategies developed using this model would be effective, though not optimal, if applied in experiments.

Control via moving or fixed actuators

In order to actuate control, we inject fluid from specific points at the side walls with time-dependent amplitude $\mathbf{A}(t)$. The system can be generically represented as $\mathbf{F}(\mathbf{x}, \dot{\mathbf{x}}, \mathbf{A}) = \mathbf{0}$ where $\mathbf{x}(t)$ is a vector that describes the system state (the current interface shape) and $\mathbf{A}(t)$ describes the injection amplitude. The simplest case to analyse is when actuator position is fixed within the frame of the bubble, so actuator action is steady as perceived by the bubble. For simplicity we use a linear feedback control strategy $\mathbf{A}(t) = -\mathbf{K}(\mathbf{x}(t) - \mathbf{x}_T)$ towards a target state \mathbf{x}_T . Various standard algorithms can be employed to choose a feedback gain \mathbf{K} that (linearly) stabilizes the resulting steady solution.

We test our control strategies in nonlinear time-dependent simulations of the depth-averaged model. Choosing the unstable solution of the uncontrolled system (figure 1(b)) as the target state \mathbf{x}_T , the stable solution (figure 1(a)) as the initial condition, and using a pair of actuators placed a distance $d = 1$ (half the channel width) in front of the bubble centroid, we can successfully control the system towards the target solution, see figure 2(a). The transition between states is rapid and the bubble moves only a short distance along the channel.

Figure 2: (a) Time evolution of a bubble, presented in the lab frame, starting with the stable solution as initial condition and evolving towards the unstable target solution. The actuator distance d is half of the channel width. The first and last interfaces are superposed with the stable and unstable solutions, in blue and red dashed lines respectively. (b) Eigenvalue plotted as a function of the actuator centre d . The steady state is successfully stabilized for values of d between d_{min} and d_{max} .

A more realistic setup actuator setup is via an array of injection points fixed in the lab frame. In the frame of the bubble, this introduces time dependence in the control problem as the distance d between actuator and bubble depends on time. However, each fixed \mathbf{K} has a window of d where the control is able to stabilize the equilibrium state (figure 2(b)). Hence by choosing actuator spacing within this range and switching the active actuators depending on the position of the bubble we are again able to stabilize bubbles in our simulations. Importantly for CBC, this piecewise constant \mathbf{K} means that a low-dimensional parameterization of the target state is still sufficient for feedback control.

Outlook for experiments

Our analysis and simulations of control based on a depth-averaged model suggest that an unstable state can be successfully controlled via injection of fluid chosen in real time based on top view observations of the bubble. Compared to simulations, experiments present several new challenges, including noise and delay. CBC can in principle address the inevitable differences between experiment and model, as the model would be used to devise an effective control strategy which need not be optimal. It remains to be seen how closely the bifurcation structure, solution shapes and stability properties for unstable states in experiments corresponds to those predicted by the simplified model used here. We are currently developing an experimental setup to test and implement these control strategies in practice and will present experimental results for either static or moving bubbles if possible.

Summary. We present a reset control approach to achieve setpoint regulation of a PID-based motion system subject to Coulomb and velocity-dependent friction, including the velocity-weakening (Stribeck) effect. While classical PID control results in persistent oscillations around the setpoint (hunting), the proposed reset mechanism ensures asymptotic stability. Robustness for unknown static friction levels, and an unknown Stribeck contribution is obtained. The working principle of the controller is demonstrated experimentally on a motion stage of an electron microscope, showing superior performance over classical PID control.

Introduction

We present a reset integral control approach for stabilization of motion systems with unknown Coulomb and Stribeck friction. Friction is a performance-limiting factor in many high-precision motion systems, in the sense that it limits the achievable positioning accuracy and the settling times. Many different control techniques for frictional motion systems have been presented in the literature. Several control solutions rely on developing as-accurate-as-possible friction models, used for online compensation in a control loop, see, e.g., [1]. Also non-model-based solutions have been proposed, e.g., impulsive control (see [2]) or sliding-mode control.

Despite the availability of a wide range of control techniques for frictional systems, linear controllers are still used in the vast majority of industrial motion systems due to the existence of intuitive design and tuning tools. In the industry, the classical proportional-integral-derivative (PID) controller is most commonly used for motion systems with friction. In particular, the integrator action is capable of compensating the unknown static friction, due to the the control force increment arising from integrating the position error. However, PID control does not generally achieve stability in the presence of Stribeck friction, resulting in poor positioning accuracy. While the integrator action compensates for the static part of the friction, friction overcompensation occurs as the velocity increases due to the velocity-weakening effect. As a result, the system overshoots the setpoint and ends up in stick-slip oscillations (*hunting*). In order to eliminate these persistent oscillations, we propose a reset integral controller that induces asymptotic stability of the setpoint, despite the presence of *unknown* static friction, and an *unknown* velocity-weakening effect in the friction characteristic.

Reset controller design

Consider a single-degree-of-freedom mass m sliding on a horizontal plane with position z_1 and velocity z_2 , subject to a control (force) input u and a friction force belonging to a set $\Psi(z_2)$, governed by the dynamics

$$\dot{z}_1 = z_2, \quad \dot{z}_2 \in \frac{1}{m} (\Psi(z_2) + u), \quad z_2 \rightrightarrows \Psi(z_2) := -F_s \text{Sign}(z_2) - \alpha z_2 + f(z_2), \quad (1)$$

where F_s is the static friction, $\text{Sign}(\cdot)$ is the set-valued sign function (i.e., with $\text{Sign}(0) := [-1, 1]$), αz_2 the viscous friction contribution (where $\alpha \geq 0$ is the viscous friction coefficient), and f is a nonlinear velocity-dependent friction contribution, encompassing the Stribeck effect. Define the setpoint $(z_1, z_2) = (r, 0)$ for any constant position reference r . Let us first present a *classical* PID controller for input u in (1), i.e.,

$$u = -k_p(z_1 - r) - k_d z_2 - k_i z_3, \quad \dot{z}_3 = z_1 - r, \quad (2)$$

where z_3 is the integral state of the PID controller, and k_p, k_d, k_i represent the proportional, derivative and integral gains, respectively, satisfying $k_p > 0$, $k_i > 0$, and $k_p k_d > m k_i$. Finally, we embrace the (mild) assumption that the friction characteristic satisfies $|f(z_2)| \leq F_s$ for all z_2 , that $z_2 f(z_2) \geq 0$ for all z_2 , that f is globally Lipschitz with Lipschitz constant $L > 0$, and that, for some (potentially arbitrarily small) $\varepsilon_v > 0$ and $L_2 \in (k_d + \alpha, L]$, $f(z_2) = L_2 z_2$ for all $|z_2| \leq \varepsilon_v$.

In order to achieve closed-loop stability, we enhance the integrator in (2) with *resets*. The integrator performs two particular resets, where the key mechanism of these resets is to enforce that the integrator control force (given by $k_i z_3$) *always points in the direction of the setpoint*. To this end, we introduce a boolean state $b \in \{-1, 1\}$, characterizing whether the mass moves *towards* the setpoint (then $b = 1$), or *away from* the setpoint (then $b = -1$, typically after an overshoot of the position error). Then, the inequality $b z_2 (z_1 - r) \leq 0$ is always satisfied. The first reset that we propose entails a sign change of the integrator state z_3 at a zero-crossing of the position error $z_1 - r$. We also toggle b at this instant, because a zero-crossing of the position error marks the start of an overshoot phase, i.e.,

$$z_3^+ = -z_3, \quad b^+ = -b, \quad \text{when } z_1 - r = 0 \text{ and } b = 1, \quad (3)$$

Figure 1: Experimental setup.

Figure 2: Position error response and experimental control force with the classical PID (red), and the reset PID (blue).

where the notation “ x^+ ” represents the value of the considered state x after an instantaneous change, i.e., the controller reset. Besides recovering stability of the setpoint, the reset in (3) results also in some overshoot reduction. The second reset involves resetting to zero the integrator state z_3 when the velocity z_2 hits zero *after the overshoot*, i.e.,

$$z_3^+ = 0, \quad b^+ = -b, \quad \text{when } z_2 = 0 \text{ and } b = -1. \quad (4)$$

The reset in (4) also results in a reduction of the duration of the stick phases occurring when the mass stops after the overshoot. Summarizing, the closed-loop system with the proposed reset PID controller is given by (1)-(4).

Closed-loop stability is analyzed as follows. First, we write the closed-loop system in the hybrid systems framework of [3], where we use a *hybrid* description of the Coulomb friction element in (1), as presented in [4]. We then prove that solutions to the closed-loop system (1)-(4) are also contained in said hybrid model. We then exploit the hybrid model to show that (under the aforementioned mild assumptions on the controller gains and friction characteristics) the setpoint is globally asymptotically stable, using a Lyapunov function and a recent hybrid invariance principle [5].

Experimental case study

We demonstrate the working principle and the effectiveness of the proposed reset controller on an industrial motion platform (a sample manipulation stage of an electron microscope), see Figure 1. A servo motor is connected via a spindle and a nut to a carriage, whose position is measured by a linear encoder. The goal is to position the carriage within a desired accuracy band of 10 nm. The main sources of friction are two bearings supporting the motor axis, and the contact between the spindle and the nut. We have implemented both the classical PID controller, and the proposed reset PID controller (with the same gains). For the latter one, we have designed suitable robustified conditions capable of triggering the controller resets (3), (4) also in the presence of measurement noise. Figure 2 shows the position error response and the control force for an experiment with the *classical* PID controller (red), and with the proposed *reset* PID controller (blue). The classical PID controller induces a persistent oscillation, limiting the achievable setpoint accuracy. For the reset controller experiment, the reset enhancements are activated at the time instant indicated by the blue vertical dashed line (up to this time instant, a classical PID controller is active). Then, the challenging desired accuracy band of 10 nm, indicated by the horizontal black dotted lines in the top subplot, is achieved after two controller resets. The corresponding control force is discontinuous due to the controller resets, visualized in the lower subplot and highlighted in the inset.

Conclusions

We proposed a reset PID control strategy for motion systems with unknown Coulomb and velocity-dependent friction, including the Stribeck effect. Our reset strategy recovers global asymptotic stability of the setpoint (lost by the hunting effect associated to the classical PID). The working principle and effectiveness of the controller are experimentally demonstrated on an industrial high-precision positioning device.

Summary. This work proposes some iterative procedures for estimating additive measurement biases in multi-agent non-linear systems. The bias is a constant additive offset in the relative measurement of states between agents. In contrast to existing literature which estimate biases asymptotically or does adaptive control to remove the impact of bias, we provide an iterative procedure that estimates the bias in a finite number of steps in the noiseless case.

Introduction

The multi-agent formalism enables treating problems that arise in many application domains such as engineering [3], sociology [5] or biology [9]. Consensus and synchronization were mainly studied for agents with linear dynamics interacting through a graph, see [6] for instance. However, there are also studies with nonlinear dynamics, see for example [8] which considers oscillators dynamics, or [3] on non-holonomic robots. However, the effect of measurement biases have not been well explored in this context. In [11], the authors develop an adaptive control to correct biases in a double integrator but it is not clear how this method can be adapted to general non-linear systems. In [2] and [7], the authors proposed algorithms to estimate sensor offsets in wireless sensor networks. These methods only partially compensate the offsets and never completely eliminate the bias. Recently, in [10], the authors propose a distributed bias removal strategy using a consensus type algorithm, however, the convergence of the estimate to the true bias is asymptotic.

Our main contribution is to provide a method of bias *removal in finite time* when dealing with nonlinear multi-agent systems subject to constant bias measurements. The method proposed here requires a limited number of communication instances and can be implemented either in a centralized manner through *cloud computing* or in a decentralized manner as long as *two interacting agents can measure the same reference point*.

Problem formulation: We consider a network of n interacting agents, where the interactions are described by a graph $G = (V, E)$. Each agent $i \in V$ is described by a state $x_i \in \mathbb{R}^{n_x}$. $\mathcal{N}_i = \{j \in V \mid (i, j) \in E\}$ specifies the neighborhood of agent i and represents the set of neighbors whose relative states can be measured by i . However, the measurements made by any agent i have a constant additive bias b_i which must be removed in order to accomplish the overall common goal. For any $j \in \mathcal{N}_i$, agent i has access to the measurement $z_{i,j}(t) = x_j(t) - x_i(t) + b_i$ and implements a distributed control $g(z_i)$ in order to achieve a cooperative task.

The agent dynamics is given by

$$x_i(t+1) = f_i(x_i(t), g(z_{i,j})). \quad (1)$$

We assume that the above algorithm performs well when the additive bias is 0. However, the presence of the additive bias leads to significant deterioration in performance and this must be corrected by taking $\bar{z}_{i,j} = z_{i,j} - \hat{b}_i(t)$, with $\hat{b}_i(t)$ assumed to be an estimate of the bias. Our objective is to estimate b_i for all i in finite time, using communication with a cloud or only among neighboring agents when a reference can be measured.

MAIN RESULTS

Estimating the additive biases without communication with neighbors is not possible since all the measurements have the same bias and this parameter can not be removed. In the following, we provide the assumptions on communication and on the graph structure so that bias can be estimated in a finite number of steps . .

Bias removal for non-bipartite connected graphs

Assumption 1 *We look at connected, undirected and non-bipartite graphs and assume that all agents can identify the tag of their neighbors and themselves.*

We use L^+ to denote the sign-less Laplacian which can be defined as having $L_{ij}^+ = 1$ when $j \in N_i$, $L_{ii}^+ = |N_i|$ if $i = j$ and 0 otherwise.

Lemma 1 ([4]) *The matrix L^+ is invertible when the graph is non-bipartite.*

We assume that all agents can communicate with the cloud which will then process all the information it has to estimate the bias. In the proposed procedure, all agents i will measure $z_{i,j}(0)$ for all its neighbors j and communicate this information to the cloud (synchronously or asynchronously). Once all agents have communicated their measurements to the cloud, it can use the following result to estimate all their biases.

*This work was partially funded by CEFIPRA under the grant 6001-A

Proposition 1 Under Assumption 1, the cloud can estimate the bias for all agents as $\hat{b} = (L^+)^{-1}\delta$ where

$$\delta_i = \sum_{j \in N_i} z_{i,j} + z_{j,i}. \quad (2)$$

From [1], we know that all non-bipartite graphs contain an odd-ring as a sub-graph. So the above procedure can work as long as the graph contains an odd-ring. In the absence of a cloud/central entity, the following distributed procedure may be used.

Remark 1 When there is no central-cloud, if all agents have sufficient memory and can communicate with their neighbors, then all agents can estimate their bias in N steps. At each step all agents will communicate all the new information they have collected in the last step allowing them to aggregate all the information required to apply proposition 1.

Distributed bias estimation with a reference

Assumption 2 The graph is connected and there exist at least two neighboring agents i, j who can measure a common reference r .

We use $z_{i,r}$ to denote the relative measurement of the reference with respect to agent i . In this case, we propose a distributed procedure for bias estimation in finite time. First, all agents i communicate $z_{i,j}(0)$ and $z_{i,r}(0)$ (if the reference can be measured by i) to all its neighbors.

Proposition 2 Under Assumption 2, at least one agent i will be able to estimate

$$\hat{b}_i = z_{i,r}(0) - (z_{j,r}(0) - z_{j,i}(0)). \quad (3)$$

after it receives communication from its neighbor j which can also measure the reference.

We propose the following distributed procedure for bias estimation in finite steps (at most N) for the remaining agents. The algorithm applied by any agent i can be described as follows.

Data: At time 0, measure and communicate $z_{i,j}(0)$ and $z_{i,r}(0)$ (if available) to all neighbors j .

if $z_{j,r}(0)$ and $z_{i,r}(0)$ are known after receiving communication from neighbor j **then**

 estimate \hat{b}_i using proposition 2.

else

$d_{i,j} \leftarrow z_{i,j}(0) + z_{j,i}(0)$

end

while \hat{b}_i is not estimated **do**

 Wait for transmissions ;

if some neighbor j transmits \hat{b}_j **then**

 Estimate $\hat{b}_i \leftarrow d_{i,j} - \hat{b}_j$

end

end

Transmit \hat{b}_i to all neighbors.

Algorithm 1: Procedure of bias estimation

Since the graph is connected due to Assumption 2, the iterative procedure described above will have all agents estimating their own biases within N steps at most.

Summary. This work focuses on the design of a control strategy for consensus of fleets of nonholonomic robots in presence of noisy measurements. The proposed strategy leads to a hybrid behaviour of the closed-loop dynamics of each robot. Precisely, the robots sporadically compute references that are kept constant until the next update. Between two updates of the reference the robots will apply a tracking controller allowing them to approach exponentially fast their targets. The main contributions are related to both the control design and the analysis of the resulting hybrid closed-loop dynamics. Simulations and real experiments will be presented at ENOC.

Introduction

During the last decades the design of control laws for nonholonomic robots received a lot of attention. This is mainly due to the fact that Brockett conditions [2] required for smooth stabilisation do not hold for this class of dynamics. To overcome the fact that smooth state-feedback controllers stabilizing the position and orientation of the robot do not exist, different discontinuous control laws have been proposed [5, 1]. We also point out that a control design for tracking a smooth trajectory has been also proposed for nonholonomic robots [4]. It is noteworthy that, all these strategies consider a stand-alone robot that is continuously controlled. *Our objective is to control a fleet of nonholonomic robots in a decentralized manner and in a harsh environment hampering continuous communications between robots.*

The main contribution of our work is twofold: first, the design of a hybrid control strategy for consensus of nonholonomic robots and second, the stability analysis of the closed-loop system providing minimum dwell-time conditions guaranteeing the overall system stability. As shown in the Figure 1 below, our strategy contains two loops. The external loop takes place in discrete time and uses local information related to neighbouring robots state in order to sporadically compute references of the robots. The internal loop takes place in continuous time, does not require communication with (or information from) other robots and uses a standard tracking (or point stabilization) controller such as the one proposed in [4].

Figure 1: Control structure

Problem formulation

We consider a fleet of n nonholonomic robots that have to reach a consensus in the positions without requiring specific final orientation of the agents. For the sake of simplicity we remove the time argument t when it is not explicitly needed. We denote by $r_i = (r_{x_i}, r_{y_i})$ the 2D reference position for the robot i and we fix $r_{\theta_i} = 0$ its heading reference. The Cartesian coordinates of the center of mass of each vehicle with respect to the fixed inertial frame are denoted using vector $X_i = (x_i, y_i)$. Denoting $e_i = (e_{x_i}, e_{y_i}, e_{\theta_i})^\top$ the dynamics of the i^{th} robot is described by the following differential equations

$$\dot{e}_i = g(e_i)u_i, \quad g(e_i) = \begin{bmatrix} \cos e_{\theta_i} & 0 \\ \sin e_{\theta_i} & 0 \\ 0 & 1 \end{bmatrix}, \quad u_i = \begin{bmatrix} v_i \\ \omega_i \end{bmatrix}. \quad (1)$$

where v_i is the linear velocity and ω_i is the angular velocity of the mobile robot; e_{x_i} and e_{y_i} are the Cartesian coordinates of the center of mass of the vehicle with respect to a frame positioned on the reference position r_i , and e_{θ_i} is the angle between the heading direction and the x -axis of this frame.

The point stabilization control considered in this work is the continuous piecewise smooth control law introduced in [3]. Basically, one considers a map $F : \mathbb{R}^3 \mapsto \mathbb{R} \times (-\pi, \pi]$ relating $e_i \in \mathbb{R}^3$ to $z_i = (a_i, \alpha_i)^\top \in \mathbb{R} \times (-\pi, \pi]$. Taking $K, \gamma > 0$ the control law $u_i = \kappa(e_i) = (-\gamma b_1(e_i)a, -b_2(e_i)v - Ka)^\top$, where b_1, b_2 are explicitly defined in [3], exponentially stabilizes the origin of the planning reference frame $e_i = 0$. In the following, we denote $\varepsilon_i = (e_{x_i}, e_{y_i})$ the 2D Cartesian error coordinates *i.e.* $\varepsilon_i = X_i - r_i$.

Lemma 1 *Let us consider the closed loop dynamics $\dot{e}_i = g(e_i)\kappa(e_i)$ with $\kappa(e_i)$ defined above. Then, there exist positive constants c_ε and λ_ε such that $\forall t \geq t_0$ one has $\|\varepsilon_i(t)\|_\infty \leq \sqrt{n}c_\varepsilon \|\varepsilon_i(t_0)\|_\infty e^{-\lambda_\varepsilon(t-t_0)}$, $\forall i \in \{1, \dots, n\}$.*

*This work was partially funded by the Région Grand Est and CEA Tech Metz

As we previously said, the external loop designs references for each robot based on the sensing of relative positions of some neighbouring robots. These "interactions" are mathematically captured by a time-varying digraph (directed graph) $\mathcal{G}(t) = (\mathcal{V}, \mathcal{E}(t))$, where the vertex-set \mathcal{V} represents the set of robots and the edge set $\mathcal{E}(t) \subset \mathcal{V} \times \mathcal{V}$ collects the interactions between robots at time t . A *path of length p* in a digraph $\bar{\mathcal{G}} = (\bar{\mathcal{V}}, \bar{\mathcal{E}})$ is a union of directed edges $\bigcup_{k=1}^p (i_k, j_k)$ such that $i_{k+1} = j_k, \forall k \in \{1, \dots, p-1\}$. The node j is *connected* with node i in $\bar{\mathcal{G}} = (\bar{\mathcal{V}}, \bar{\mathcal{E}})$ if there exists at least a path in $\bar{\mathcal{G}}$ from i to j (i.e. $i_1 = i$ and $j_p = j$). A *strongly connected digraph* is such that any of its two distinct elements are connected. In the sequel we consider the set of instants when at least one robot updates its reference as $\mathcal{T} = \{t_k : t_k \in \mathbb{R}^+, t_k < t_{k+1}, \forall k \in \mathbb{N}, \lim_{k \rightarrow \infty} t_k = \infty\}$. Moreover, we define $\mathcal{T}_i \subset \mathcal{T}$ selecting the instants when robot i updates its reference (i.e. $\mathcal{T} = \bigcup_{i=1}^n \mathcal{T}_i$). At each instant $t_k \in \mathcal{T}$ a graph structure $\mathcal{G}(t_k) = (\mathcal{V}, \mathcal{E}(t_k))$ defines the interactions between neighbours. Let $\alpha \in (0, 1)$, $\beta \in (1/2, 1)$ be given. To each graph structure $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ we uniquely associate a row stochastic matrix P satisfying the following properties: $P_{i,j} = 0$, if $(i, j) \notin \mathcal{E}$, $P_{i,i} > \beta$, $\forall i = \{1, \dots, n\}$, $P_{i,j} > \alpha$, if $(i, j) \in \mathcal{E}$.

Assumption 1 (Connectivity) The digraph $\mathcal{G} = \bigcup_{k \geq k_0} \mathcal{G}(t_k)$ is strongly connected for all $k_0 \in \mathbb{N}$.

Assumption 2 (Bounded Intercommunication Interval) If $(i, j) \in \mathcal{E}(t_k)$ infinitely often, then there is some $L \in \mathbb{N}$ such that, for all $t_k \in \mathcal{T}$, $(i, j) \in \mathcal{E}(t_k) \cup \mathcal{E}(t_{k+1}) \cup \dots \cup \mathcal{E}(t_{k+L-1})$.

Main results

The closed-loop hybrid dynamics associated with the i -th robot ($i \in \{1, \dots, n\}$) can be formulated as:

$$\begin{cases} \dot{r}_i(t) = 0, & \dot{e}_i(t) = g(e_i(t))\kappa(e_i(t)) \quad \text{for } t \in \mathbb{R}^+ \setminus \mathcal{T}_i, \\ r_i(t_k) = \sum_{j=1}^n P_{i,j}(t_k) \varepsilon_j(t_k^-) + \sum_{j=1}^n P_{i,j}(t_k) r_j(t_k^-) + \delta_i(t_k), & \varepsilon_i(t_k) = \varepsilon_i(t_k^-) + r_i(t_k^-) - r_i(t_k) + \delta_i(t_k) \text{ for } t_k \in \mathcal{T}_i, \end{cases}$$

where $\delta_i(t_k)$ represents the measurement bias whose infinity norm is upper-bounded by $\bar{\delta} \in \mathbb{R}^+$. Our main objective is to analyse the ISS property of the overall dynamics of n robots defined above w.r.t the following set:

$$\mathcal{A} = \left\{ \varepsilon, r \in \mathbb{R}^{2n} \mid \varepsilon = 0, r_{x_i} = r_{x_i}, r_{y_i} = r_{y_i}, \forall i, j \in \{1, \dots, n\} \right\}.$$

Theorem 1 Let Assumptions 1-2 hold. Then the overall dynamics of n systems defined above is ISS w.r.t. the set \mathcal{A} , if the time between any two consecutive updates of the reference for each robot is larger than τ^* with

$$\tau^* = \frac{1}{\lambda} \ln \max \left\{ \frac{\eta_2 c N}{1 - \eta_1} \sum_{l=0}^{2L-1} a^{\frac{2L-1-l}{2L-1}}, \frac{c(\eta_3(N-1)+1)}{(1 - n(2L-1)\eta_3)a} \sum_{l=0}^{L-1} a^{\frac{2L-1-l}{2L-1}} \right\} > 0,$$

with $\eta_1 = 1 - \alpha^L$, $\eta_2 = 4 - 2\alpha$, $\eta_3 = 1 - \beta$ and $a = \frac{1+\eta_1}{2}$.

Remark 1 • We note that theorem above does not fix the update instants but only provide a minimum dwell-time between updates of the reference of the same robot. Consequently, very frequent updates are forbidden.

- When $\bar{\delta} = 0$ (i.e. the sensors provide perfect measurements) the theorem above states that \mathcal{A} is GUAS for the overall closed-loop dynamics of n nonholonomic robots.

Conclusions

This work formulates a decentralized control strategy for fleets of nonholonomic robots with biased measurements. The control is designed as follows. In a first step, at sporadic time-instants the robots compute a reference based on measurements of relative positions of some neighbours. In a second step, the robots continuously apply a state-feedback tracking controller. This yields a hybrid behaviour of the closed-loop dynamics. We show that consensus can be achieved as far as a certain minimum dwell-time condition between the reference updates of each robot is respected. Simulations and real experiments will be presented at ENOC.

Summary. In this paper, nonlinear vibration control of a plate is investigated using Nonlinear Modified Positive Position Feedback (NMPPF) method that is applied through a piezoelectric layer on the plate. NMPPF controller consists of a resonant second-order nonlinear compensator for vibration suppression at targeted resonance. In this model, transverse vibrations are studied and stimulations are performed for the primary resonance. Using time-space separation of the differential equations of the model and Galerkin method the temporal nonlinear equations governing the system have been found. Then, the free and forced vibrations of the structure with the NMPPF controller has been solved using Method of Multiple Scales to obtain an analytical solution. Results show that the NMPPF controller reduces the amplitude of the vibration by inducing an increase to the damping coefficient. In addition, the NMPPF controller provides a higher level of suppression in the overall frequency domain response by increasing the compensator gain. Finally, the results of the analytical solution for the closed-loop NMPPF controller are presented and compared with the result of the conventional Positive Position Feedback (PPF) controller and nonlinear integral resonant controller (NIRC).

Introduction

Controllers are one of the most effective ways to control linear and nonlinear vibrations. Hence, different control strategies have been presented and utilized [1]. One of the methods for nonlinear vibration control is to use of active control. The advantage of using active control is its real-time adjustment according to the condition of the system and alternations in the input disturbance force on the system. In order to have the highest level of suppression in the vibration control process, it is essential to design a controller compatible with the nonlinear characteristics of the system oscillations. Linear and nonlinear active vibration controllers typically employ piezoelectric actuators. Active vibration control is usually applied using piezoelectric ceramics as actuators and sensors, as an example, piezoelectric actuators are used in Atomic Force Microscopes to produce high-frequency vibrations. The purpose of this paper is to obtain the equations of nonlinear vibrations and controller system for elastic plate with a piezoelectric layer that follows the classical theory of Kirchhoff. In addition, Van Karman's nonlinear strains have been used to investigate geometrical nonlinear effects. This plate has a piezoelectric layer at its upper surface. This layer actually is utilized to actively suppress the vibrations of the plate. The external force applied to the piezoelectric layer is divided into two groups: 1) the control force ($F_c(t)$), the control force via the controller's compensator will be logged; and 2) the harmonic excitation force distributed uniformly on the plate as the disturbance. The constitutive equations for piezoelectric layer is utilized to implement the effect of applied voltage into the electromechanical model. Method of Multiple Scales is utilized for calculation of the frequency response of the system and the controller. The resulting modulation equations are, then, used to verify the effectiveness of the proposed controller. Having the solution for the controllers, results are graphically demonstrated and discussed. In order to understand the performance of the controllers in more detail, sensitivity analysis on the closed loop system responses is performed and the influence of each parameter on the control output have been investigated.

MATHEMATICAL MODELING OF THE STRUCTURE

In this section, the nonlinear dynamic model of the structure is investigated. The structure is composed of two layers of square plates, a substructure layer and a piezoelectric layer with the different thickness on top of the substructure, as shown in Fig. 1. It is assumed that the h_p and h_s are thicknesses of the piezoelectric layer and substructure, respectively. Also, as shown in Fig. 1, a is the side length of the plate. The origin of the coordinate system is placed on the corner of the middle plane of the substructure layer. The boundary conditions of the plate are considered as simply support and u , v and w are the displacement of the plate in the x , y and z directions respectively.

Figure 1. The symmetric unimorph piezoelectric plate.

Using Hamilton's principle, equations of motion of the plate based on classical theory and von Karman strain and then applying Galerkin method for simply supported B. C. in all edge of plate, nonlinear temporal equations can be expressed as:

$$\ddot{W}(t) + \omega_w^2 W(t) + \tilde{\alpha} W^3(t) + \tilde{\eta}_w \dot{W}(t) = \tilde{F} \cos(\tilde{\Omega} t) \quad (1)$$

The control force, $F_c(t)$, will be added to the equation. Also, ω_w^2 consists of two parts of the natural frequency created in the sheet with the piezoelectric layer and a coefficient of the voltage created from the piezoelectric layer to the elastic

layer. The equation is created for the natural frequency of $\omega_w^2 = \omega^2 + s_1 V_e$ where s_1 is the constant coefficient of the voltage applied to the plate. The method of Multiple Time Scales is used to find a uniform nonlinear structure. The nonlinear system of Equation (1) under NMPPF controllers are defined as follows

$$\bar{F}(t) + \tilde{\eta}_r \bar{r}(t) + \omega_r^2 \bar{r}(t) + \tilde{\delta} \bar{r}^3(t) = \tilde{k}_r U(t) \quad (2)$$

$$\bar{s}(t) + \omega_s \bar{s}(t) = \tilde{k}_s U(t)$$

where $\bar{r}(t)$ and $\bar{s}(t)$ are compensatory first and second order state variables, respectively. k_r and k_s are the inputs of the control. The control law pertains to the modified positive position feedback controls system in the main system of Equation (1) as $F_c(t) = \tau_r r(t) + \tau_s s(t)$; that are τ_r and τ_s respectively, are first order compensator and second in a closed loop system. Using Multiple time scale method, the coupled equations obtained for the frequency are the response of the main system and the controller domain.

$$\left(\frac{\hat{f}}{2}\right)^2 = \left[\left(\frac{\hat{\eta}_u}{2} + \frac{\hat{\tau}_s \hat{k}_s}{2}\right)a + \frac{\hat{\tau}_r \hat{\eta}_r b^2}{2\hat{k}_r a}\right]^2 + \left[\frac{3\hat{\alpha}}{8}a^3 + \frac{\hat{\tau}_s \hat{k}_s}{2}a - \frac{3\hat{\delta} \hat{\tau}_r b^4}{8\hat{k}_r a} - \frac{\hat{\tau}_r}{\hat{k}_r}(\sigma_r - \sigma_f)\frac{b^2}{a} - \sigma_f a\right]^2 \quad (3)$$

$$\left[1 - \frac{\hat{\eta}_r^2 b^2}{\hat{k}_r^2 a^2}\right]^{\frac{1}{2}} = \frac{3\hat{\delta} b^3}{4\hat{k}_r a} + \frac{2}{\hat{k}_r}(\sigma_r - \sigma_f)\frac{b}{a}. \quad (4)$$

Results and discussions

This part has discussed the vibration range in the resonant frequency region and the performance of the controllers in controlling the vibration amplitude in the resonance region. The frequency response of main system is given in Fig. 2. Fig. 3 indicates the frequency response of the closed loop system with the PPF controller. Implementation of PPF controller reduces vibration range in the resonant frequency region ($\sigma_f = 0$). This controller amplifies the production of two-peak amplitudes with relatively large amplitude around the frequency. Fig. 4 shows the frequency response of NMPPF controlled systems. In this Fig., the right peak has higher amplitude. Also, Fig. 5, shows the comparison of the effects of these nonlinear controllers on the frequency response of smart plate.

Fig 2. Frequency response of the uncontrolled system

Fig 3. Frequency response of the PPF controlled

Fig 4. Frequency response of the NMPPF controlled system

Fig 1. Comparison of the PPF, NIRC, and NMPPF controller performances

Conclusion

In this article, active nonlinear vibrations control of a simply supported smart plate using the NMPPF controller introduced. The system response also studied under NIRC and PPF control approaches. It is shown that the PPF controller had a weaker control effect than the other two controllers. Also, the NMPPF controller reduced the vibration amplitude on a large bandwidth in the frequency domain better than the other two methods.

Strongly Nonlinear Forced Damped Model for the Dynamics of the Valve Spring

Majdi Gzal and Oleg V. Gendelman

Faculty of Mechanical Engineering, Technion – Israel Institute of Technology, Haifa, Israel

Summary. The preloaded valve spring of an internal combustion engine is mathematically modeled as a one-dimensional finite non-homogenous forced-damped chain using the Hertzian contact law, and its strongly nonlinear dynamics is analytically studied. An approximated analytical single-frequency solution in the form of time-periodic and spatially localized state is derived. The theoretical results are confirmed by numerical simulations as well as experimental test results. This indicates that the strongly nonlinear chain allows a single-frequency approximate solution.

Introduction

The interplay between nonlinearity and discreteness supports time-periodic and spatially localized solutions, which are commonly referred to as discrete breathers (DBs) [1]. Exact solutions for symmetric discrete breathers were derived for the Hamiltonian model [2] and for the case of a homogenous external forcing with restitution coefficient less than unity [3]. Recently, we developed a discrete nonhomogeneous model for the nonlinear dynamics of the valve spring [4]. This model revealed two qualitatively different states of the periodic responses; we referred to them as propagating states and edge states. The propagating states are characterized by weak localization, and the edge states—by strong localization at the forced edge. To meet more realistic conditions of the valve train, in this study, we extend our previous model in two ways. First, using the Hertzian contact law to describe all the valve-valve seat interactions in each period of excitation. Second, we include the preload effect. This implies that in our model, both the precompression and the non-smooth behavior caused by the separation exist.

Model description and analytical treatment

Following our previous paper [4], the valve spring is mathematically described as a one-dimensional finite non-homogenous chain, as illustrated in Figure 1. The model includes a heavy mass, denoted by M , which represents the valve mass together with the mass of the upper element of the spring, and N light masses, each with mass m , i.e. the mass of one spring element. The masses are interconnected in series by linear springs and dampers, denoted by k and λ , respectively, resulting to total spring stiffness of k/N and total internal damping of the spring material of λ/N . In realistic settings of the valve train, the valve spring is preloaded by a static load of kd_0/N , resulting to total preload displacement of d_0 (as shown in Figure 1, middle). Then, the preloaded valve spring is closed by a rigid wall in such a way that the heavy mass interacts with the wall, as illustrated in Figure 1, right. We assume that this interaction is given by Hertzian contact law. This constraint on the displacement of the heavy mass represents the interaction between the valve and valve seat. Regarding the boundary conditions, the N th light mass is fixed while the heavy mass is subjected to an external displacement $h(t)$, which represents the cam lobe profile, through a flexible connection called tappet, modeled by the spring k_c and damper λ_c .

Figure 1: A mathematical model for the valve spring dynamics: free spring (left), preloaded spring in the static state (middle) and the forced spring with the contact constraint (right)

Let u_n denotes the dynamic displacement (relative to the preloaded state) of the n th mass. Thus, the equations of motion for the forced valve spring (Figure 1, right) are given as follows:

$$\begin{aligned}
 n = 0: \quad & M\ddot{u}_0 + \lambda(\dot{u}_0 - \dot{u}_1) + k(u_0 - u_1) + \lambda_c \dot{u}_0 + k_c u_0 = \alpha [\Delta - u_0]_+^{3/2} - \frac{kd_0}{N} + \\
 & + k_c a_0 + [k_c a + \lambda_c \Omega b] \cos(\Omega t) + [k_c b - \lambda_c \Omega a] \sin(\Omega t) \\
 1 \leq n < N-1: \quad & m\ddot{u}_n + \lambda(2\dot{u}_n - \dot{u}_{n-1} - \dot{u}_{n+1}) + k(2u_n - u_{n-1} - u_{n+1}) = 0 \\
 n = N: \quad & u_N = 0
 \end{aligned} \tag{1}$$

Here in (1), the parameter Δ represents the equilibrium displacement induced by the preload force kd_0 / N , resulting to $\Delta = (kd_0 / \alpha N)^{2/3}$, α is a material parameter (depending on the elastic properties and the geometric characteristics of the heavy mass and the wall). The $(+)$ subscript is used to emphasize that the bracketed term is non-zero only if the term inside the bracket is positive and zero otherwise. The parameter Ω describes the frequency of the applied excitation, which was assumed to be given by the first harmonic approximation $h(t) = a_0 + a \cos(\Omega t) + b \sin(\Omega t)$. We assume that the response of each oscillator has a dominant harmonic component with the frequency equal to the frequency of the applied excitation, then, the following single-frequency solution is introduced:

$$u_n = U_0 \left(1 - \frac{n}{N}\right) + C_n \cos(\Omega t) + S_n \sin(\Omega t) \quad (2)$$

Introducing the suggested solution (2) into (1) and expanding the non-smooth term into Fourier series to obtain static and dynamic components as follows:

$$\left[\Delta - U_0 - C_0 \cos(\Omega t) - S_0 \sin(\Omega t)\right]_+^{3/2} = \beta_0 + \sum_{r=1}^{\infty} \beta_r \cos(r\Omega t) + \sum_{r=1}^{\infty} \gamma_r \sin(r\Omega t) \quad (3)$$

For the first harmonics, one obtains:

$$\begin{aligned} \beta_0 &= \frac{\sqrt{2}A^{3/2}}{3\pi} \left[(3\sigma^2 - 4\sigma + 1) \mathbf{K}(\bar{\sigma}) + 8\sigma \mathbf{E}(\bar{\sigma}) \right] \\ \beta_1 &= \frac{2\sqrt{2}A^{3/2} \cos(\phi)}{5\pi} \left[(-\sigma^2 + 4\sigma - 3) \mathbf{K}(\bar{\sigma}) + 2(\sigma^2 + 3) \mathbf{E}(\bar{\sigma}) \right] \\ \gamma_1 &= -\frac{2\sqrt{2}A^{3/2} \sin(\phi)}{5\pi} \left[(-\sigma^2 + 4\sigma - 3) \mathbf{K}(\bar{\sigma}) + 2(\sigma^2 + 3) \mathbf{E}(\bar{\sigma}) \right] \end{aligned} \quad (4)$$

Here we denote $\bar{\sigma} = \sqrt{2\sigma + 2} / 2$, $\sigma = (\Delta - U_0) / A$, $\phi = \arctan(-S_0 / C_0)$, $A = -\sqrt{C_0^2 + S_0^2}$, $\mathbf{K}(\bar{\sigma})$ represents the complete elliptic integral of the first kind, and $\mathbf{E}(\bar{\sigma})$ is the complete elliptical integral of the second kind.

Substituting equations (2), (3) and (4) into (1) and applying the harmonic balance method, one obtains a set of $(2N + 3)$ nonlinear algebraic equations in the unknowns U_0 , C_n and S_n , $n = 0, 1, \dots, N$.

Conclusions

In this work, we introduce a strongly nonlinear mathematical model to describe the dynamics of the preloaded valve spring taking into account the valve-valve seat interaction, which has been described by the essentially nonlinear (nonlinearizable) Hertzian contact law. The dynamics of the chain is analytically studied under the assumption that the response of each oscillator has a dominant harmonic component with a frequency equal to the excitation frequency. Depending on the location of the applied frequency in the dispersion curve of the linear chain, the model under consideration reveals two different periodic responses, namely, propagating and edge breathers. The propagating breathers have main frequency in the propagation zone, and are characterized by weak localization, in which the energy can spread among all the masses. The edge breathers (we referred to them as edge states) possess frequency in the attenuation zone, these states are characterized by strong localization at the forced end of the chain, i.e. maximal concentration of energy in the excited mass against small-amplitude oscillations in the rest of the chain. This implies that in the edge states regime, the coupling between the zeroth and first masses can be removed, and the strongly nonlinear forced oscillator can be considered as a single DOF that excites the linear chain. Comparison of the analytical solution with numerical simulations and experimental test results yields close agreement.

Tuned Mass Systems with a Hybrid Hysteresis Model

Khogesh K Rathore and Saurabh Biswas

*Indian Institute of Technology Jammu, Jammu 181221, India

Summary. Tuned-mass-dampers are used in mechanical systems to reduce the dynamic response of the primary structures. The damping plays a significant role in a tuned-mass-damper system. In many engineering systems, damping is hysteretic in nature. Here, we study tuned mass systems with a hybrid version of hysteresis model with the Bouc-Wen model and a recently developed scalar hysteresis model. The sine sweep responses show two resonance peaks. The sine sweep responses indicate the amplitude vs. frequency of the systems. We compare the numerical results obtained for two different hysteresis models.

Introduction

Tuned mass dampers (TMD) are often used in practical systems to reduce the high amplitude vibrations. There have been extensive researches on TMDs and their applications to engineering problems. TMD devices are extensively used for vibration control, including long span cable bridges, tall buildings, tall water tanks, etc. Much researches have been done over the last several decades on the passive and active control of structures using TMD, see e.g., [1,2].

The damper of the TMD device plays a very important role. Both linear and nonlinear dampers are used in the TMD systems, see e.g., [3,4]. TMD systems with linear viscous damping are often analytically tractable. On the contrary, TMD systems with nonlinear damping models are mathematically challenging.

In many engineering systems, energy dissipation occurs in the form of rate-independent hysteresis. In general, rate-independent hysteresis introduces *signum* nonlinearities in systems. Several researchers used hysteretic dampers in the TMD systems, e.g., [5]. In [6], a hysteretic tuned mass damper is used for structural vibration reduction. In [7], the Bouc-Wen hysteresis model [8,9] is used as the damper in the TMD.

With the above motivation, we will study TMD systems with the Bouc-Wen model and a rate independent scalar hysteresis model developed in [10]. The hysteresis model of [10] is motivated by a study of an elastic plate with several frictional microcracks.

The above two models are briefly discussed below.

The Bouc-Wen hysteresis model is given by

$$\ddot{x}(t) = -\gamma \left\{ A - [\beta \operatorname{sgn}(\dot{x}(t)) f(t) + \gamma] |f(t)|^n \right\} \quad (1)$$

where $A > 0, \beta > 0, \gamma \in [-\beta, \beta]$ and $n > 0$ are the model parameters. Here, $z(t)$ is the given input and $f(t)$ is the corresponding hysteretic output of the system.

The rate-independent scalar hysteresis model of [10] is given by

$$\dot{\theta}(t) = \frac{\kappa}{|z(t)| + \epsilon} \{ \theta_a + \beta_0 \operatorname{sgn}(z(t) \dot{x}(t)) - \theta(t) \} \cdot |\dot{x}(t)| \quad (2)$$

where $z(t)$ is the input displacement to the system and θ is an internal variable. Here, $\theta_a, \kappa, \beta_0$ are model parameters and ϵ is a small regularizing parameter. The hysteretic force is given by

$$f(t) = \theta(t) \cdot z(t) \quad (3)$$

We use the Bouc-Wen model and the scalar hysteresis model of [10] in parallel in TMD systems. We compare the numerical results obtained for both cases.

TMD with the Bouc-Wen hysteresis and the hysteresis model of [10] in parallel

Figure 1(left) shows a TMD system with the Bouc-Wen hysteresis model and the hysteresis model of [10] in parallel. Here, m_1 is the mass of the primary system, k_1 is the stiffness of the spring on which m_1 is mounted, m_2 is the mass of the secondary structure which is attached to the primary mass with a spring of stiffness k_2 and two hysteretic dampers in parallel indicated by h_1 and h_2 . Here, the damper h_1 is governed by the hysteresis model of [10], and the damper h_2 is governed by the Bouc-Wen model. A harmonic force $F_0 \sin(\omega t)$ is applied to the primary mass.

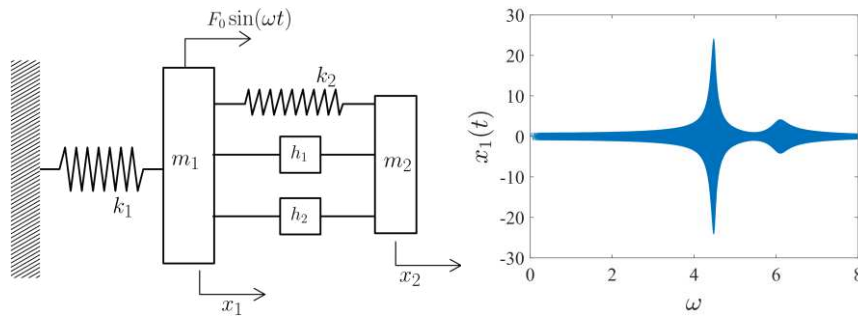

Fig. 1 Left: A tuned mass system with the Bouc-Wen hysteresis and the hysteresis model of [10] in parallel. Right: Response of the TMD with the Bouc-Wen and the model of [10] in parallel. Parameters used: $m_1 = 1$, $m_2 = 1/10$, $k_1 = 1$, $k_2 = 1/10$, $A = 1$, $n = 1$, $\beta = 0.5$, $\gamma = 0.1$, $\kappa = 4$, $\theta_a = 2$, $\beta_0 = 1.8$, $\epsilon = 10^{-6}$, $F_0 = 1.2$, $\alpha = 0.01$, $\alpha_1 = 0.7$ and $\alpha_2 = 0.9$.

Equations of motion of the system are as follows:

$$m_1 \ddot{x}_1 + (k_1 + k_2)x_1 - k_2 x_2 - f = F_0 \sin(\omega t) \quad (7)$$

$$m_2 \ddot{x}_2 - k_2 x_1 + k_2 x_2 + f = 0 \quad (8)$$

$$\dot{\theta}(t) = \frac{\kappa}{|x_2(t) - x_1(t)| + \epsilon} \{ \theta_a + \beta_0 \operatorname{sgn}[(x_2(t) - x_1(t))(\dot{x}_2(t) - \dot{x}_1(t))] - \theta(t) \} |\dot{x}_2(t) - \dot{x}_1(t)| \quad (9)$$

$$f = \alpha_2 \left[|\dot{x}_2(t) - \dot{x}_1(t)| \left\{ A - [\beta \operatorname{sgn}(h_2(t)(\dot{x}_2(t) - \dot{x}_1(t))) + \gamma] |h_2(t)|^n \right\} \right] \quad (10)$$

Here, $h_1 = \alpha_1 \cdot \theta \cdot (x_2(t) - x_1(t))$

and

$$f = \alpha (h_1 + h_2)$$

where α_1 and α_2 are scalar multipliers that control the level of damping. Note that, the input displacement to the dampers is $(x_2(t) - x_1(t))$.

We use a slowly time varying frequency $\omega = 10^{-5}t$ for the frequency sweep calculations. Figure 1(right) shows a frequency sweep response of the primary mass for the TMD with the Bouc-Wen hysteresis and the hysteresis model of [10] in parallel. Resonance peaks are seen in the frequency sweep response. In Figure 1(right), the frequency sweep responses indicate the amplitude vs. frequency of the primary mass. We can see the primary and secondary resonances of the TMDs. By tuning the parameters of the TMDs, we can get the desired resonant amplitudes for our systems.

Conclusions

In this paper, we have numerically studied tuned mass systems with the Bouc-Wen hysteresis model and the hysteresis model of [10] in parallel as the dampers. The net damping force is numerically controlled by two parameters. The goal of the paper was to numerically study the sine-sweep frequency responses of the TMDs. The sine-sweep response gives a clear idea of how the amplitude of the system varies with the frequency. The study helps to develop the idea to tune the model parameters in order to achieve desired resonant responses.

Summary. Friction interfaces can be almost found in all engineering structures which has major influence on their dynamical response. Previous experiments found that mesoscale geometrical characteristics of friction interfaces have a significant impact on the nonlinear modal properties of assembled systems but their effects on nonlinear dynamics has not numerically explored due to the complex coupling between tribology and dynamics. This work proposes an efficient multi-scale approach to investigate the influence of meso-scale interface geometry of friction interfaces. It is applied to a realistic “Dogbone” test rig designed to assess the effects of aero-engine blade root geometries in a fan blade system. The friction interface with different meso-scale profiles are effectively investigated.

Introduction

Friction interfaces have been widely used in assembled structures to connect components and transfer the mechanical loads. They are regarded as the main source of nonlinearities and uncertainties in an assembled structure. The relative motion occurring on friction interfaces often leads to a significant change of its dynamics such as reducing overall stiffness, shifting resonance frequencies and decreasing vibration amplitude through strong energy dissipation. A number of experiments have shown that the nonlinear dynamical behavior of the system is very sensitive to the geometry of friction interfaces [1, 2], which can greatly change the static and dynamic properties such as with crowning interface geometries. However, the effects of meso scale interface geometry on nonlinear dynamics has not been much investigated. However, there is a lack of efficient numerical approaches to design and analyse the influence of such meso-scale interface geometries on the nonlinear dynamical properties.

Methodology

This work proposes a multi-scale modelling framework to study the effects of meso-scale interface geometries on the nonlinear dynamics of complex dynamical systems with friction interfaces. The approach mainly consists in the integration of micro/meso-scale friction interfaces into macro-scale FE model. As shown in Eq.1, nonlinear static analysis (with a flat-on-flat contact interface) is firstly performed to evaluate overall contact loads on the friction interfaces under different pre-loadings. Then, based on overall contact loads from the nonlinear static analysis, a highly efficient semi-analytical solver based on the boundary element method shown in Eq.2 and 3 is performed to obtain the pressure and gap distribution from the contact interface with different geometrical characteristics [3]. The static pressure and gap distribution are then used as the input for a frequency domain nonlinear vibration solver to evaluate nonlinear vibration response of the whole assembled structures where the governing equation is shown in Eq.4. The detailed methodology for nonlinear dynamic analysis can refer to [4].

$$\mathbf{K} \mathbf{u}(t) + \mathbf{F}_{nl}(\mathbf{u}(t)) = \mathbf{F}_s(t) \quad (1)$$

$$u_z(x, y) = \frac{1 - \nu^2}{\pi E} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \frac{p(\xi, \eta)}{\sqrt{(\xi - x)^2 + (\eta - y)^2}} d\xi d\eta \quad (2)$$

$$u_z(i, j) = K_{zz} \otimes p = \sum_{k=1}^{N_x} \sum_{l=1}^{N_y} p(k, l) K_{zz}(i - k, j - l) \quad (3)$$

$$\mathbf{M} \ddot{\mathbf{u}}(t) + \mathbf{C} \dot{\mathbf{u}}(t) + \mathbf{K} \mathbf{u}(t) + \mathbf{F}_{nl}(\mathbf{u}(t)) = \mathbf{F}_e(\gamma, \varphi, \Omega, t) \quad (4)$$

Test case and results

The test case for this study is based on a fan blade root test rig setup as shown in Fig.1 (a). The “Dogbone” rig consists of two main components: a set of identical solid root-block disks and a set of “bones” for different root designs [5]. Fig.1(b) shows the FE model representing the test rig which is performed in Hypermesh where matching mesh has been used on four friction interfaces. The 3D node to node contact element as shown in Figure 1(c) has been used to simulate the contact force. Different meso-scale interface geometries are considered including the different interface shapes including central bump, Y wise bump, edge wise radius. The geometry of the central bump is constructed using defined ellipse curves in both directions with maximum height in the central point similar to [2]. Figure 2 (a) shows the pressure distribution of the central bump contact interface with different maximum heights. With the increase of bumpiness of central bumper,

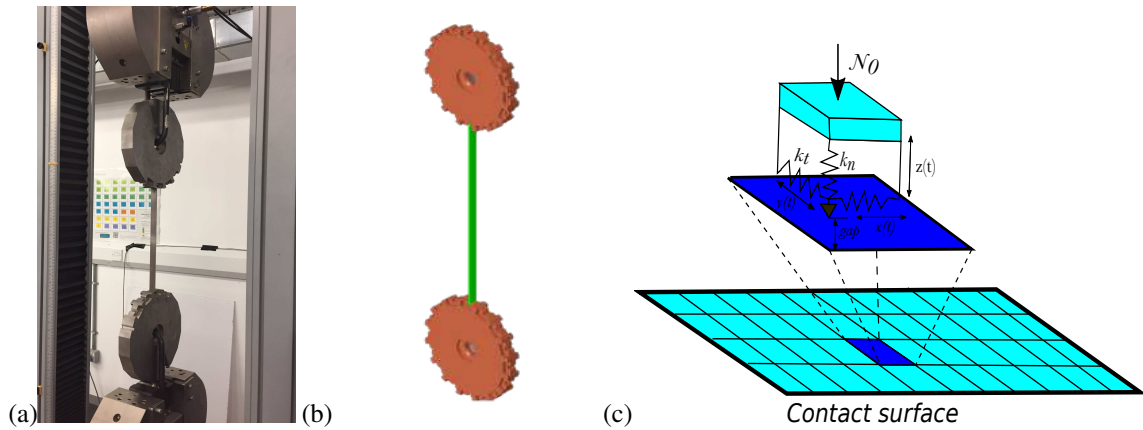

Figure 1: (a) Dogbone Test rig setup; (b) FE model of the Dogbone rig (c) Contact friction element

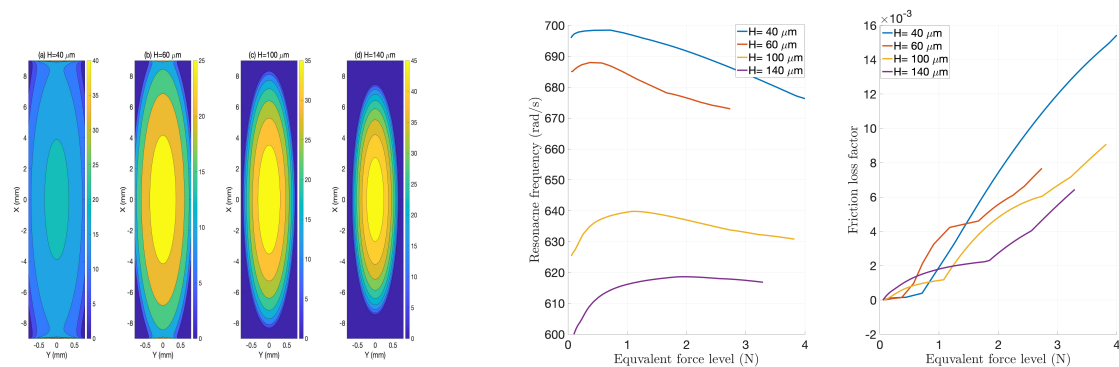

Figure 2: (a) Normal contact pressure and (b) Nonlinear modal properties of the Central Bump for different levels of bumpiness

the pressure distribution becomes more centralized in middle of the contact interface with higher stress amplitude. Figure 2 (b) shows the nonlinear modal properties of these central bump contact interfaces at different force levels. With the increasing bumpiness, it shows the static resonance frequency is reduced from 700 to 600 rad/s mainly because of the increasingly reduced contact area making jointed friction interfaces become less and less stiff. With the increase of force level, for all the cases, the resonance frequency increases initially and then gradually decreases with further increase of energy levels.

Conclusions

This work presents a multi-scale-based approach to efficiently evaluate the effects of meso-scale interface geometries on the nonlinear dynamical response of structures with frictional interfaces. The proposed approach was applied to design and analysis of a blade root Dogbone test rig (similar to fan blade dovetail joints) to evaluate the effects of blade root geometries on the overall dynamic response of the system. Different meso-scale interface profiles including different shapes, level of bumpiness and edge radius were investigated. The studies show the proposed multi-scale approach can efficiently evaluate the influence of meso-scale interface profiles on the contact pressures at a much lower cost. The effects of meso-scale interface profiles on the damping and resonant frequency behavior are significant which should not be ignored in the design and analysis of jointed structures. The developed tool can also be used to design and optimize the friction interface for improved nonlinear dynamics.

Summary. The stability of steady-state solutions is typically assessed by means of local criteria. As an example, the eigenvalues' real parts indicate linear stability of an equilibrium position against small perturbations. However, realistic dynamical systems may exhibit multiple co-existing solutions. If the perturbations are not small, local stability measures have only a limited value for evaluating the effective probability of arriving at one of the multiple solutions. Therefore, global methods are required to evaluate the attractiveness of a state for finite perturbations. This work illustrates the concept of basin stability for a frictional oscillator that exhibits bi-stability. The results indicate how the global basin stability measure can complement conventional stability considerations.

Introduction

Dynamical systems are well-known to exhibit multistability, i.e. multiple stable states co-exist at a given system configuration. In this scenario, only the initial conditions and instantaneous perturbations dictate on which state the system will end up. For example, Gräbner et al. [1] report experimental observations of bi-stability in brake system vibrations. Recently, Jahn et al. [2] have discussed a friction-excited system that exhibits multistability via periodic orbits that compete with chaotic dynamics. Classical linearization-based approaches, such as eigenvalues or Lyapunov exponents, assess a state's stability by investigating the local behavior of small perturbations. The absolute values of those metrics quantify the rate of convergence (for stable states), or divergence (for unstable states), and classify the stability in a binary fashion. For example, the eigenvalue's real part indicates the growth of small perturbations in the vicinity of a fixed point, and hence the equilibrium is stable for a negative real part. However, local linear stability concepts cannot indicate the most desirable state amongst the multiple co-existing ones. This scenario is particularly unsatisfactory if some of the stable states are undesired for reasons of increased vibrations, noise, wear, or fatigue. The concept of basin stability [3] relates to the volume of the basin of attraction \mathcal{B} . The basin stability $S_{\mathcal{B}}$ of a particular state indicates the volumetric fraction of initial states that converge to the attracting set with respect to the overall state space volume. Therefore, it is a global nonlinear measure for the attractiveness of states, i.e. the basin stability can adequately assess the stability of a state under non-small perturbations. In practical system dynamics, the knowledge of multiple solutions and their stability, as typically displayed in bifurcation diagrams, is only one piece of information. The likelihood of the system arriving at one of those solutions may be of even greater importance during the operation of a mechanical structure or machine. This work strives to illustrate the concept of basin stability on the example of a bi-stable frictional oscillator.

Methods

We study the dynamics and stability of a single-degree-of-freedom system $m\ddot{x} + c\dot{x} + kx = F$, see Figure 1 (a), following

$$\begin{aligned} F &= -N\mu(v_{\text{rel}}) \operatorname{sign}(v_{\text{rel}}), & v_{\text{rel}} &\neq 0, & v_{\text{rel}} &= \dot{x} - v_d \\ |F| &< \mu_{\text{st}}N, & v_{\text{rel}} &= 0, \\ \mu(v_{\text{rel}}) &= \mu_d + (\mu_{\text{st}} - \mu_d) \exp\left(-\frac{|v_{\text{rel}}|}{v_0}\right), \end{aligned} \quad (1)$$

that experiences friction-induced vibrations (FIV). The friction formulation features a velocity-dependent weakening-strengthening behavior that gives rise to an instability of the steady sliding solution, see Figure 1 (b). A self-excited stick-slip limit cycle exists for the parameter range $0 \leq \tilde{v}_d \leq 1.84$ and, most importantly, co-exists with the steady sliding solution in the bi-stability regime $1.11 \leq \tilde{v}_d \leq 1.84$ resulting from the subcritical Hopf bifurcation. Hence, in this parameter range, there exist two stable states in parallel, as depicted in Figure 1 (c). Depending on the initial condition or instantaneous perturbations, the system will either end up in the low-energy steady sliding state, or on the high-intensity stick-slip cycle.

Results

Conventionally, the stability of the equilibrium solution, i.e. the steady sliding state, is assessed by the eigenvalue's real part $\Re(\lambda)$. However, in realistic systems, it is often unknown what type of perturbations the system may experience during operation. In our model, the unstable periodic orbit (UPO) represents the separatrix between the basins of attraction \mathcal{B} for the two stable states. A perturbation of $\tilde{x} < -0.65$ at $\tilde{v}_d = 1.5$ would result in a jump from the steady sliding state to the limit cycle. The eigenvalue in Figure 2 (a) grows for a decline in belt velocity, indicating that the steady sliding state becomes less stable against perturbations up to $\tilde{v}_d = 1.11$. However, the linear stability analysis is unable to show how fast the basin \mathcal{B} of the steady sliding state shrinks for declining belt velocities \tilde{v}_d . Hence, the eigenvalue analysis does not detect the critical transition at $\tilde{v}_d = 1.84$ where the systems transits into the bi-stability regime. On the contrary, the basin

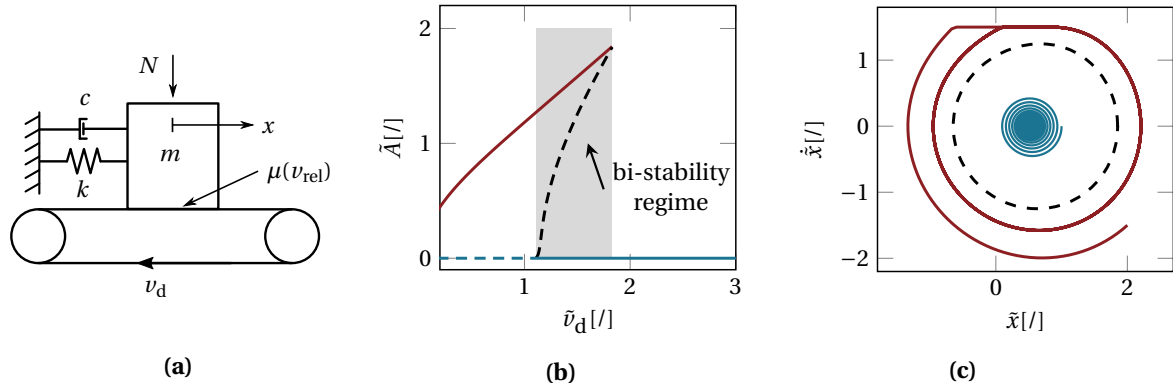

Figure 1: (a) single-degree-of-freedom frictional oscillator, (b) bifurcation diagram for the non-dimensional belt velocity \bar{v}_d , and (c) phase plane for $\bar{v}_d = 1.5$. Stable (unstable) solutions are indicated by solid (dashed) lines. The stable steady sliding state (blue spiral trajectory) co-exists with the unstable periodic orbit (black dashed line) and the stable stick-slip limit cycle (red trajectory). The non-dimensional system (̄) is evaluated for $\mu_d = 0.5$, $\mu_{st} = 1$, $\xi = 0.05$, $N = 1$ and $\bar{v}_0 = 0.5$ following the work [4]

stability S_B in Figure 2 (b) indicates the *global degree of stability*, which changes quickly at the transition point. Here, S_B is a much more reliable proxy for detecting the critical transition of the steady sliding state. While the linear analysis states a negative eigenvalue at $\bar{v}_d = 1.5$, S_B indicates that the likelihood of converging to the steady sliding state is in fact only $S_B = 0.255$. Hence, the system is three times more likely to exhibit stick-slip vibrations if the initial conditions or perturbations were randomly drawn from the given state space regime.

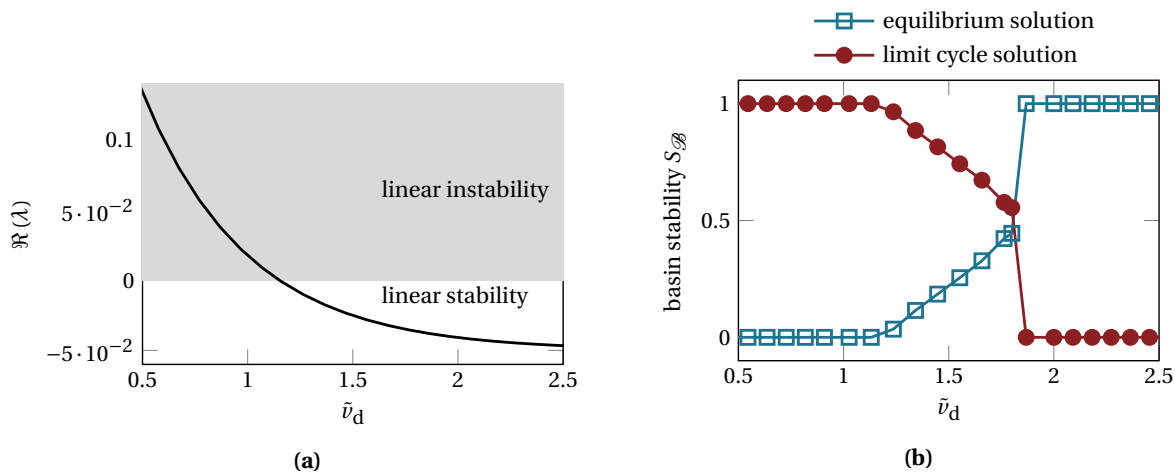

Figure 2: (a) eigenvalue's real part as a function of the belt velocity. The linearly unstable regime for $\Re(\lambda) > 0$, shaded in gray, is reached at $\bar{v}_d = 1.11$. (b) basin stability S_B of the steady sliding equilibrium and the stick-slip limit cycle. Initial conditions were drawn from $\bar{x}_0 \in \{-2, 3\}$ and $\bar{\dot{x}}_0 \in \{-2, 2\}$ using a uniform grid of 20×20 points.

Conclusions

The basin stability is studied as a measure for the state's relevance in a multistability scenario. While the (nonlinear) stability of this small oscillator is rather straight-forward, the basin stability seems to be a particularly useful stability measure for more complex, i.e. higher-dimensional, systems that feature a complicated multi-stability behavior [5]. Regarding the actual motion during operation, the basin stability is likely to contribute to higher prediction quality of numerical models of mechanical structures. As a second model, a frictional oscillator with multiple degrees of freedom and a more complicated dynamical behavior [2] will be studied in the full conference proceeding.

Dept. of Engineering “Enzo Ferrari”, University of Modena and Reggio Emilia, Modena, Italy
Intermech Mo.Re Centre, Modena, Italy^[1,2]

Summary. The nonlinear vibrations of a homogeneous, isotropic, and shallow spherical cap under a harmonic pressure field are investigated. The problem is tackled using a semi-analytical method based on Novozhilov’s nonlinear thin shell theory. The partial differential equations (PDEs) are reduced to a set of ordinary differential equations (ODEs) through the Rayleigh-Ritz approach and Lagrange equations. The final equations of motion are numerically solved using both continuation and direct integration techniques. Results depicted the activation of non-symmetric vibrational states, with the presence of multiple bifurcations and chaotically-modulated oscillations.

Introduction

The characterization of thin-walled structures under dynamic loads has always received considerable research attention due to the large number of applications in Engineering from macro to nanoscales (e.g. propellant tanks, micro-electro-mechanical systems, nanotubes).

This study proposes a method to analyze the dynamics of a homogeneous, isotropic, and thin-walled shallow spherical cap under a uniform, time-varying pressure distribution, see Figure 1.

Despite most of the previous studies on this topic being limited to the axisymmetric vibrations, which neglected the possible onset of non-symmetric vibrations, some authors suggest retaining asymmetric modes into the analysis to improve the matching among experimental and numerical results [1].

To this end, the formulation here presented uses Novozhilov’s thin shell theory [2], a follower pressure to model the external load distribution [3], and it retains the asymmetric modes into the reduced-order model. Complete details regarding the present study are reported in Refs [4,5].

Figure 1: Spherical cap reference system: (a) side and (b) top view.

Results and Discussion

Following the analyses presented in Refs [4,5], a 38 dofs reduced-order model is considered. The structure is loaded by a uniform static pressure superimposed to a harmonic one. The frequency of the harmonic pressure varies about the first axisymmetric mode resonant frequency $\omega_{1,0}$. Using a continuation method to analyze the stability of periodic solutions, and directly integrating the equations of motion, a dynamic scenario characterized by multiple bifurcations and chaos is shown.

In Figure 2, the frequency-response diagram of the asymmetric modal coordinate $f_{w,1,2}^{(d)}$ is given. The continuation method (black-solid line) shows the presence of period-doubling bifurcations (PD) leading to the onset of asymmetric oscillations. The stability loss of the periodic responses (black-dotted line) agrees with the irregular response trend prompted by the direct integration of the equations of motion (red-dashed/blue-solid line).

Since an irregular frequency-response diagram suggests chaotic oscillations, Figure 3 shows the time response of $f_{w,1,2}^{(d)}$ for a normalized forcing frequency $\Omega = 1.09 \cdot \omega_{1,0}$. Two different phenomena could be observed: a slow dynamic, which module the oscillation amplitude, and a fast dynamic governed by rapid burst. This pattern has some periodicity, and the evolution of the Poincaré map clearly shows weekly chaotic vibrations: by reporting the section for an increasing number of periods n_p , the sparse cloud contour becomes regular, and a dense kernel becomes noticeable.

Figure 2: Asymmetric mode activation after period doubling bifurcation: continuation method VS direct time integration.

Summary. In this contribution, a parameter identification technique is introduced for delayed time-periodic differential equation, which is based on the so-called impulse dynamic subspace (IDS). The description is tested on the delayed Mathieu equation. Then, a possible application is discussed for chatter detection technique in machine tool vibrations, and its limitation due to arising nonlinear behaviour is summarized.

Introduction

The main goal of this work is to characterize the dynamical behaviour of delayed periodic systems without substantial knowledge of the underlying model. Our assumptions are that the system is a linearized version of a nonlinear phenomenon and the time-period is known. The main idea is to capture the dominant spectral properties of the system from its impulse response. In order to achieve this, the so-called impulse dynamic subspace (IDS) is used [1]. This is an efficient description for possible automatic parameter fitting for mechanical structures. Originally, the method is developed for linear time-invariant systems. It is based on the evaluation of frequency response functions by using Green function representation of the homogeneous dynamics. However, in this work, we slightly modify the original ideas of the method to make it suitable for periodic systems. In this way, here, we apply this method for periodic non-autonomous systems and we characterize its Floquet multipliers (characteristic multiplier), consequently, we characterize the stability properties of the underlying system without knowing its parameters. The method and its applicability is tested on a time-periodic delay-differential equation (DDE), the so-called delayed Mathieu equation by using time signal generated by numerical integration. Finally, one possible application field is discussed from the topic of machine tool vibrations, namely quantitative chatter detection and stability prediction method in milling operations [2].

Impulse dynamic subspace description for periodic non-autonomous case

The IDS can describe the relevant dynamics of a structure by means of the singular value decomposition applied on the Green function representation of the vibration signal $x(t)$ of a periodic non-autonomous system with time-period T . For detailed derivation on the IDS description, the reader is referred to [1]. The so-called block-Hankel matrix representation of the Green function for time-periodic system is

$$\mathbf{G} = \begin{bmatrix} \mathbf{x}_0 & \mathbf{x}_1 & \dots & \mathbf{x}_N \\ \mathbf{x}_1 & \mathbf{x}_2 & \dots & \mathbf{x}_{N+1} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{x}_N & \mathbf{x}_{N+1} & \dots & \mathbf{x}_{2N} \end{bmatrix}, \quad (1)$$

where \mathbf{x}_i is the discretized state vector along a period T . It form as

$$\mathbf{x}_i = [x(iT + \Delta t) \ x(iT + 2\Delta t) \ \dots \ x(iT + (n-1)\Delta t)] = \text{row}_{j=0}^{n-1} x(iT + j\Delta t), \quad (2)$$

where the number of sampled points in one period is n and the discretized time step is $\Delta t = T/n$. Note that in case of time-periodic systems, the blocks are shifted by 1 time-period in the Hankel matrix. By using singular value decomposition (SVD) of the Hankel matrix $\mathbf{G} = \mathbf{V}\mathbf{\Sigma}\mathbf{W}^H$, the dominance of subsystems can be identified. Here \mathbf{V} and \mathbf{W} are the stroboscopic- and sampled-singular-responses (SR) (alike singular-IRF in [1]), respectively. By taking an appropriate singular set, as a result, using the truncated versions of the stroboscopic-SR $\tilde{\mathbf{V}}$, a discrete map can be defined as

$$\mathbf{B} = \tilde{\mathbf{V}}^H \mathbf{S} \tilde{\mathbf{V}}, \quad (3)$$

where \mathbf{S} is a shift matrix with non-zero elements $S_{i,i} = 1$. The eigenvalues of \mathbf{B} are the Floquet multipliers of the periodic non-autonomous (time-variant) system.

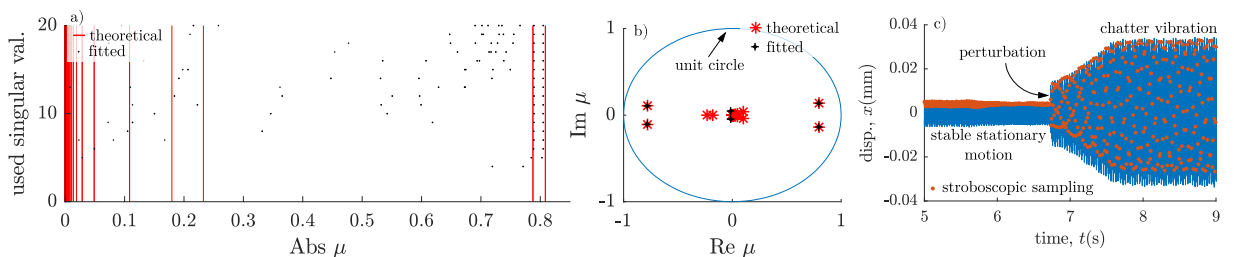

Figure 1: Effect of truncation on fitted multipliers (a), dominant multipliers in the complex plane (b); bistable machining process (c).

Test case

In this section, the time periodic DDEs are detailed, on which IDS description was applied. The general form of the delayed Mathieu equation reads

$$\ddot{x}(t) + a_1 \dot{x}(t) + (\delta + \varepsilon \cos t) x(t) = b_0 x(t - \tau) . \quad (4)$$

where the time-period is $T = 2\pi$. Here, the special case will be investigated, when the time delay is just equal to the principal period ($\tau = T$). For periodic systems, the stability condition is provided by the Floquet theory.

In order to validate the description by IDS, we test it on the delayed Mathieu equation, where the fitted dominant multipliers are compared directly to the theoretically ones calculated by the semidiscretization method (SDM) [3]. The IDS description is applied on numerically generated time signal, with parameters $\delta = 3.1605$, $\epsilon = 1$, $a_1 = 0$, $b_0 = -0.6246$ and initial function $[x_0 \ \dot{x}_0]^\top = \mathbf{0}$ if $t \in [-\tau, 0)$ and $[x_0 \ \dot{x}_0]^\top = [0 \ 1]^\top$ if $t = 0$. The number of the simulated periods are $2N = 120$ and the discretized number of points during 1 period is $n = 100$. Consequently, the size of the Hankel matrix is $N \times n \times N$. The size of the problem is decreased by truncating the Hankel matrix squarely, thus, considering only $N \times N$ elements. Then, the IDS description is applied with several truncated versions of the stroboscopic-SR $\tilde{\mathbf{V}}$, also (see Eq. 3).

The magnitude of the fitted multiplier are plotted in Fig. 1a with black dots together with the theoretical values (red vertical lines) as a function of the truncation of $\tilde{\mathbf{V}}$. For a few considered stroboscopic-SR, the IDS description can capture 2 complex conjugate pair of multipliers with large magnitude with good accuracy. On the other hand, taking into account more stroboscopic-SR, the fitted multipliers start to scatter. To select the appropriate number of stroboscopic-SR, the singular values of the Hankel matrix can be analysed, see more details in [1]. In this case, we select 6, since all the other singular values were merely close to zero. This case is illustrated in the complex plane in Fig. 1b. As shown in the figure, the IDS description is not only able to capture the magnitude of the multipliers, but its imaginary and real components as well. However, as cons of the proposed method, it could not identify multipliers with small magnitude, since solution segments relating to these terms are decaying very fast. Nevertheless, from the practical point of view, those are usually not relevant in engineering applications.

Stability prediction in machining

One possible application of the described method can be used in the operational stability prediction in milling processes [2]. During machining, an undesired phenomenon, the so-called chatter vibration can lead to unacceptable surface quality and possible damage in the machine components. Therefore, avoidance, or at least, the prediction of these vibrations is necessary.

During the operational stability prediction technique, the stability of the machining process can be characterized through the Floquet multipliers. They can be determined during machining by applying the above discussed method. By changing technological parameters, the variation of the modulus of the Floquet multipliers can be monitored, by which, precise stability limit can be extrapolated while the manufacturing parameters remain in the safe region.

On the other hand, according to practical observations, usually there is a bistable region near the linear stability boundary due to unmodelled nonlinear effects. This is also unsafe zone since two attractive motions coexist: stable cutting and large amplitude chatter, which are separated by an unstable periodic motion [4, 5]. In this range, the vibration can jump from the linear attraction zone to the chatter motion due to a large-enough perturbation, as shown in Fig. 1c. Consequently, one cannot excite a stable stationary solution in this range and thus one cannot determine the multipliers of the linearized system.

Test Rig with Drive Belt: Modelling and Simulation of Parametrically Excited Vibrations

Markus H. E. Messer and Bernhard Gass

*Fachbereich Maschinenbau, Mechatronik, Materialtechnologie (Mechanical Engineering),
Technische Hochschule Mittelhessen (University of Applied Sciences), Friedberg, Germany*

Summary. This paper deals with the modelling and simulation of parametrically excited vibrations in a test rig with a drive belt. The structure is modelled as a dynamical system with time-periodic coefficients and four degrees of freedom (two rotational and two translational degrees of freedom). Stiffness parameters are obtained from experimental load-displacement diagrams, and mass parameters are calculated by hand or by CAD software. The system's proportional damping parameters are derived from measured damping ratios of the structure. Finally, the parametrically excited vibrations are studied numerically by using fourth-order Runge-Kutta method. The simulation results are considered to be very valuable for the upcoming measurements and the analysis of experimental data.

Introduction

Machines with drive belts often exhibit parametrically excited vibrations [1]. The test rig in figure 1 uses a V-rippled L-profile drive belt. For the most part, the drive belt consists of vulcanized rubber material. In addition to that, the drive belt contains a load-carrying tension member (high strength fibres) for transmitting the longitudinal forces. This type of drive belt can be found in many different machines, e.g. sheet-fed offset printing machines. Recent work of one of the authors showed, that the drive belt can be modelled as a spring with time-periodic stiffness. This parametric stiffness excitation leads to numerical results that match very well with measured vibrations [2].

Parameters:

$$\begin{aligned} \Theta_1 &= 1.64 \cdot 10^{-3} \text{ kg m}^2, \Theta_2 = 2.21 \cdot 10^{-2} \text{ kg m}^2, \\ m_3 &= m_4 = 1.25 \text{ kg}, d_1 = 0.104 \text{ m}, d_2 = 0.164 \text{ m}, \\ e &= 0.005 \text{ m}, k_3 = k_4 = k_5 = 492 \text{ N/m}, \\ \alpha &= 2.45 \text{ s}^{-1}, \beta = 8.37 \cdot 10^{-4} \text{ s} \end{aligned}$$

Drive belt's geometry and stiffness:

$$\begin{aligned} L &= 0.991 \text{ m}, h = 0.007 \text{ m}, b = 0.038 \text{ m}, \\ k_1 &= k_2 = 6.78 \cdot 10^5 \text{ N/m} \cdot \left[1 + 0.175 \cdot \cos\left(\frac{\dot{q}_1 \pi d_1 t}{L}\right) \right] \end{aligned}$$

Figure 1 (left): Photograph of the test rig. Figure 2 (right): Sketch and parameters of the dynamical system.

Dynamical system

Figure 2 displays a sketch of the dynamical system. The rotational degrees of freedom of the two belt pulleys are denoted by q_1 and q_2 . The two masses m_3 and m_4 have translational degrees of freedom (q_3 and q_4). An asynchronous motor fed from a frequency converter delivers the drive torque M_1 to the small belt pulley. According to [3], the drive belt's stiffness can be different for tight span (k_1) and slack span (k_2). k_3 , k_4 and k_5 represent helical compression springs.

Applying Newton's Second Law yields the following equations of motion:

$$\Theta_1 \ddot{q}_1 + (k_1 + k_2) \frac{d_1^2}{4} q_1 - (k_1 + k_2) \frac{d_1 d_2}{4} q_2 - M_1 = 0 \quad (1)$$

$$\Theta_2 \ddot{q}_2 + (k_1 + k_2) \frac{d_2^2}{4} q_2 - (k_1 + k_2) \frac{d_1 d_2}{4} q_1 + k_3 e^2 \sin(q_2) \cos(q_2) - k_3 e \cos(q_2) q_3 = 0 \quad (2)$$

$$m_3 \ddot{q}_3 + (k_3 + k_4) q_3 - k_4 q_4 - k_3 e \sin(q_2) = 0 \quad (3)$$

$$m_4 \ddot{q}_4 + (k_4 + k_5) q_4 - k_4 q_3 = 0 \quad (4)$$

Kammer experimentally acquired the linear load-displacement diagram for the helical compression springs used in the test rig [4]. This leads to $k_3 = k_4 = k_5 = 492$ N/m. Furthermore, the authors' colleagues Pyttel and Wiesner carried out a tensile test of the drive belt [5]. The measured load-displacement relationship is nonlinear, but linearizing the progressive (hardening) curve at the operating point (belt tension: 278 N) leads to: $k = 6.78 \cdot 10^5$ N/m. In accordance with recent work of one of the authors, the drive belt is modelled as a spring with time-periodic stiffness as follows [2].

$$k_1 = k_2 = k \cdot [1 + \varepsilon \cdot \cos(\omega_{PE} t)] \quad (5)$$

Neglecting slip, the parametric excitation frequency ω_{PE} relates to the drive belt's length L as follows:

$$\omega_{PE} = \frac{\dot{q}_1 \pi d_1}{L} \quad (6)$$

For $\dot{q}_1 = \dot{q}_2 = 0$ (non-rotating belt pulleys) Kammer measured free vibrations of m_3 and m_4 and identified eigenfrequencies (20 rad/s, 34 rad/s) and corresponding damping ratios (0.07, 0.05) [4]. Consistent with [2], proportional damping ($\underline{D} = \alpha \underline{M} + \beta \underline{K}$) is assumed, and α and β are chosen to yield the system's above-mentioned damping ratios.

Simulation of parametrically excited vibrations

Since the drive torque M_1 hasn't been measured yet, the dynamical system is simulated for the scenario $\dot{q}_1 = \text{const.}$ Figure 3 shows simulation results for $\varepsilon = 0.175$, which is in line with [2]. Maximum amplitudes in figure 3 occur at order $0.33 = \pi d_1 / L$ (first drive belt order). Simulation results will be compared with impending measurements.

Summary. Parametric resonance in floating bodies is well known for large amplitude pitch and roll oscillations with a slower period than the wave induced motions. The pitch and roll dynamics exhibit characteristics of the damped Mathieu equation, due the restoring torque being dependent on the heave position, which is oscillating in response to the input waves. Therefore, when ocean waves are approximated as a sinusoid, the monochromatic input wave can cause parametric resonance to occur in the system when the input frequency is around twice the pitch/roll natural frequency. However, in reality ocean waves contain a spectrum of frequencies. This paper examines the motion of floating bodies subject to input waves represented by sinusoids and by standard ocean wave spectra. The occurrence of parametric resonance is compared for these two cases. A test case, considering a spar-type heaving cylinder from the literature, is presented, showing the resulting parametrically induced pitch and roll motions for the different input waves.

Parametric resonance in floating bodies

Parametric resonance is caused by the time-varying changes in the parameters of a dynamical system, resulting in an exponential increase in oscillation amplitude [1]. Parametric resonance is known to cause large amplitude pitch and roll oscillations in floating bodies. This phenomena was first noted by Froude in 1861 [2], where large amplitude roll motions were observed for a ship when the input wave frequency was half the roll frequency. Parametric pitch/roll is relevant in a number of fields, such as shipping [3], spar-buoy platforms [4], marine based wireless sensor networking [5] and offshore renewable energy [6].

Dynamics

The pitch and roll dynamics of a floating body (we consider a heaving, spar-type cylinder as depicted in Figure 2-(b)) can be well approximated by the Damped Mathieu Equation [1]:

$$\ddot{x}(t) + b\dot{x}(t) + a(t)x(t) = 0. \quad (1)$$

Mechanically, this equation describes the motion, $x(t)$, of a mass-spring-damper system with a time-varying spring stiffness term, $a(t)$. For harmonic variation of the parameter, $a(t)$, the system is known to become unstable at certain frequencies and amplitude thresholds. For a floating body, the spring stiffness in the pitch and roll degrees of freedom, depends on the heave position, which varies in time due to wave induced oscillations. Therefore, the wave induced heave motion of a floating body can trigger parametric resonance in the pitch and roll modes of motion. This is depicted in Figure 1, showing the heave and pitch motions of a floating cylinder subjected to a sinusoidal input wave with a frequency twice the pitch natural frequency.

Figure 1: The heave and pitch response of a floating cylinder, subject to an input sinusoidal wave, showing the transfer of energy from heave to pitch

Ocean waves

While the analysis of parametric resonance and Mathieu instability is well known for sinusoidal waves, real ocean waves are stochastic [7]. For engineering purposes, ocean waves are often approximated by Fourier analysis, described by a wave spectrum, with the sea surface well represented by a linear superposition of harmonic components. Figure 2-(a) shows standard wave spectra, JONSWAP and Pierson-Moskowitz, whose shape and bandwidth depends on the wind speed and fetch distance over which the wind blows.

Figure 2: (a) Comparison of the JONSWAP spectrum for varying fetch, F , distance (dashed lines) against the Pierson-Moskowitz (PM) spectrum for a 12m/s wind speed (from [5]) (b) Schematic of the generic spar-type structure in the test case (from [9]).

Test case

As an illustrative example, we consider a heaving, spar-type cylinder, as depicted in Figure 2-(b), whose dynamic instability was previously examined in [8, 9, 10]. The pitch/roll natural frequency of the cylinder is twice the pitch/roll natural frequency which makes the cylinder particularly prone to parametric resonance. Numerical simulations of the cylinder motion are presented, considering a range of monochromatic and polychromatic wave inputs and the occurrence of parametric resonance in the different wave regimes compared. We compare the occurrence of parametric resonance in floating bodies, for experiments considering single frequency or multi-frequency input waves. For the multi-frequency spectra, the effect of the bandwidth is also investigated, comparing narrowband with broadband spectra.

Stability of Stationary Solution of Time Periodic Nonlinear Single DoF Time Delayed System Based on Impulse Response Function

Zoltan Dombovari^{*,†}

^{*}MTA-BME Lendület Machine Tool Vibration Research Group, Budapest, Hungary

[†]Dynamics and Control Department, Ideko, Elgoibar, Spain

Summary. An extension of the semidiscretization method to impulse dynamic subspace (IDS) is summarized. This domain is the eigenspace of a measured impulse response function (IRF), which is commonly used in the industry. By considering the special properties of the measurement the stability of a single degree of freedom (DoF) milling model is presented as a representative example. Convergences are shown for Hopf and Period Doubling (PD) induced instabilities.

Introduction

In the verge of the new technological revolution more and more automatized solutions will appear in the daily life and very much in the manufacturing sector. One of the most difficult processes to be automatized are the ones that rely on human pattern recognition like understanding traffic situations. Dynamic characterization of machine tools are one of these problems, due to the special parameter identification techniques and selection methodologies used nowadays in the industry. In order to avoid that the impulse dynamic subspace (IDS, [1]) is used for carrying dynamic information.

In this work, a modeling technique is presented where the determination of model parameters is avoided and the process is directly described in the IDS. The main aim is to show that it is possible to derive theoretically the stability properties of a time-periodic milling process by only using the measurable IRF. The time-periodic nature of the milling process induces a stationary solution, which is always apparent and it directly determines the surface quality. However, this stationary solution can loose its stability by setting 'wrong' parameters, and can lead to a high amplitude, limiting oscillation. This limiting oscillation is mathematically stable, although the engineering jargon calls this as chatter instability [2], which refers mathematically to the unstable nature of the stationary time-periodic solution.

The main reason of this oscillation is the regenerative effect, when the consecutive tooth of the milling cutter cuts the surface left by the previous teeth. Since then many methods have been developed in time- and frequency- domain for determining stability of the corresponding stationary solution. Frequency domain solutions, like zeroth order approximation (ZOA, [2]) and multi-frequency (MF, [2]) solution, based on D-subdivision, and Hill's infinite determinant method, can include the measured frequency response functions (FRFs). However, this advantage comes with a huge disadvantage, namely, these methods only provide the critical (non-hyperbolic) limits and not actually the stability boundaries. Also to define the 'measure of stability' (distance from the border) is not straightforward in this case. One needs extremely specialized theorems to perform optimization. Time-domain methods like semidiscretization, time-finite element, collocation methods and spectral element methods, provide the Floquet-multipliers [3], whose magnitude are excellent to 'measure' stability for optimization purposes. However, all these methods rely on time-consuming modal parameter fitting, which computation time adds to the already slow extensive scanning of the parameter space constructing a given stability chart. In order to help on this disadvantage a method is proposed here by performing process modeling based on the IDS [4], which essentially a good candidate for avoiding manual fitting. Moreover by using time-domain based methods the 'measure' of stability is also granted by the magnitude of the multipliers.

Stationary Solution

There are plenty of papers dealing with modeling of regenerative milling processes [2, 5, 1]. In general, the milling process is not only time-periodic, but also nonlinear due to the degressive characteristic of the specific cutting force $f_{tra}(h)$ (N/m) [6] given in (tra) (figure 1a) coordinate system. In milling, each i th ($i = 1, \dots, Z$) tooth cuts different thickness of the workpiece h_i material during the rotation of the tool with angular velocity Ω . On the other hand, the chip thickness is also state dependent due to the regeneration [2], that is, $h_i(t) := h_i(t, x_t(\xi))$ ($\xi \in [-\tau, 0]$, $x_t(\xi) = x(t + \xi)$). In general, the resultant cutting force is time-periodic in its coefficients ($F_x(t, \bullet) = F_x(t + T, \bullet)$) and has the form (more detail in [6])

$$F_x(t, x_t(\xi)) := F_x(t, f_{tra}(h_i(t, x_t(\xi)))) = F_{x,0}(t) + \Delta F_x(t, x_t(\xi)) + g_x(t, x_t(\xi)), \quad (1)$$

where the stationary part of the force is $F_{x,0}(t) = F_x(t, \bar{x}_t(\xi))$, while the linear variational part and the higher order terms are $\Delta F_x(t, x_t(\xi))$ and $g_x(t, x_t(\xi))$, respectively. The structural behavior of the machine tool is supposed to be linear, thus, it can be represented with an IRF as $h(\theta) = (\mathcal{F}^{-1}\{H(\omega)\})(\theta)$ subjected to the causality $h(\theta \leq 0) = 0$. If that is true, the response behaviour for a zero initial value can be represented by the Duhamel's integral as $\bar{x}_t(\theta) := \int_0^\theta h(\theta - \vartheta) F_x(t + \vartheta) d\vartheta$. Since the stationary solution is time-periodic $\bar{x}_t(\theta) = \bar{x}_{t+T}(\theta) = \bar{x}_t(\theta + T)$, Duhamel's representation actually works for the nonlinear state-dependent forcing case too, if the stationary solution is considered frozen for the time period T in the interval $\theta \in [0, T]$. The stationary solution is then shifted with a sufficient enough transient time T_1 to ensure periodicity and the boundary problem is solvable in both time and frequency domain with

$$\bar{x}_0(\theta) = \int_{-\infty}^\theta h(\theta - \vartheta) F_x(\vartheta, \bar{x}_\vartheta(\xi)) d\vartheta = \int_0^{T_1+T} h(\theta + T_1 - \vartheta) F_x(\vartheta, \bar{x}_0((\xi + \vartheta) \bmod T)) d\vartheta. \quad (2)$$

Figure 1: a) sketch of the milling model, b) stability charts with Hopf (H) and flip (PD) curves. Convergence for the solutions is checked in c) by varying the discretisation resolution N_{SDM} at H and PD points depicted in b).

Linear Stability of Stationary Solution

Perturbation is introduced around the time periodic stationary solution as $x = \bar{x} + u$. By neglecting the nonlinear terms g_x in (1), the linear variational system can be expressed in the following linear form

$$u_t(\theta) = \int_0^\infty G(\theta, \vartheta) \Delta F_u^-(t - \vartheta) d\vartheta + \int_0^\theta h(\theta - \vartheta) \Delta F_x^+(t + \vartheta, u_{t+\vartheta}(\xi)) d\vartheta, \Rightarrow u_t(\theta) = u_{IF,t}(\theta) + u_{F0,t}(\theta, u_t(\xi)). \quad (3)$$

The first term u_{IF} of (3) represents the response for initial (variational) forcing ΔF_u^- (IF, alternative to initial condition), while the second term u_{F0} describes the solution for actual forcing $\Delta F_x(t, u_t(\xi)) = a K_c A_x(t)(u(t) - u(t - \tau))$ (see (1)) combined with the transient solution for zero initial condition (F0). In the first term the so-called Green function can be replaced with the IRF as $G(\theta, \vartheta) := h(\theta + \vartheta) = \mathbf{V}(\theta) \Sigma \mathbf{W}^H(\vartheta)$, whose two left-singular-IRF for a single DoF system $\mathbf{V}(\theta) = [V_1(\theta) \ V_2(\theta)]$ can be used to introduce the new IDS as a result of SVD explained in [4]

$$u(t + \theta) = \mathbf{V}(\theta) \mathbf{q}(t), \Rightarrow \dot{\mathbf{q}}(t) = \mathbf{A} \mathbf{q}. \quad (4)$$

By defining the product $\langle \mathbf{a}(\xi), \mathbf{b}(\xi) \rangle := \int_0^\infty \mathbf{a}^H(\xi) \mathbf{b}(\xi) d\xi$ the system matrix can be derived as $\mathbf{A} = \langle \mathbf{V}(\theta), \mathbf{V}'(\theta) \rangle$ (using $\mathbf{V}'(\theta) = \langle G'(\theta, \vartheta), \mathbf{W}(\vartheta) \rangle \Sigma^{-1}$, $G'(\theta, \vartheta) := h'(\theta + \vartheta)$, $h'(\theta) := (\mathcal{F}^{-1}\{i\omega H(\omega)\})(\theta)$, [4]). Describing the behavior in the IDS ($\mathbf{q}_i = \mathbf{q}(t_i)$, $t_i = i \Delta t$, $\Delta\theta = \Delta t$) and considering that only physical displacement space $u_i = u(t_i)$ is needed for the calculation of the process force, the size of the problem can be significantly decreased. Thus

$$\mathbf{q}_{i+1} = e^{\mathbf{A} \Delta t} \mathbf{q}_i + \langle \mathbf{V}(\theta), u_{F0,i+1}(\theta, u_i, \sigma_t(u_{i-l})) \rangle, \quad l = 0, 1, 2, \dots, r, \quad r = \left\lceil \frac{\tau}{\Delta\theta} - \frac{1}{2} \right\rceil + \left\lfloor \frac{p}{2} \right\rfloor, \quad (5)$$

where $u_{IF,i+1}(\theta) := u_{IF,t_i+\Delta t}(\theta) = \mathbf{V}(\theta + \Delta t) \mathbf{q}_i$, $u_{F0,i+1}(\theta, u_t(0), u_t(-\tau)) := u_{F0,t_i+\Delta t}(\theta, u_t(\xi)) = a K_c \int_0^{\Delta t} h(\theta - \vartheta) A_x(t + \vartheta) (u_{t+\vartheta}(0) - u_{t+\vartheta}(-\tau)) d\vartheta$ and $u_t(0) := u_i$, $u_t(-\tau) \approx \sigma_t(u_{i-l}) = \sum_{k=0}^p P_k(t) u_{i-r+k}$. Using the homogeneous solution operator (exponential term in (5)) as $e^{\mathbf{A} \Delta t} = \langle \mathbf{V}(\theta), \mathbf{V}(\theta + \Delta t) \rangle$ [4] the following semidiscretization map can be derived

$$\begin{aligned} \mathbf{q}_{i+1} &= \langle \mathbf{V}(\theta), \mathbf{V}(\theta + \Delta t) \rangle \mathbf{q}_i + \mathbf{D}_i u_i + \dots + \mathbf{D}_{i-r+1} u_{i-r+1} + \mathbf{D}_{i-r} u_{i-r}, \\ u_{i+1} &= \mathbf{V}(\Delta t) \mathbf{q}_i, \\ \mathbf{D}_{i-l} &= -a K_c \left\langle \mathbf{V}(\theta), \int_0^{\Delta t} h(\theta - \vartheta) A_x(t_i + \vartheta) P_{r-l}(t_i + \vartheta) d\vartheta \right\rangle, \quad P_r(t) = -1. \end{aligned} \quad (6)$$

Conclusion

The map presented in (6) can be used to approximate the monodromy operator of the time-periodic milling system in order to calculate stability properties (figure 1c) of the corresponding stationary solution \bar{x} . This converging solution (figure 1c) uses the IDS which actually originated from measured IRF by using a well posed SVD on the homogeneous core of the dynamics ($G(\theta, \vartheta)$ at (3)). This theoretical framework can be extended for the entire period by facilitating larger portion of the corresponding IRF function by using nested convolutions.

Summary. This work is devoted to how the frequency of an external force effects the resonances in a one-dimensional initial-boundary value problem for a nonhomogeneous wave equation involving a Robin type of boundary condition with a time-dependent coefficient. By setting the frequency of the external force equal to ω , and the time-dependent boundary coefficient in the boundary condition equal to $k(t)$, different kinds of resonances can be obtained by numerical simulations. Next, by using the method of d'Alembert and wave reflections, we can calculate the solution $u(x, t)$ by dividing the time domain into finite intervals of length 2. Finally, the resonance results can be analyzed by the map of the solution from $t = 2n$ to $t = 2(n + 1)$, which are in agreement with those obtained by using a numerical method.

Statement of the problem

Figure 1: The transverse vibrating string with a time-varying spring-stiffness support at $x=L$.

In this paper we study resonance for a nonhomogeneous wave equation (see Figure 1), where one end is attached to a spring for which the stiffness properties change in time (due to fatigue, temperature change, and so on). By using Hamilton's principle, the system can be written as:

$$\rho u_{tt}(x, t) - Pu_{xx}(x, t) = \varepsilon \cos(\omega t), \quad 0 < x < L, \quad t > 0, \quad (1)$$

where ρ is the mass density, P is the axial tension which is assumed to be constant, L is the distance between the supports, and u describes the lateral displacement of the string. $\varepsilon \cos(\omega t)$ is an external force acting on the whole string, where ε and ω are constants. The boundary conditions are:

$$u(0, t) = 0, \quad Pu_x(L, t) + k(t)u(L, t) = 0, \quad t > 0, \quad (2)$$

where $k(t)$ is the time-varying stiffness of the spring at $x = L$. The boundary condition at $x = 0$ is a Dirichlet type of boundary condition, and the boundary condition at $x = L$ is a Robin type of boundary condition with a time-dependent coefficient $k(t)$. Based on the Buckingham Pi theorem, the governing equation (1), the boundary conditions (2), and the initial conditions can be transformed to the following non-dimensional form:

$$\begin{cases} u_{tt}(x, t) - u_{xx}(x, t) = \varepsilon \cos(\omega t), & 0 < x < 1, \quad t > 0, \\ u(0, t) = 0, \quad u_x(1, t) + k(t)u(1, t) = 0, & t > 0, \\ u(x, 0) = f(x), \quad u_t(x, 0) = g(x), & 0 < x < 1. \end{cases} \quad (3)$$

Numerical example of Resonance

This section is devoted to presenting some numerical simulations on the dynamical resonance behavior of system (3) for two cases. Let us first assume that $\varepsilon = 1$ and the following initial conditions are given:

$$f(x) = \sin^2(1.7155x), \quad g(x) = 0, \quad 0 < x < 1. \quad (4)$$

Case 1: $k(t)$ is constant

Choosing $k(t) = 2$ and setting $\omega = \lambda_1$ (λ_i satisfies the transcendental equation $-\frac{1}{k}\lambda_i = \tan(\lambda_i)$) the solution of the nonhomogeneous wave equation (3) can be obtained, and is given as in Figure 2-1 (where a resonance arises).

Case 2: $k(t)$ is not constant ($k(t) = \frac{1}{at+1}$)

Let $k(t) = \frac{1}{at+1}$. We know the eigenvalues λ satisfy approximately $-(at+1)\lambda = \tan(\lambda)$ (see Figure 3). By giving fixed values for " ω " and " a ", different solution shapes can be obtained as time increases (see Figure 2-2 to 2-4). Resonances might occur (or not) depending on the choices for " ω " and " a ".

 Figure 2-1: The solution $u(x, t)$ with $k=2$, $\omega=2.2889$.

 Figure 2-2: $\omega = 1.329$, resonance zone is around (2, 16).

 Figure 2-3: Resonance arises when $\omega = \frac{\pi}{2}$.

 Figure 2-4: No resonance when $\omega = \pi$.

Resonance (unbounded solution) analysis

The analytical solution based on the method of d'Alembert

According to the method of d'Alembert (see [1]), the general solution to Eq.(3) is given by

$$u(x, t) = \frac{1}{2}[f(x-t) + f(x+t)] + \frac{1}{2} \int_{x-t}^{x+t} g(s)ds + \varepsilon \int_0^t (t-\tau) \cos(\omega\tau) d\tau.$$

It should be noted that the functions f and g are only defined on the interval $[0, 1]$. To extend f and g on the whole domain $(-\infty, +\infty)$, the boundary conditions should be considered.

The nonhomogeneous wave equation we considered above in Eq.(3) has a propagation speed of 1, which implies that the vibration information at the point $x = x_i$ and $t = 0$ will propagate into two different directions with speed 1, and the information will be back to the position x_i at $t = 2$ as shown Figure 4-1. Furthermore, Figure 4-2 shows the domain of dependence. Then by treating the state at $t = 2$ as a new initial condition and using the same extension procedures, the information needed to calculate the solution of the equation up to every time can be obtained (for details see [2]).

 Figure 3: The resonance produced by different values of ω .

Figure 4-1: Wave reflections.

Figure 4-2: Domain of dependence.

Solution and mapping

The resonance results can be analyzed by the map of the solution based on the proposed method (the method of d'Alembert), from $t = 2n$ to $t = 2(n+1)$, which turns out to be in complete agreement with those obtained by using a numerical method.

Summary. Human balancing on rolling balance board in the sagittal plane is analyzed by a two-degree-of-freedom mechanical model. Human body is modeled by an inverted pendulum. The geometry of the balance board can be adjusted: the radius of the wheels and the elevation between the top of the wheel and the board can be changed. The central nervous system is modeled by a delayed proportional-derivative (PD) controller, where the constant feedback delay corresponds to the human reaction time. A critical delay can be defined for each setting of the balance board geometry: if the reaction time is larger than the critical delay, then there are no control gains that can stabilize the system. The critical time delays were determined by a numerical method for four balance board geometry with different radii. Balancing trials by a human subject were analyzed and the reaction time was estimated by comparing the theoretical and experimental results. In this particular balancing task, the reaction time was estimated to be 170 ms.

Introduction

Stabilization of the human body around an unstable equilibrium is controlled by the central nervous system (CNS). The sensory organs obtain information about the spatial position and velocity of the body and the CNS determine the corrective movement in order to maintain equilibrium. This process requires certain amount of time, therefore the balancing task can be modeled as a delayed control system, where the feedback delay is identical to the reaction time. In this study, CNS is assumed to obtain information about the angular position and angular velocity of the balance board and the human body, therefore delayed PD controller with constant time delay τ is used in the model. Nowadays, more and more accidents are caused by loss of balance during everyday activities, especially in the elderly societies. One of the main reasons of falls is the increased reaction time. Understanding the control concept and the effect of increasing feedback delay, therefore may help to predict and prevent falls.

Mechanical model

Human balancing on rolling balance board with adjustable geometry is analyzed in this work. The radius R of the wheels and the elevation h between the top of the wheel and the board can be changed, which highly influence the difficulty of balancing. Previous experiments showed that ankle strategy is dominant during balancing on rolling balance board in the sagittal plane, and oscillations at the hip are negligible compared to that at the ankle. Therefore, human body was modeled as an inverted pendulum which connects to the balance board through the ankle joint as can be seen in Fig. 1a. The control torque

$$T(t) = P_\varphi \varphi(t - \tau) + D_\varphi \dot{\varphi}(t - \tau) + P_\vartheta \vartheta(t - \tau) + D_\vartheta \dot{\vartheta}(t - \tau) \quad (1)$$

is applied at the ankle, where $P_\varphi, P_\vartheta, D_\varphi, D_\vartheta$ are the proportional and derivative control gains with respect to the generalized coordinates, which are the angle φ of the human body and angle ϑ the balance board measured from the equilibrium. Following [2], the passive stiffness s of the ankle is determined using the mass m_h and height l of the balancing subject as

$$s = 0.91 m_h g \frac{l}{2}. \quad (2)$$

The position of the ankle are described by parameter e and f as shown in Fig. 1a. The center of gravity, mass m_h and mass moment of inertia I_h of the human body were determined based on the literature [1]. The same parameters for the balance board (l_b, m_b, I_b) were calculated using the actual geometry.

Stability analysis

After deriving the governing equations of motion of the system, and linearization about the equilibrium, the mathematical model is obtained as a system of delay differential equations of the retarded type. Stability is analyzed in the four-dimensional space of the control gains $P_\varphi, P_\vartheta, D_\varphi, D_\vartheta$ for a fixed delay τ . If the value of the delay is increased, then the size of the stable domain of gains decreases and it completely disappears at a specific value, which is called critical delay (τ_{crit}). Stability analysis was performed over a non-uniform grid in the four-dimensional space ($P_\varphi, P_\vartheta, D_\varphi, D_\vartheta$) such that $\pm 10\%$ inaccuracy was allowed the control gains. The critical delay was determined numerically using the Walton-Marshall method [3] above the four-dimensional grid for four different radius of the balance board ($R = 125, 100, 75, 50$ mm). The board elevation $R - h$ was the same in all cases, such that the board was adjusted to the lowest position of the wheel. The calculated critical delays are shown in Fig. 2. It is assumed that if the reaction time of the balancing subject is lower than the critical delay obtained based on the mechanical model, then the subject is able to stand on the balance board.

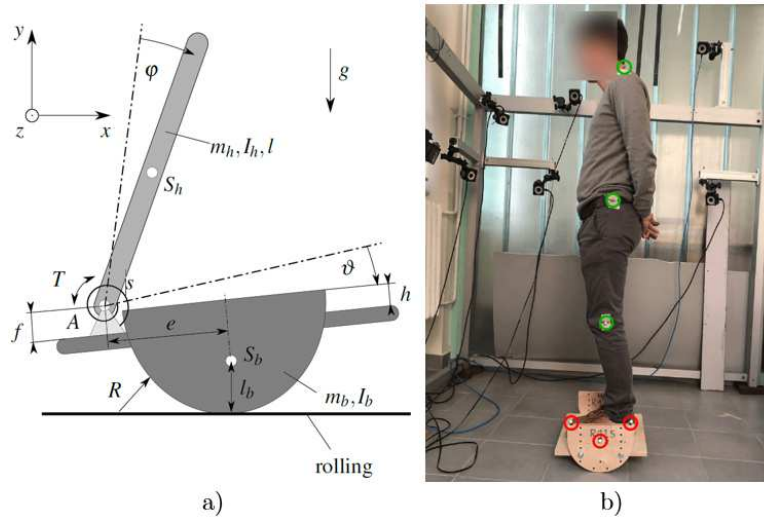

Figure 1: a) Mechanical model of human balancing on rolling balance board in the sagittal plane. b) Measurement setup.

Figure 2: Estimation of reaction time based on experimental and numerical results.

Experimental analysis

The numerical results of the mechanical model were compared with actual balancing trials. A balancing subject was asked to stand on the balance board with radius 125, 100, 75, and 50 mm. The task was to stand at least 60 s long with stretched legs and open eyes. The arms had to be held at the back as shown in Fig. 1b. Standing on the balance board with radius 125, 100, and 75 mm was successful, however, the subject was not able to stand on the balance board associated with 50 mm radius as indicated by green and red colors in Fig. 2. This means that the reaction time is between the critical delays obtained for 50 and 75 mm, which gives approximately 170 ms.

Conclusion

The reaction time can be estimated by comparing experimental and numerical results of a balancing task. The reaction time of the subject is 170 ms, which is in the range of the values that can be found in the literature [4, 5]. In the future, the calculations and experiments will be repeated involving larger number of participants.

Summary. Time-delayed dynamical systems (TDSs) materialize in situations where distant, point-wise, nonlinear nodes exchange information that propagates at a finite speed. They are akin in their complexity to spatially extended *dissipative and diffusive* systems. However, they are considered devoid of dispersive effects, which are known to play a leading role in pattern formation and wave dynamics. It explains why the existence of nonlinear conservative TDSs remains an open problem. In this work we show how dispersion may appear naturally in a wide class of delayed systems that can lead to conservative dynamics. We exemplify our result considering a dispersive micro-cavity containing a Kerr medium coupled to a distant external mirror. At low energies and in the long delay limit, a multi-scale analysis shows the equivalence with the nonlinear Schrödinger equation.

Introduction

Delayed dynamical systems describe a large number of phenomena in nature and they exhibit a wealth of dynamical regimes such as localized structures, fronts and chimera states [1, 2, 3, 4, 5]. The presence of delayed terms is connected with the finite propagation speed of signals, hence delayed systems are widely used to model, e.g., networks, map lattices or optical systems. A fertile perspective lies in their interpretation as spatially extended *diffusive* systems which holds in the limit of long delays [6]. This correspondence enables a direct interpretation of purely temporal phenomena in terms of diffusive, dissipative spatio-temporal dynamics. It was shown recently[7] that a more general class of singularly perturbed TDSs allows to cancel this generic diffusive behavior which lead to a dispersive response and the purely imaginary eigenvalue spectrum typical of reversible systems. However, the question whether conservative solitons can be obtained in such TDSs remains open. In this contribution, we demonstrate the existence, that remained elusive so far, of nonlinear, time-reversible, conservative TDSs leading to conservative solitons.

Results

We consider a micro-cavity containing a nonlinear Kerr medium coupled to an external mirror as depicted in Fig. 1 (a). Our theoretical approach follows the method developed in [8] and the dynamical model for the slowly varying electromagnetic field envelopes in the micro-cavity E and the external cavity Y reads

$$\dot{E} = (-1 + i|E|^2)E + hY, \quad (1)$$

$$Y = r_e e^{i\varphi} [E(t - \tau) - Y(t - \tau)]. \quad (2)$$

We scale time to the photon lifetime in the micro-cavity and the cavity enhancement is scaled out allowing E and Y to be of the same order of magnitude leading to a simpler input-output relation: The cavity output $O = E - Y$ is the combination of the intra-cavity photons transmitted by the micro-cavity and those reflected. Finally, the field intensities are scaled by the intra-cavity enhanced Kerr saturation parameter. The coupling between the fields E and Y is given in Eq. (2). Due to the absence of the time derivative, the latter is a Delay Algebraic Equation (DAE) that takes into account all the multiple reflections in the external cavity. The field is re-injected after a round-trip τ with the attenuation factor $r_e e^{i\varphi}$, where r_e is the external-mirror reflectivity and the phase φ contains both the propagation phase as well as that of the external mirror. The light coupling efficiency in the cavity is given by the factor $h = (1 + |r_2|)(1 - |r_1|)/(1 - |r_1 r_2|)$, where $|r_{1,2}|$ are the upper and lower distributed Bragg mirror reflectivities (cf. Fig. 1 (a)). In particular, for a perfectly lossless bottom mirror $|r_2| = 1$ yields $h = 2$, which corresponds to the Gires-Tournois regime [9]. Second- and third-order dispersion are naturally captured by Eqs. (1,2) as was shown in [7].

The system (1,2) possesses infinitely many degrees of freedom and its eigenvalue spectrum is a countably infinite set. In the long delay limit $\tau \rightarrow \infty$ the spectrum becomes quasi-continuous [10] and the real part of the eigenvalues, obtained

Figure 1: a) A schematic of a micro-cavity enclosed by two distributed Bragg mirrors with reflectivities $r_{1,2}$. It is coupled to a long external cavity with round-trip time τ which is closed by a mirror with reflectivity r_e . E is the field inside the micro-cavity while Y is the field impinging upon the top mirror. b) The eigenvalue spectrum of Eqs. (3,4) for different values of h and r_e . For $h < 2$ and $r_e < 1$ (red dots) the spectrum resembles an inverted parabola. When $h \rightarrow 2$ (blue dots) it flattens as $\gamma_m \tau = \ln r_e$. For $r_e \rightarrow 1$, the spectrum converges to the imaginary axis.

around the $(E, Y) = (0, 0)$ solution, $\lambda_m = \gamma_m + i\omega_m$ can be expressed as a function of its imaginary part as [7]

$$\gamma_m = \frac{1}{\tau} \left(\ln r_e + \frac{h-2}{1+\omega_m^2} \right), \quad (3)$$

$$\omega_m \tau + 2 \arctan \omega_m = \frac{h-2}{1+\omega_m^2} \omega_m + 2\pi m, \quad (4)$$

with $m \in \mathbb{Z}$, see the red dots in Fig. 1 (b). Note that for $h = 2$ the real part γ_m does not depend on ω_m yielding a vertical, yet lossy, spectrum which is shifted from zero by $\ln r_e / \tau$ (blue dots). In what follows we consider the lossless cavity limit that corresponds to $(r_e, h) = (1, 2)$ and where λ_m converges towards the unitary spectrum presented in solid black in Fig. 1 (b). In itself, a unitary spectrum is rather surprising in the context of TDSs since it implies the possibility to integrate linear perturbations backward in time without any particular problem.

The link between Eqs. 4(1),(2) and the nonlinear Schrödinger (NLS) equation can be clarified by performing a multi-scale. We introduce the two time representation by defining $\sigma \in [0, \tau]$ and $\theta \in \mathbb{N}$ so that time can be expressed a $t[\sigma, \theta] = \sigma + \theta\tau$. Assuming a field with carrier frequency δ as $E(t) = A(t) \exp(i\delta t)$ one obtains the following amplitude equation

$$i(\partial_\theta + v\partial_\sigma)A + \tilde{\varphi}A - \frac{\beta_2}{2}\partial_\sigma^2 A - i\frac{\beta_3}{6}\partial_\sigma^3 A + \gamma|A|^2 A = 0, \quad (5)$$

that is, the NLS equation with third order dispersion. Changing the carrier frequency allows to modify the sign and even cancel the second order dispersion coefficient β_2 which corresponds to the transition from anomalous to normal dispersion while third order dispersion β_3 can also cancel for some particular value of the carrier frequency $\delta_\pm = \pm 1/\sqrt{3}$. In this case Eq. (5) is equivalent to the classical NLS equation up to fourth order. From this equivalence, we observed that in the anomalous dispersion regime the Eqs. (1),(2) allows for the existence of bright hyperbolic secant solitons while we also observed dark solitons for normal dispersion. Our results were confirmed using the continuation package ddebiftool [11]. Finally, one can rewrite the Eqs. (1),(2) as a Neutral Differential Delayed Equation (NDDE)

$$E + \dot{E} - i|E|^2 E = \left(E_\tau - \dot{E}_\tau + i|E_\tau|^2 E_\tau \right) e^{i\varphi}. \quad (6)$$

The Eq. (6) is a so-called bilateral NDDE which preserves its type under time inversion. This property, as well as the presence of a purely imaginary nonlinearity that corresponds to the Kerr effect allows to demonstrate the reversibility in time of the dynamics under the parity-conjugation symmetry.

Conclusions

We discussed how second and third order dispersion can be implemented in delayed dynamical systems using delay algebraic equations and how this particular form of dynamical systems appears naturally as a boundary conditions on a partially reflecting micro-cavity. Using a realistic photonic example, we have demonstrated that nonlinear reversible TDSs exist and that they can host conservative solitons in the long delay limit, thereby bridging the gap with the results known for dissipative TDSs. The essential structure consists of a bilateral NDDE with an imaginary cubic nonlinearity which preserves the solution smoothness upon forward and backward propagation and may generate a unitary spectrum. The normal form identifies with the NLS equation, thereby allowing for bright and dark solitons. We believe that bilateral NDDEs open an avenue for the potential realization of conservative nonlinear dynamics in TDSs, such as, e.g., the Fermi-Pasta-Ulam-Tsingou [12] recurrence or the observation of the Korteweg-de-Vries solitons.

Destabilizing effect of back electromotive force along the cyclic coordinate in case of a digitally controlled Furuta pendulum

Mate Benjamin Vizi and Gabor Stepan

Department of Applied Mechanics, Budapest University of Technology and Economics, Budapest, Hungary

Summary. Two usually neglected effects are considered in the mechanical model of the Furuta pendulum: the additional viscous damping caused by back electromotive force and the sampling delay caused by the digital control. These effects have relevant influence on the choice of the control algorithm and on the stability properties of the upward position of Furuta pendulum.

Introduction

The Furuta pendulum [1] is a relatively simple two degree of freedom mechanical device (see the left panel of Figure 1), which has become a commonly used equipment for demonstrating various control algorithms applied on a highly nonlinear dynamical system. The arm is usually driven by an electric DC motor and the pendulum hangs freely, so this system is underactuated. The control signal is the input voltage of the motor, and its calculation by means of a digital controller requires the consideration of both the sampling delay and the additional viscous damping caused by the back electromotive force appearing in the real system. This work considers these two often neglected effects; the consequences on stability and possible control algorithms are discussed.

Governing equations

The nonlinear equations of motion of the Furuta pendulum can be obtained by means of the Lagrangian equations of the second kind in the form of:

$$(J_a + J_p \sin^2 \theta) \ddot{\varphi} - (m_2 r l \cos \theta) \ddot{\theta} + 2J_p (\sin \theta \cos \theta) \dot{\theta} \dot{\varphi} + (m_2 r l \sin \theta) \dot{\theta}^2 = M, \quad (1)$$

$$J_p \ddot{\theta} - (m_2 r l \cos \theta) \ddot{\varphi} - J_p (\sin \theta \cos \theta) \dot{\varphi}^2 - m_2 g l \sin \theta = 0, \quad (2)$$

where θ is the pendulum angle, φ is the arm angle, $J_p = m_2 l^2 + J_2$ and $J_a = m_1 (r/2)^2 + m_2 r^2 + J_1$ are corresponding mass moments of inertia; the other mechanical parameters are shown in Figure 1. The control torque M applied on the arm is usually provided by a DC motor, for which the output torque can be determined based on the governing equations of the electric motor as a function of the input voltage U_{in} and the motor angular speed which is proportional to the arm angular velocity $\dot{\varphi}$ of the Furuta pendulum:

$$M = N U_{in} - K \dot{\varphi}. \quad (3)$$

The constants N and K are the motor parameters related to the input voltage and back electromotive force, respectively. Note that substituting this into the equation of motion, the back electromotive force is analogous to a viscous damping force applied at the arm. Considering that the input voltage is determined by a digital microcontroller, sampling delay appears in the feedback loop in the following form

$$U_{in}(t) = -P_1 \theta(t_{j-1}) - D_1 \dot{\theta}(t_{j-1}) + D_2 \dot{\varphi}(t_{j-1}), \quad t \in [t_j, t_{j+1}), \quad (4)$$

where P_1, D_1, D_2 are the control gains; $t_j = j\tau$, $j \in \mathbb{Z}$ is the j^{th} sampling instant, and τ is the sampling time, which is assumed to be constant. Alternatively, if the angular velocity $\dot{\varphi}$ cannot be measured, then the application of an integral term can be considered in the feedback loop:

$$U_{in}(t) = -P_1 \theta(t_{j-1}) - D_1 \dot{\theta}(t_{j-1}) - I_1 \tau \sum_{i=0}^{j-1} \theta(t_i), \quad t \in [t_j, t_{j+1}), \quad (5)$$

In what follows, we discuss the case of Equation (4).

Results

The sampling delay causes stability problems in the control systems as shown in [3, 4]. Based on the linearized system model, the critical sampling time can be calculated; this is the maximal sampling time of the digital control for which the pendulum can be stabilized with appropriate control gains. The minimal value of $D_{2,\min} > 0$ control gain can also be determined, which means the simplest $P_1 D_1$ controller (with $D_2 = 0$) cannot stabilize the system. In other words, the upward pendulum position $\theta = 0$ is unstable for any P_1, D_1 control gains without feedback of the arm angular velocity (or the integral of the pendulum angle, see (5)). This instability is caused by the back electromotive force of the DC motor, which is similar to the viscous damping along the cyclic coordinate, while the inverted pendulum is underactuated

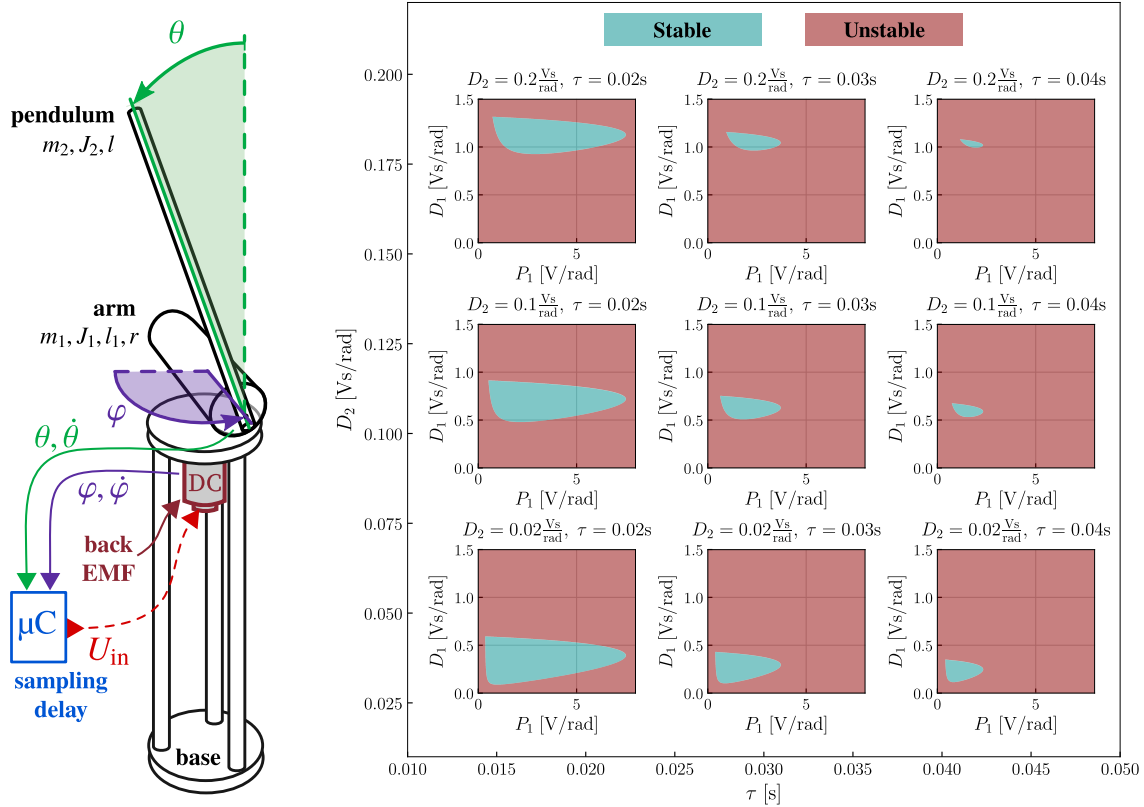

Figure 1: The Furuta pendulum (left) and the four dimensional stability chart of the Furuta pendulum which takes into account the back electromotive force of the DC motor and the sampling delay of the feedback loop (right).

due to the control force applied along the cyclic coordinate only. In case of standard positioning tasks of fully actuated systems, the back electromotive force does not cause such kind of instability, moreover, it is often considered useful because of its extra damping effect. In case of the underactuated control task like the Furuta pendulum, the presence of back electromotive force makes the system inherently unstable in case of classical PD control, this is the reason why an improved control law is needed to achieve stable system behavior: either the feedback of the arm (motor) angular velocity $\dot{\varphi}$ with a $D_2 > D_{2,min}$ control gain is needed, or an integral gain has to be used with respect to the pendulum angle θ . The results of the corresponding calculations are represented by stability charts in the right panel of Figure 1, in the space of four parameters: the sampling time τ and the three control gains P_1, D_1, D_2 . It can be seen, that the size of the stable parameter region becomes smaller with increasing sampling time τ and it completely vanishes at the identified critical values. The effect of the parameter D_2 is similar: the stable regions disappear above maximal and below minimal gain values. The stability charts are similar if the integral gain I_1 is applied as shown in Equation (5).

Conclusions

It was found that the simple $P_1 D_1$ control law applied on the pendulum angle θ and angular speed $\dot{\theta}$ is insufficient in the presence of cyclic viscous damping or back electromotive force; an improved control algorithm is necessary, by extending the $P_1 D_1$ controller with an extra derivative term D_2 applied on the angular speed $\dot{\varphi}$ or with an extra integral term I_1 applied on the pendulum angular position θ . The critical sampling times of the digital control loops can also be determined, which are identified also by laboratory experiments on the Furuta pendulum.

Summary. We study theoretically the formation and dynamics of phase-locked temporal localized states (TLSs) and frequency combs that can be generated from a high finesse Fabry-Perot microcavity containing a Kerr medium that is coupled to an external cavity in the presence of optical injection. These TLSs possess a strongly asymmetrical oscillating tail which results from third order dispersion induced by the cavity. Using a first principle model based on delay algebraic equations and applying a combination of direct numerical simulations and path continuation methods, we disclose sets of multistable dark and bright TLSs coexisting on their respective bistable homogeneous backgrounds. In particular, we show that the detuning of the injection with respect to the microcavity resonance controls the region of existence of TLSs and its change can lead to a period-doubling route to chaos. Further we discuss a transformation of the original delay model to a normal form given by a partial differential equation using a rigorous multiple time scale analysis and a functional mapping approach.

Introduction

Time-delayed systems (TDS) describe a large number of phenomena in nature and they proposed for hosting localized structures, fronts and chimera states [1, 2, 3, 4, 5, 6, 7]. They also have been analyzed from the perspective of their equivalence with spatial extended systems [8]. In general, the expansion of a delayed term leads to drift and diffusion. However, it was shown [9] that considering a more general class of singularly perturbed TDS allows to cancel the generic diffusive behavior which leads to a dispersive response. Here, an example of TDS giving rise to second and third order dispersion (TOD), which combined with Kerr effect and optical injection is able to generate temporal localized states (TLSs), as well as molecules induced by third order dispersion [10].

Figure 1: A schematic of the coupled cavity configuration. E denotes the field amplitude in the Kerr region. The output and injection fields in the external cavity are represented by O and Y , respectively. The round-trip time is τ

Model

Our schematic setup is depicted in Fig. 1 in which we show i) the intra-cavity field E and ii) the external cavity field Y . We follow the approach of [11] that consists in solving the field propagation in the linear sections of the micro-cavity. That way one obtains a dynamical model linking the two fields E and Y . Their coupling is achieved considering the transmission and reflection coefficients of the top Distributed Bragg Mirror (DBR). After normalization, one obtains the rate equations for the fields E and Y

$$\frac{dE}{dt} = \left[-1 + i \left(\gamma |E|^2 - \delta \right) \right] E + hY, \quad Y = \eta [E(t - \tau) - Y(t - \tau)] + \sqrt{1 - |\eta|^2} Y_0. \quad (1)$$

The field cavity enhancement can be conveniently scaled out using Stockes relations allowing E and Y to be of the same order of magnitude. This leads to the simple input-output relation $O = E - Y$. The cavity-enhanced complex nonlinear coefficient is $\gamma = \gamma_r + i\gamma_i$, where γ_r stands for the self-phase modulation and γ_i models the two-photon absorption. The effects of the external mirror and signal extraction (e.g., a beam-splitter or transmission through the mirror itself) are combined in the attenuation factor $\eta = r_e \exp(i\varphi)$. The coupling between the intra-cavity and the external cavity fields E and Y is given in Eqs. (1) by a delay-algebraic equation (DAE). The latter takes into account all the multiple reflections in a possibly high finesse external cavity for which $|\eta| \lesssim 1$ [9]. Note that in the limit of a very low external mirror reflectivity $\eta \ll 1$, one would obtain $Y = \eta E(t - \tau) + O(\eta^2)$ leading to the so-called Lang-Kobayashi model [12].

Results

In [SCH19], the DAE system (1) was successfully used to prove the existence of multistable dark and bright TLS coexisting on their respective bistable homogeneous continuum wave (CW) backgrounds for fixed parameter values, see Fig. 2

Figure 2: (a) Bistable cavity response under CW injection (dotted line). The lower and upper snaking branches (full lines) correspond to the trains of bright (b) and dark (d) TLSs observed as a function of time t . The inset shows the dynamics over many roundtrips. The respective frequency combs are depicted in panels(c) and (e), where the injection frequency was cut for clarity.

Here, we conduct extensive direct numerical simulations of DAEs (1) in the combination with path continuation methods. In particular, the influence of the detuning δ is analyzed in details. We show that it controls the region of existence of TLSs and its change can lead to a period-doubling route to chaos.

Figure 3: A part of the branch of the TLS (blue) of DAEs (1) as a function of the injection Y_0 , obtained with the continuation methods together with the results of the direct numerical simulations (red). A period-doubling route to chaos is visible. Green line indicate a branch of period-doubled solutions.

Further, the influence of attenuation factor η will be studied. In particular, the regimes of low and high η will be assessed. We demonstrate that in the so-called good cavity limit ($\eta \rightarrow 1$), the dynamics is dominated by TOD leading to a wide region of multistability between bright and dark TLS.

Finally we discuss a transformation of the original DAE model (1) to a normal form at the onset of optical bistability given by a partial differential equation using a rigorous multiple time scale analysis and a functional mapping approach.

Entrainment of Self-Organized Synchronized States in Delay-Coupled Oscillators

Dimitrios Prousalis, Frank Jülicher and Lucas Wetzel

*Max Planck Institute for the Physics of Complex Systems, Nöthnitzer Straße 38, 01187 Dresden, DE

Summary. This work presents how synchronized states that self-organize in networks of mutually coupled oscillators can be entrained by an external reference oscillator. A second-order Kuramoto model with time-delayed coupling is used to predict the phase-differences in the network and the stability of the entrained states. The model predictions are then verified by experimental measurements.

Introduction

Synchronization is important for well-defined and concerted operations and provides the means to establish and keep time-synchronization in networks of spatially distributed clocks [1]. In technical applications synchronization is usually achieved by entraining an oscillator with a periodic signal of a high quality reference oscillator [2]. In natural systems self-organized synchronization is prevalent and based on a mutual coupling between, e.g., cellular oscillators. In this manuscript we study the complex dynamics in finite system of inert, mutually delay-coupled oscillators when subject to an external forcing. The theoretical results for the minimal case, where a reference entrains a network of two mutually delay-coupled oscillators, are verified by experiments with electronic phase-locked loop (PLL) oscillators [4]. We discuss the experimental results taking into account the basins of attraction of the synchronized states that are studied.

Model for Studying the Entrainment of Networks of Mutually Delay-Coupled Oscillators

The dynamics in networks of inert, delay-coupled oscillators can be studied using a second-order Kuramoto model [3, 4]

$$m_k \ddot{\theta}_k(t) + \dot{\theta}_k(t) = \omega_k + \frac{K_k}{n_k} \sum_{l=1}^N c_{kl} h(\theta_l(t - \tau_{kl}) - \theta_k(t)), \quad (1)$$

where $k = 1, \dots, N$ indexes the N oscillators, $\omega_k \in \mathbb{R}$ denotes the intrinsic frequencies, $h(\cdot)$ a periodic coupling function, $K_k \geq 0 \in \mathbb{R}$ the coupling strength, $m_k \geq 0 \in \mathbb{R}$ an inertial parameter, $n_k \geq 0 \in \mathbb{N}_0$ the number of inputs of oscillator k , $\theta_i(t) \in S^1$ for $i = \{k, l\}$ the phases of the oscillators' output signals with $\dot{\theta}(t)$ and $\ddot{\theta}(t)$ denoting their first and second time derivatives, $c_{kl} = \{0, 1\}$ the components of the network's adjacency matrix, and $\tau_{kl} \in \mathbb{R}$ denotes the cross-coupling time delays. The ansatz to study synchronized states and their linear stability is

$$\theta_k(t) = \Omega t + \beta_k + \epsilon q_k(t), \quad (2)$$

where Ω denotes the global frequency of a synchronized state, $\epsilon q_k(t)$ a small perturbation ($\epsilon \ll 1$), and β_k a phase-offset.

Network of mutually delay-coupled oscillators: frequency and phase differences of synchronized states

Using the ansatz (2) in Eqs. (1) and expanding $h(\cdot)$ to first order with respect to ϵ , we obtain the properties of synchronized states from $\mathcal{O}(\epsilon^0)$: $\Omega = \omega_k + K h(-\Omega \tau_{kl} + \beta_{kl})$, where $\beta_{kl} = \beta_k - \beta_l$, e.g., equal to 0 or π for identical oscillators. The linear stability of these states depends on the the oscillator's parameters and the properties of the synchronized states [4].

Individual oscillator entrained by a reference: phase difference with respect to reference oscillator

Here, the frequency of the synchronized state is determined by the reference $\Omega = \omega_R$. The phase difference is $\beta = -h^{-1}[(\omega_R - \omega)/K] - \omega_R \tau$. The stability depends only on the detuning of the frequencies and the coupling strength [5].

Networks of mutually delay-coupled oscillators entrained by a reference: phase differences

Here, we consider a network of heterogeneous oscillators, making the ansatz (2) for $\Omega = \omega_R$. The entrainment is accounted for by assigning the reference oscillator with $k = 1$ and setting $c_{1l} = 0 \forall l$. The $N - 1$ phase differences can then be obtained from

$$\omega_R = \omega_k + \frac{K_k}{n_k} \sum_{l=1}^N c_{kl} h[-\omega_R \tau_{kl} - \beta_{kl}]. \quad (3)$$

Example of a Minimal Entrained Network and Experimental Verification

We study a network of two mutually coupled oscillators one of which is forced by an external reference, see Fig. 1. From Eq. (3) the phase differences between the mutually coupled oscillators $\beta_{23} = \omega_R \tau_{32} + h^{-1}[(\omega_R - \omega_3)/K_3]$ and that to the reference $\beta_{R2} = \omega_R \tau_{R2} + h^{-1}[(\omega_R - \omega_2)/K_2 - h[-\omega_R \tau_{23} - \beta_{23}]]$ are obtained. The theoretical predictions and the experimental results β_{23} and β_{R2} of the synchronized states are shown as a function of the reference frequency in Fig. 2c. The range of reference frequencies for which synchronized states are linearly stable is shown in green. In experiments however, we only find stable synchronized states in a smaller range than predicted. This can be explained by the basins of attraction obtained from time-series simulations shown in Figs. 2a, 2b. They show the basins for different initial phase histories for $t \in [-\tau, 0]$. In Fig. 2a all oscillators are initially free-running, as can be realized in the experimental setup.

Figure 1: a) Sketch of entrainment of a network of two mutually delay-coupled oscillators. b) The experimental setup consists of a microcontroller that organizes the delay-coupling between the two mutually coupled PLLs and the entrainment by a virtual reference derived from its internal clock. For details about the experimental setup see reference [4].

In Fig. 2b, the simulation starts in the entrained synchronous state, similarly to linear stability analysis. Their x- and y-axis represent the phase differences $\phi_1 = \theta_3(0) - \theta_2(0)$ and $\phi_2 = \theta_3(0) - \theta_1(0)$ between the oscillators at $t = 0$, respectively. The color encodes the asymptotic value of the order parameter for any combination (ϕ_1, ϕ_2) , obtained from a time series simulation of the oscillator network using the Eqs. (1). The order parameter has been modified such that it is equal to one if the phase configuration of the entrained synchronous state under investigation is achieved [3]. From Fig. 2a it can be understood that the basin of attraction has zero volume close to the boundaries of linear stability. Hence, we cannot find entrained synchronous states with the experimental setup (Fig. 1b) that always starts from an initially free-running state.

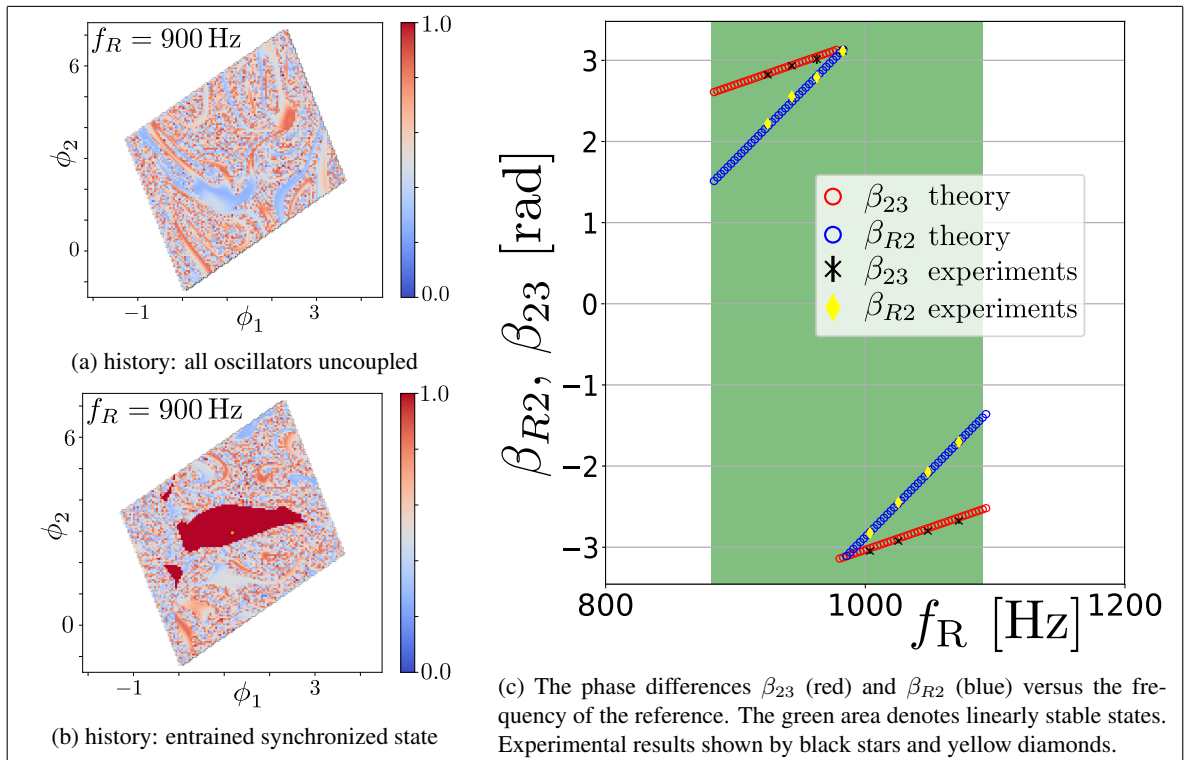

Figure 2: Parameters: $\omega_2 = 1004 \cdot 2\pi$ Hz, $\omega_3 = 996 \cdot 2\pi$ Hz, $K_2 = 423 \cdot 2\pi$ Hz, $K_3 = 408 \cdot 2\pi$ Hz, and $\tau_{R1} = \tau_{12} = 0.265$ s.

Conclusions

This work studies the entrainment of self-organized synchronous states. Our phase oscillator model takes into account time-delays in the coupling and inert oscillator response. It predicts the properties of entrained synchronous states as verified here by experimental results obtained from electronic oscillators. Self-organized synchronous states can be viewed as an effective oscillator that has emerged over a network of mutually coupled oscillators. This effective oscillator is characterized by its quiescent frequency Ω and the frequency range within which it can lock to a reference. Both properties affect the linear stability of entrained synchronous states and depend on the delays within the mutually coupled oscillators. The delay between reference and network only affects the phase differences of the entrained synchronized states.

Human positioning of a planar pendulum

Bence Szaksz and Gabor Stepan

Department of Applied Mechanics, Budapest University of Technology and Ec., Budapest, Hungary

Summary. The human positioning of a planar pendulum is investigated. The system is modelled with two particles which are connected with a rope. Collocated proportional-derivative control acts with human reaction delay at the suspension point of the pendulum that can only move horizontally. The Hopf bifurcation analysis of the system is executed which leads to closed form algebraic expressions for the Poincaré-Lyapunov coefficient and for the amplitude of oscillation.

Introduction

The motion of a planar pendulum is examined at its downward position considering human position control. The human intervention is modelled with a proportional-derivative (PD) controller subjected to constant reaction delay, which leads to a system of delay differential equations (DDEs). The inclusion of the time delay implies that the stability region in the PD-plane will be bounded and sub- and supercritical Hopf bifurcations appear along the stability boundary. The stability and amplitude of the periodic solutions close to the bifurcation point are calculated analytically leading to closed form algebraic equations. We follow the algebraic procedures of Hopf bifurcation calculation as given in [1, 2, 3].

Mechanical model

The coupled hand-held pendulum system is modelled with two point masses connected with a rope as shown in Fig. 1. The human hand is modelled with the mass m_1 on which the control force F acts; this is the pivot point of the planar mathematical pendulum with mass m_2 and length l . The controlled mass can slide in a linear guide so that it can only move along the x axis. The horizontal displacement of the hand and the bottom point of the pendulum are denoted with x_1 and x_2 , respectively. The equations of motion of the system are derived with respect to the two generalized coordinates

Figure 1: In-plane model of the coupled hand-pendulum system

x_1 and x_2 [4]. These expressions are highly nonlinear, therefore, their Taylor series are calculated up to third order in x_1 and x_2 leading to the governing equations:

$$\ddot{x}_1 = \frac{F}{m_1} + \frac{m_2}{m_1} \frac{g}{l} (x_2 - x_1) - \frac{m_2}{m_1} \left(\left(\frac{m_2}{m_1} + \frac{1}{2} \right) \frac{g}{l^3} (x_2 - x_1)^3 - \frac{1}{l^2} (x_2 - x_1) (\dot{x}_2 - \dot{x}_1)^2 + \frac{F}{m_1 l^2} (x_2 - x_1)^2 \right), \quad (1)$$

$$\ddot{x}_2 = -\frac{g}{l} (x_2 - x_1) + \left(\frac{m_2}{m_1} + \frac{1}{2} \right) \frac{g}{l^3} (x_2 - x_1)^3 - \frac{1}{l^2} (x_2 - x_1) (\dot{x}_2 - \dot{x}_1)^2 + \frac{F}{m_1 l^2} (x_2 - x_1)^2, \quad (2)$$

where the time derivative is denoted by dot. The control force can be chosen in different ways. In this study, a collocated PD control is investigated which means that the human operator acts based on the displacement and velocity of his/her hand:

$$F(t) = -P x_1(t - \tau) - D \dot{x}_1(t - \tau). \quad (3)$$

Here, τ stands for the delay caused by the reaction time, while P and D are the proportional and derivative gain parameters, respectively.

Stability analysis

Introduce the dimensionless distances $\tilde{x}_i = x_i/l$ (for $i = 1, 2$) and the dimensionless time $\tilde{t} = t/\tau$, furthermore, the transformed characteristic exponents and angular frequencies $\tilde{\lambda} = \tau \lambda$ and $\tilde{\omega} = \tau \omega$, respectively. By abuse of notation we

drop the tildes and introduce the dimensionless parameters: $\mu = m_2/m_1$, $\alpha = \tau\sqrt{g/l}$, $p = P\tau^2/m_1$, and $d = D\tau/m_1$. Then the characteristic equation assumes the form:

$$D(\lambda) = \lambda^4 + d\lambda^3 e^{-\lambda} + \alpha^2(1 + \mu)\lambda^2 + p\lambda^2 e^{-\lambda} + \alpha^2 d\lambda e^{-\lambda} + \alpha^2 p e^{-\lambda} = 0. \quad (4)$$

When the real characteristic exponent crosses the origin at $\lambda = 0$, saddle-node bifurcation appears at $p = 0$. Hopf bifurcation occurs when a pair of complex conjugate roots lies on the imaginary axis at $\lambda = i\omega$, which yields the stability boundary curve:

$$p_{cr} = \left(1 - \frac{\mu\alpha^2}{\omega^2 - \alpha^2}\right) \omega^2 \cos \omega, \quad d_{cr} = \left(1 - \frac{\mu\alpha^2}{\omega^2 - \alpha^2}\right) \omega \sin \omega. \quad (5)$$

Let the proportional gain p be the bifurcation parameter. Then the real part of the root tendency $\lambda' = d\lambda(p_{cr})/dp$ assumes the form:

$$\Re(\lambda') = \frac{\omega}{4(a^2 + b^2)} \left(\sin \omega + \omega \cos \omega + \mu\alpha^2 \frac{\omega^2 + \alpha^2}{(\omega^2 - \alpha^2)^2} \sin \omega - \frac{\omega\mu\alpha^2}{\omega^2 - \alpha^2} \cos \omega \right), \quad (6)$$

where a and b can be expressed as

$$a = \frac{1}{2}\omega \left(1 - \frac{\mu\alpha^2}{\omega^2 - \alpha^2}\right) \left(\frac{1}{2}\sin(2\omega) - \omega\right), \quad b = \omega + \frac{\omega\mu\alpha^4}{(\omega^2 - \alpha^2)^2} - \frac{1}{2}\left(1 - \frac{\mu\alpha^2}{\omega^2 - \alpha^2}\right) \sin^2 \omega. \quad (7)$$

The Poincaré-Lyapunov coefficient Δ and the amplitude of oscillation A are obtained in the form:

$$\Delta = \frac{\mu}{8(a^2 + b^2)} \left(\frac{\omega^2}{\omega^2 - \alpha^2}\right)^4 \left(1 - \frac{\mu\alpha^2}{\omega^2 - \alpha^2}\right) \left(\frac{1}{4}\omega \sin(2\omega) - \frac{1}{2}\omega^2\right) \left(2\omega^2 - \frac{3}{2}\alpha^2\right), \quad (8)$$

$$A = \sqrt{-\frac{\Re(\lambda')}{\Delta}(p - p_{cr})} = \left(\frac{\omega^2 - \alpha^2}{\omega^2}\right)^2 \sqrt{-\frac{2 \sin \omega \left(1 + \mu \frac{\omega^2 \alpha^2 + \alpha^4}{(\omega^2 - \alpha^2)^2}\right) + \omega \cos \omega \left(1 - \mu \frac{\omega \alpha^2}{\omega^2 - \alpha^2}\right)}{\mu \left(1 - \mu \frac{\alpha^2}{\omega^2 - \alpha^2}\right) \left(\frac{1}{4}\omega \sin(2\omega) - \frac{1}{2}\omega^2\right) \left(2\omega^2 - \frac{3}{2}\alpha^2\right)} (p - p_{cr})}. \quad (9)$$

The first two terms of Eq. 8 are nonnegative, therefore the last three terms determine the sign of Δ and so the sense of the bifurcation. Fig. 2 shows the saddle node and Hopf bifurcation curves of the system indicating the sub- or supercritical nature as well. The boundary of the stable region is always supercritical.

Figure 2: Stability chart in the PD plane. The numbers indicate the number of unstable characteristic exponents. ($\mu = 1/30$, $\alpha = 1.1437$)

Conclusions

The model can explain why hand-held pendulums often oscillate in spite of the intention of the human operator.

Small and large amplitude, free oscillations of a pinned spherical interface

Yashika Dhote, Partha S. Goswami and Ratul Dasgupta
 Department of Chemical Engineering, IIT Bombay, Mumbai, India

Summary. We investigate using linearised theory and numerical solution to the incompressible Euler equation, the effect of density ratio and perturbation amplitude on shape oscillations of a pinned spherical interface. The interface in the base state is a spherical cap separating quiescent fluids and may be pinned at any angle lying in the interval $[0, \pi]$. The linearised analysis presented in [1] which takes into account the density of fluid inside the spherical cap only, is further extended to account for the density of fluids inside (ρ^I) as well as outside (ρ^O). The limits of linearised theoretical predictions are tested via numerical simulations by exciting the first eigenmode of the system at various pinning angles (α). For sufficiently small perturbation amplitude, the agreement with linearised predictions found to be quite good. A systematic nonlinear correction to frequency is observed as the perturbation amplitude is increased, becoming particularly discernable after the first few oscillations. The simulations are carried out using the open source code Gerris [8] and we quantify the effect of non-linearity and droplet ejection is observed due to increasing perturbation amplitude. We investigate the bubble limit and the droplet limit respectively where density of fluid inside the cap is negligible compared to that outside and vice versa.

Inviscid oscillations of a pinned interface

Natural and forced oscillations of a pinned spherical cap due to surface tension is of interest in numerous applications both in engineering as well as in the natural sciences and remains a topic of active research interest [2]. The frequency spectrum of small amplitude free oscillations of an inviscid free drop of unperturbed radius R_0 and density ρ^I due to the restoring force of surface tension T was first obtained by Rayleigh [9]. The effect of the second fluid on the spectrum was studied by Lamb [5] lead to the classical dispersion relation for shape oscillations of liquid drops ($\rho^I \gg \rho^O$) and bubbles ($\rho^O \gg \rho^I$):

$$\omega_0^2 = \frac{T}{R_0^3} \frac{l(l+1)(l-1)(l+2)}{\rho^I(l+1) + l\rho^O} \quad (1)$$

where l is a positive integer arising from the spherical harmonic $\mathbb{Y}_l^m(s, \psi)$. In many engineering applications like vibration induced atomisation [4], it is necessary to know the modification to the Rayleigh-Lamb frequency spectrum (eqn.1) due to the droplet resting on a substrate. While a number of studies have investigated this problem under the assumption of a hemispherical cap [6], the first study which systematically studied the modification to the spectrum for the case of a droplet pinned at an arbitrary angle α was by Steen [1]. As a part of the present study, we extend the analysis of their work to take into account the density of the second fluid on the shape oscillation of pinned bubbles. For this, we closely follow the analysis by Steen employing two spherical coordinate systems as shown in fig.1(a). It maybe shown that in the inviscid, irrotational approximation [3, 7] the perturbation velocity potential ϕ and the surface perturbation η can be expressed in the standing wave form [3].

$$\eta(s, \psi, t) = a(t)y(s)\exp(il\psi), \quad \phi^I(\rho, \theta, \psi, t) = \dot{a}(t) \Phi^I(\rho, \theta)\exp(il\psi), \quad \phi^O(\rho, \theta, \psi, t) = \dot{a}(t) \Phi^O(\rho, \theta)\exp(il\psi) \quad (2a,b,c)$$

Here, $\dot{a} \equiv \frac{da}{dt}$ and it maybe be further shown that $a(t)$ satisfies the simple harmonic oscillator equation $\ddot{a} + \omega_0^2 a(t) = 0$. The pinned frequency ω_0^2 is calculated by solving a generalised eigenvalue problem employing the Green function formalism suggested in [1] and additionally also taking into account both densities [3]. We test predictions made in the droplet and in the bubble limits using the open-source code Gerris [8] and these are described below in fig. 2, 3 and 4.

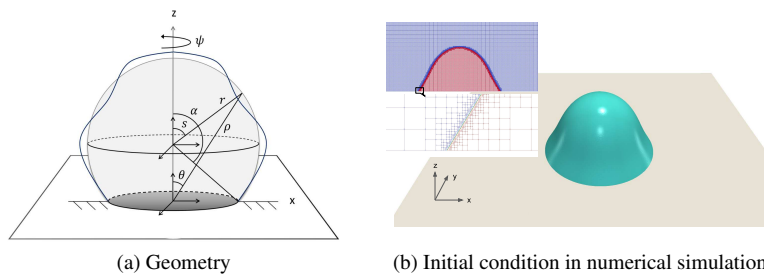

Figure 1: (a) A cartoon representation of a spherical cap (in the base state) pinned at an angle α on a substrate [1]. In close analogy to the linearised analysis by [1], we employ two spherical coordinates systems viz. one centred on the substrate with scaled coordinates (ρ, θ, ψ) and another centred at the spherical cap with scaled coordinates (r, s, ψ) . The density of the fluid inside is taken as ρ^I while that outside is ρ^O . (b) The initial deformation is obtained from linear theory by computing the eigenmodes which may be represented as $r = R_0 + a_0\eta(s, \psi)$. Shown here is the lowest axisymmetric eigenmode for a pinning angle of 80° . For consistency and to justify the neglect of gravity, R_0 is chosen to be much smaller than the capillary length scale. Grid density of 2048×2048 is used near the interface and 512×512 is used away from the interface.

Droplet Limit ($\rho^O/\rho^I \rightarrow 0$): Axisymmetric modes and comparison of linear theory with simulations

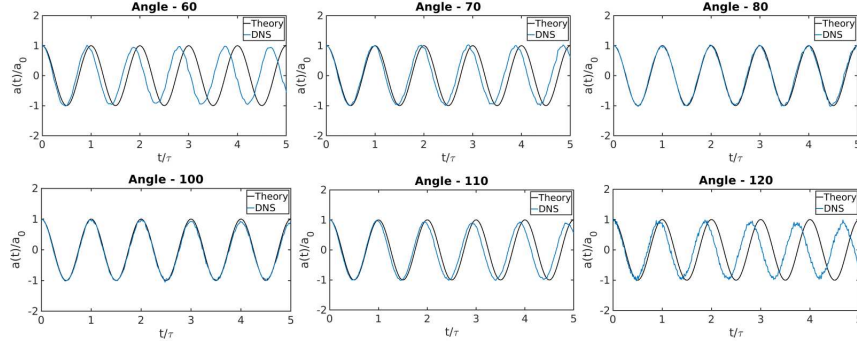

Figure 2: Time signal from oscillatory response of the interface obtained from numerical solution to the incompressible Euler equation (labelled as DNS in the plots) with surface tension (72 dyne/cm). We distort the spherical cap at the indicated pinning angle using the axis-symmetric eigenmodes with zero perturbation velocity as shown in fig.1b. In the droplet case, these eigenmodes are provided in [1] and correspond to the droplet limit. ($R_0 = 0.1 \text{ cm}$, $\rho^O/\rho^I = 0.001$). The time signals are measured at the interface at a location slightly off the apex of the spherical cap and compared to a sinusoidal signal with the frequency obtained by solving a generalised eigenvalue problem in Matlab [1, 3]. Note that the time t is non-dimensionalised by the time period τ predicted from linear theory [1]. A good agreement with linear predictions is seen in simulations with small disagreement in the predicted frequency around $\alpha = 60^\circ$ and $\alpha = 120^\circ$.

Bubble Limit ($\rho^O/\rho^I \rightarrow \infty$): axisymmetric modes and comparison with simulations

Figure 3: Oscillatory response obtained from numerical simulations in the bubble limit ($\rho^O/\rho^I = 1000$) and comparison with linearised predictions [3]. A reasonably agreement is seen in all cases for comparison of linear theory with simulations.

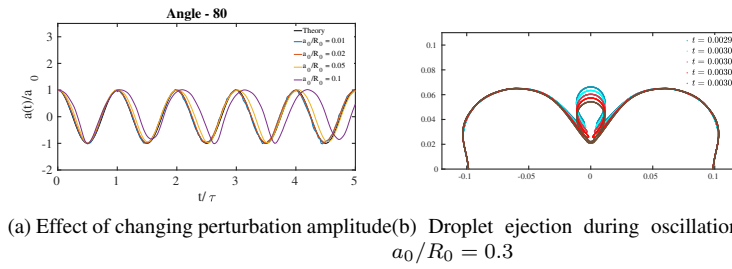

Figure 4: Effect of change of perturbation amplitude for a spherical cap pinned at 80° .

Fig. 4(a) shows the effect of increase of the perturbation amplitude a_0 . It is seen that the time signal becomes distinctly non-sinusoidal with a frequency which increases with increasing a_0 . Panel (b) of the same figure shows a large amplitude simulation where a droplet is (nearly) detached from the spherical cap as a result of large amplitude deformation. Systematic comparisons of nonlinear effects for free and pinned droplets will be discussed at the meeting.

Conclusions

We extend the theoretical formalism developed in [1] to include the effect of internal as well as external (linearised) fluid inertia for pinned spherical interfaces. For sufficiently small amplitude, we find good agreement with linearised theoretical predictions both in the droplet as well as the bubble limit. For perturbation amplitude exceeding about 10 percent of the spherical cap radius, discernable nonlinear effects are seen in the numerical simulations and in the large amplitude regime, droplet ejection is observed.

Summary. An attempt to solve the problem and to conduct a qualitative analysis of the forced vibration of the spring pendulum containing nonlinear springs connected in series is made in the paper. The method of multiple scales in time domain (MMS) has been employed in order to carry out the analytical computations. The MMS allows one, among others, to predict the resonances which can appear in the systems. The approximate solution of analytical form has been obtained for vibration at main resonance.

Introduction

Elastic elements arranged in various kinds of connections (in serial, in parallel or in branching) are widely applied in many mechanisms, mechatronic devices and more and more often in micromechanical systems [1], [7]. When the massless springs are connected in series or in branching, modelling of them as massless elastic links, commonly used in discrete approach, leads to the mathematical model equations among which there are algebraic equations beside the differential ones. The algebraic equations describe then the equilibrium of the nodes at which the springs connect with each other. In the linear case, spring connections of such types create no greater difficulties. Depending on the degree of complexity of the connection, the equivalent spring constant can be introduced or one can retain in the mathematical model the algebraic equations that are linear, which results in a positive semi-definite mass matrix [2]. In nonlinear systems, the principle of superposition does not apply, which is a source of certain computational difficulties. It should be emphasized the serial springs connections increase the whole system pliancy, thus its nonlinear character manifests itself even more.

Various nonlinear oscillators with serially connected springs were investigated by many authors mostly numerically. An approximate analytical approach to the free vibration of oscillators with two nonlinear springs or one linear and another nonlinear spring is used among other in papers [4-5] and [3], [6] respectively. The free vibration of two mechanical systems with springs connected in series is studied using MSM in [5].

Mathematical model

The pendulum with two serially connected springs, presented in Fig. 1, is constrained to the motion on the vertical plane. Z_1 and Z_2 stand for the total elongation of the springs whereas L_{0i} denotes the length of the i th non-stretched spring. The springs nonlinearity is of the cubic type, i.e. $F_i = k_i(Z_i + \Lambda_i Z_i^3)$ for $i = 1, 2$, and the nonlinear contributions to the whole elastic force are assumed to be small. There are two purely viscous dampers in the system. The system is loaded by the torque of magnitude $M(t) = M_0 \cos(\Omega_2 t)$ and by the force \mathbf{F} whose magnitude changes also harmonically i.e. $F(t) = F_0 \cos(\Omega_1 t)$. Although the system has two degrees of freedom, its state is unambiguously determined by three time functions: the elongations Z_1 and Z_2 and the angle Φ .

Figure 1: Forced and damped spring pendulum with two nonlinear springs

Two equations of motion, obtained using the Lagrange formalism, and the equilibrium equation of the join S govern the dynamic behaviour of the pendulum. They are as follows:

$$\begin{aligned} & \left(1 + \frac{dZ_1}{dZ_2}\right)^2 (m\ddot{Z}_2 + C_1\dot{Z}_2) + m\left(1 + \frac{dZ_1}{dZ_2}\right)\dot{Z}_2^2\ddot{Z}_1 + k_2Z_2(1 + \Lambda_2Z_2^2) + \\ & k_1Z_1(1 + \Lambda_1Z_1^2)\frac{dZ_1}{dZ_2} - m\left(1 + \frac{dZ_1}{dZ_2}\right)((L_0 + Z_1 + Z_2)\Phi^2 + g \cos \Phi - f_0 \cos(\Omega_1 t)) = 0, \end{aligned} \quad (1)$$

$$m(L_0 + Z_1 + Z_2)^2\ddot{\Phi} + C_2\dot{\Phi} + 2m(L_0 + Z_1 + Z_2)\left(1 + \frac{dZ_1}{dZ_2}\right)\dot{Z}_2\dot{\Phi} + \quad (2)$$

$$mg(L_0 + Z_1 + Z_2) \sin \Phi - M_0 \cos(\Omega_2 t) = 0,$$

$$k_2Z_2(1 + \Lambda_2Z_2^2) = k_1Z_1(1 + \Lambda_1Z_1^2), \quad (3)$$

where: $L_0 = L_{01} + L_{02}$.

Equations (1) – (3) are supplemented by the initial conditions of the following form

$$Z_1(0) + Z_2(0) = Z_0, \quad \dot{Z}_1(0) + \dot{Z}_2(0) = v_0, \quad \Phi(0) = \Phi_0, \quad \dot{\Phi}(0) = \omega_0, \quad (4)$$

where $Z_0, v_0, \Phi_0, \omega_0$ are known quantities.

The derivative $\frac{dZ_1}{dZ_2}$ one can calculate taking into account Eq. (3) which simplifies significantly the governing equations. The method of multiple scales in time domain with three time variables is applied to solve the considered problem. Because of the algebraic-differential character of the motion equations the use of the method requires an appropriately modified approach. Omitting the details of the adaptation, it is worth noting that at each subsequent approximation there is an additional algebraic equation that after differentiating allows one to determine the relationship between the derivatives of the mutually dependent coordinates Z_1 and Z_2 . The approximate solution obtained allowed for prediction of the resonance conditions. Then, the governing equations have been modified appropriately in order to describe the main resonance. The solution to the resonant vibration problem has semi-analytical form, because of the equations of modulation of the amplitudes and phases are solved in numerical manner.

Conclusions

The dynamics of the 2-dof system containing two serially connected nonlinear springs has been studied. The mathematical model consists of the differential and algebraic equations. The approximate solution to the governing equations, up to the third order, has been obtained using MMS with three time scales. The forced vibration of the pendulum have been analysed for two cases: far from resonance and in the resonance conditions. The analytical or semi-analytical form of the solution is the main advantage of the applied approach giving the possibility of the qualitative and quantitative study of the pendulum dynamics in wide spectrum.

Stabilisation of Rayleigh-Plateau modes on a liquid cylinder

Sagar Patankar, Saswata Basak and Ratul Dasgupta

Department of Chemical Engineering, IIT Bombay, Mumbai, India

Summary. We show stabilisation of unstable Rayleigh-Plateau(RP) modes on a liquid cylinder by subjecting it to a radial oscillatory body force. The proposed stabilisation was short lived as shown earlier in our inviscid study [5]. Viscous analysis is performed which has importance for this stabilisation. Linear stability predictions are obtained via Floquet analysis [3]. We also solve the linearised, viscous initial-value problem for free-surface perturbations obtaining an integro-differential equation governing the amplitude of Fourier mode. This equation represents the cylindrical analogue of its Cartesian counterpart [1]. Present study [4] shows that RP stabilisation can be extended longer in time using radial oscillatory forcing. Predictions from the numerical solution to this equation demonstrates RP mode stabilisation upto several hundred forcing cycles and shows excellent agreement with direct numerical simulations(DNS) of the incompressible, Navier-Stokes equations using Basilisk [7]. An expanded version of present study is under review in a journal for publication.

Dynamic stabilisation of RP modes - Linear inviscid theory

Liquid filaments, jets or annular fluid films coating the rods are susceptible to breakup into droplets via classical Rayleigh-Plateau (RP hereafter) instability [6, 8]. In our earlier inviscid study [5], Faraday waves on a liquid cylinder where dynamic stabilisation of RP modes was predicted but found to be extremely short-lived in inviscid simulations. Figure 1, shows an infinitely long, quiescent liquid cylinder of density ρ , surface-tension T , kinematic viscosity ν and radius R_0 being subject to a radial, oscillatory body force $\mathcal{F}(r, t)$. Interface perturbation is expressed as $\eta(\theta, z, t) = a_m(t; k) \cos(m\theta) \cos(kz)$, where k and m represents axial and azimuthal wavenumber.

Figure 1: A schematic representation of surface perturbation on a viscous liquid cylinder of radius R_0 subject to a radial body force $\mathcal{F}(r, t) = -h \left(\frac{r}{R_0} \right) \cos(\Omega t) \hat{e}_r$, where h and Ω are imposed forcing strength and frequency respectively. Under the linearised, inviscid, irrotational approximation, the equation governing amplitude $a_m(t; k)$ of Faraday waves on the free surface is shown to be Mathieu equation[5],

$$\frac{d^2 a_m}{dt^2} + \frac{I'_m(kR_0)}{I_m(kR_0)} \left[\frac{T}{\rho R_0^3} k R_0 (k^2 R_0^2 + m^2 - 1) + k h \cos(\Omega t) \right] a_m(t; k) = 0, \quad (1)$$

Figure 2a and 2b shows the inviscid stability chart and stabilisation of RP modes through DNS being short lived due to nonlinearity.

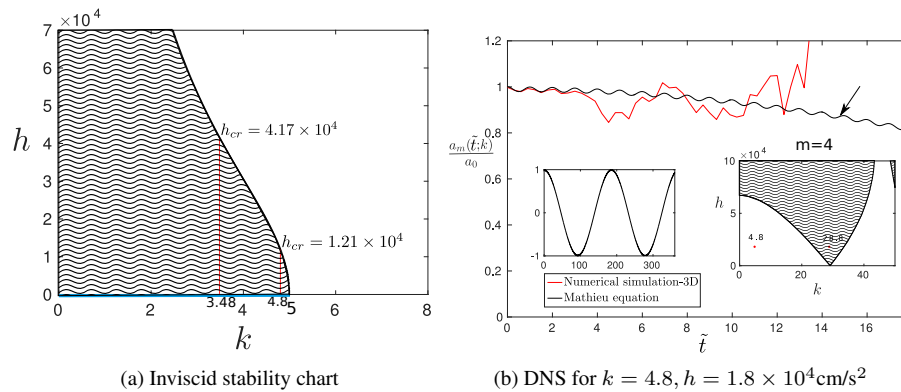

Figure 2: Shaded and white indicate unstable and stable regions respectively. **Panel (a)** Inviscid stability chart from equation 1 showing critical forcing strength h_{cr} above which RP unstable mode $k_0 = 4.8 \text{ cm}^{-1}$ will be stabilised. Parameters: $\Omega = 600\pi \text{ rad/s}$ ($f=300 \text{ Hz}$), $R_0 = 0.2 \text{ cm}$, $\rho = 0.957 \text{ gm/cm}^3$, $T = 20.7 \text{ dynes/cm}$. **Panel (b)** (Red curve) Time signal from inviscid 3D-DNS [7], ($k_0 = 4.8 \text{ cm}^{-1}$, $m_0 = 0$) excited at $t = 0$. (Black curve) Solution to equation 1, (Left inset) Zoomed out view of solution to equation 1, (Right inset) Stability chart for $m = 4$ showing unstable non-axisymmetric Fourier mode ($k = 28.8 = 6k_0$, $m = 4$) at $\tilde{t} \approx 14 \text{ s}$ causing destabilisation.

Dynamic stabilisation of RP modes - Linear viscous theory

In the *viscous* analysis presented here [4] we performed Floquet analysis following [3] to obtain viscous stability chart and solve the initial-value problem (IVP) following toroidal-poloidal decomposition [2] on a cylinder. We finally obtain an integro-differential equation (2) for $a_m(t; k)$ which has a damping and two memory terms in comparison to Mathieu equation 1. It is shown that, by carefully tuning the strength and frequency of (radial) forcing, RP modes accessible to the system may be rendered stable thus stabilising the cylinder for long time (many forcing time periods).

$$\begin{aligned} \frac{d^2 a_m}{dt^2} + 2\nu k^2 \frac{I_m''(kR_0)}{I_m(kR_0)} \frac{da_m}{dt} + \int_0^t \hat{\mathbf{L}}^{-1}(\tilde{\chi}(s)) \frac{I_m'(kR_0)}{I_m(kR_0)} \left[\frac{T}{\rho R_0^3} kR_0 (k^2 R_0^2 + m^2 - 1) \right. \\ \left. + h k \cos[\Omega(t - \tau)] \right] a_m(t - \tau) d\tau + 4\nu k \frac{I_m'(kR_0)}{I_m(kR_0)} \int_0^t \hat{\mathbf{L}}^{-1}[\zeta(s)] \frac{da_m}{dt}(t - \tau) d\tau = 0 \end{aligned} \quad (2)$$

Stabilisation of RP modes: viscous stability chart and DNS comparison

Case	Fluid	$a(0)$	m_0	k_0	$\rho^{\mathcal{I}}$	$\rho^{\mathcal{O}}$	$\mu^{\mathcal{I}}$	$\mu^{\mathcal{O}}$	R_0	h	Ω	T
1	Silicone oil	0.01	0	4.8	0.957	0.001	0.1	0.001	0.2	1.8×10^4	600π	20.7

Table 1: Parameters for stability chart and DNS (CGS units)

Figure 3: **Panel a)** Stability chart ($m = 0$) and **panel (b)** non-axisymmetric ($m = 1, 2, 3, 4$) modes with Case 1 parameters in table 1. Figure 3a shows bold black lines \rightarrow viscous tongue, black dashed line \rightarrow inviscid tongue. (Inset) complete chart. The mode ($k_0 = 4.8, m_0 = 0$) is stabilised when $h_{cr1} < h < h_{cr2}$ with $h_{cr2} = 2.05 \times 10^4$ cm/s² from $m = 4$ (see figure 3b). We select $h = 1.8 \times 10^4$ (red dot and solid red line in figure 3a and 3b respectively) for stabilisation. **Panel (c)** DNS time signal for case1 with parameters in table 1: (Red and blue dots) from DNS shows excellent agreement with solution to equation 2 (referred as Analytical in figure 3c) upto 600 forcing cycles ($\tilde{t} \equiv t\Omega/2\pi$). (Orange line) Destabilisation seen in axisymmetric DNS when $h < h_{cr1}$ and when (Pink line) $h > h_{cr2}$. Note that inviscid simulation in figure 2b where for the same k_0 , stabilisation is seen for only three forcing cycles.

Conclusions

We solved the initial-value problem (IVP) leading to a novel integro-differential equation governing the (linearised) amplitude of three-dimensional Fourier modes on the viscous liquid cylinder extending our earlier inviscid study. It is demonstrated that by suitably tuning the frequency of forcing and choosing strength $h_{cr1} < h < h_{cr2}$, RP mode (k_0) can be stabilised with all axisymmetric and three-dimensional modes that may be generated by nonlinear effects, can be prevented from destabilising the cylinder. DNS comparison have shown excellent agreement with theoretical predictions demonstrating RP stabilisation upto hundreds of forcing cycles.

On solving one-dimensional wave equations subject to nonclassical and to nonlinear boundary conditions

Wim T. van Horssen

Delft Institute of Applied Mathematics, Delft University of Technology, Delft, The Netherlands

Summary. In this paper it will be shown how characteristic coordinates, or equivalently how the well-known formula of d'Alembert can be used to solve initial-boundary value problems for wave equations on semi-infinite intervals or on fixed, bounded intervals involving non-classical and nonlinear boundary conditions. It will be shown that solutions or approximations of solutions for wave-problems can be constructed for a much larger class of problems than generally is assumed. In this paper linear and nonlinear mass-spring-damper systems will be considered at the boundary, and it will be shown how (approximations of) solutions can be constructed.

Introduction and overview

The study of a one-dimensional wave equation such as

$$u_{tt} - u_{xx} = 0 \quad , \quad t > 0, -\infty < x < \infty, \quad (1)$$

goes back to the middle of the 18th century when d'Alembert solved an initial value problem for Eq. (1) on an infinite interval (that is, on $-\infty < x < \infty$) by using characteristic coordinates. In Eq. (1) $u = u(x, t)$ is a displacement (usually a lateral displacement of a string), x is a space coordinate, and t is time. When the initial displacement, and the initial velocity are given by

$$u(x, 0) = f(x), \text{ and } u_t(x, 0) = g(x), \quad (2)$$

respectively, one obtains as solution the well-known formula of d'Alembert

$$u(x, t) = \frac{1}{2} f(x+t) + \frac{1}{2} f(x-t) + \frac{1}{2} \int_{x-t}^{x+t} g(s) ds. \quad (3)$$

On a semi-infinite interval (that is, for instance on $x > 0$) this formula (3) can also be used to solve an initial value problem for a wave equation. For a Dirichlet type of boundary condition at $x = 0$, or for a Neumann type of boundary condition at $x = 0$, it is also well-known that the functions in the classical formula of d'Alembert should be extended as odd, or as even functions in x , respectively. How the functions should be extended for a Robin type of boundary condition (with constant coefficients) at $x = 0$, is less well-known, but it was already discovered at the end of the 19th century by Bryan. Recently in [1] and [2] the extension procedures on semi-infinite intervals for problems with a linear mass-spring-damper boundary condition at $x = 0$, were presented for a string equation and for an axially moving string equation, respectively.

On a bounded interval (that is for instance on $0 < x < L < \infty$) the classical formula of d'Alembert can also be used to solve an initial value problem for a wave equation. In the literature only the cases where one has Dirichlet and/or Neumann boundary conditions, are solved by using the formula of d'Alembert, and leads to odd and/or even periodic extensions of the functions in the formula of d'Alembert. For other boundary conditions the formula of d'Alembert is not used, most likely, because it is not (well) known how to extend the functions in the formula of d'Alembert for other boundary conditions than those of Dirichlet type or of Neumann type.

Usually the method of separation of variables, or the (equivalent) Laplace transform method is used to solve initial value problem for a wave equation on a bounded interval for various types of boundary conditions with constant coefficients. However, when a Robin boundary condition with a time-dependent coefficient is involved in the problem, then the aforementioned methods are not applicable. In [3] it has been shown how characteristic coordinates or equivalently, how the classical formula of d'Alembert can be used to solve an initial value problem for a wave equation on a bounded, fixed interval with at one endpoint a Dirichlet type of boundary condition, and at the other end a Robin type of boundary condition with a time-dependent coefficient. The Robin boundary condition with a time-dependent coefficient is an interesting one to study from the applicational (and from the mathematical) point of view. When one considers the transversal vibrations of a string which at one end is attached to a spring for which the stiffness properties change in time (due to fatigue, temperature change, and so on), then a Robin type of boundary condition is obtained with a time-varying coefficient. But also in the study of longitudinal vibrations of axially moving strings with time-varying lengths (as simple models for vibrations of elevator or mining cables), one obtains, after some transformations as a first order approximation of the problem, a wave equation for which at one end a Robin type of boundary condition with a time-varying coefficient has to be satisfied.

For nonlinear or weakly nonlinear boundary conditions not so many results are known. The reader is referred to [4] (and the references in [4]) for some recent and historical approaches that have been used. In this paper a problem for a wave equation on a semi-infinite domain will be discussed. The boundary condition is assumed to be weakly nonlinear and it will be explained how a multiple time-scales perturbation method can be applied to construct approximations of the solution of the problem.

In this paper our recent results on the applicability of the formula of d'Alembert (as discussed above) will be presented. For details the reader is referred to our recent publications [1, 2, 3].

Four classes of problems

In this paper four classes of problems will be explained in detail. In the first class the vibrations of a semi-infinite string (that is, equation (1) with $x > 0$) will be studied with a spring-damper system attached at $x = 0$, that is, a boundary condition like

$$Tu_x(0, t) = ku(0, t) + \alpha u_t(0, t) \quad (4)$$

will be considered, where T is the tension in the string, k the stiffness of the spring, and α the damping coefficient of the dashpot. By using characteristic coordinates or equivalently, by using d'Alembert's formula (3) it will be shown that the extensions of the functions f and g in (3) for negative arguments in the functions f and g , have to satisfy nonhomogeneous, first order ordinary differential equations (ODEs). The solutions of these ODEs can readily be obtained, and so, reflected waves and energy dissipation can be determined.

In the second class of problems the vibrations of a semi-infinite string will be studied with a mass-spring-damper system attached at $x = 0$, that is, a boundary condition like

$$mu_{tt}(0, t) = Tu_x(0, t) - ku(0, t) - \alpha u_t(0, t) \quad (5)$$

will be considered, where m is the mass in the attached system at $x = 0$. In this case the extensions of the functions of f and g have to satisfy nonhomogeneous, second order ODEs with constant coefficients. Again reflected waves and damping properties can be determined.

In the third class of problems the vibrations of a finite string (that is, equation (1) with $0 < x < L < \infty$) will be studied with a fixed end at $x = 0$ and a spring (with a time-varying stiffness $k(t)$) attached at $x = L$, that is, with the boundary conditions

$$\begin{aligned} u(0, t) &= 0, \\ Tu_x(L, t) &= -k(t)u(L, t). \end{aligned} \quad (6)$$

It will be shown that the method of separation of variables can not be applied, but d'Alembert's formula (3) can be used. It will turn out that the extensions of the functions f and g (outside the interval $[0, L]$) have to satisfy nonhomogeneous first order ODEs and have to satisfy a certain iteration process. Again properties of the solutions can be obtained from d'Alembert's formula (3).

In the fourth class of problems the vibrations of a semi-infinite string will be studied for $x > 0$ with a (weakly) nonlinear mass-spring-damper system attached at $x = 0$, that is, a boundary condition like

$$mu_{tt}(0, t) = Tu_x(0, t) - k_1 u(0, t) - k_3 u^3(0, t) - \alpha u_t(0, t) \quad (7)$$

will be considered, where k_1 and k_3 are constants. When the displacement $u(x, t)$ is small, or when k_3 is small, perturbation methods like the two time-scales perturbation method can be used to construct accurate approximations of the solution, which are valid on a long time scale.

Conclusions and future work

In this paper it has been shown that the formula of d'Alembert can be applied to a much larger class of problems than is generally assumed. This also implies that a larger class of weakly nonlinear problems for wave equations can be studied by means of characteristic coordinates (see also recent work in [5, 6]).

Modeling non-conventional vibrational modes of micro-plates in viscous fluids

Andre Loch Gesing*, Daniel Platz* and Ulrich Schmid*

**Institute of Sensor and Actuator Systems, TU Wien, Gußhausstraße 27, 1040 Vienna, Austria*

Summary. Micro-plates exhibit extraordinarily low losses in viscous fluids when vibrating in the non-conventional roof tile-shaped modes. However roof tile-shaped modes are commonly not considered for micro-sensors due to the lack of methods to predict these modes' dynamic response in viscous fluids. We developed a numerical method to calculate the spectral displacement of micro-plates oscillating in viscous fluids with which we can predict both conventional and non-conventional vibrational modes. The method is based on the Kirchhoff-Love plate equation, which we solve with a continuous-discontinuous approach to the Galerkin Method, with the method of fundamental solutions for the linearized Navier-Stokes equations. We show-case our method with the analysis of a silicon micro-plate immersed in water. With the spectral displacement curve it is straight forward to categorize peaks correspondent to beam bending modes, torsional modes and roof tile-shaped modes. Furthermore, we calculate the fluid flow field associated to each vibrating mode of the micro-plate. Our method thus provides a crucial understanding of the flow field around an oscillating micro-plate, which may enable novel device architectures for resonantly operated micro-sensors in viscous fluids.

Introduction

Commonly micro electro-mechanical systems (MEMS) devices exploit as key building block the Euler-Bernoulli (EB) flexural bending modes, or torsional modes, of narrow beams. These modes are chosen because methods to predict their dynamic response and thermal calibration in viscous fluids are well established and straightforwardly implemented [1]. Higher order bending modes of beams in viscous fluids are subject to high viscous losses. High order roof tile-shaped modes of micro-plates, on the other hand, exhibit extraordinarily low losses in viscous fluids [2]. However numerical methods for the prediction of the dynamic response of micro-plates in viscous fluids, and thus for roof tile shaped modes, are missing. Thus, a method for the prediction of the dynamic response of micro-plates in viscous fluids is of utmost importance to improve device performance even further.

Numerical Method

Micro-plates immersed in viscous fluids is a multi-scale problem, which means its solution via traditional numerical techniques - e.g. computational fluid dynamics and finite differences - is not straight forward. Our approach is to solve the Kirchhoff-Love (KL) plate equation combined with the method of fundamental solutions for the linearized Navier-Stokes (LNS) equations. KL plate theory is based on a fourth order partial differential equation (PDE), which can't be solved with out-of-the-box Finite Element Method (FEM). We solve the KL PDE with a continuous/discontinuous method called interior penalty (IP). IP method enables us to use Lagrange-type continuous elements (C0 continuous) while minimizing discontinuities in first order derivatives (obtaining thus C1 continuity) and weakly enforcing clamped and free-end boundary conditions. For comparison purposes we also implemented the IP method for the EB beam equation. To solve the fluid-structure interaction, we assume the non-slip condition at the plate's surface and assume that the fluid velocity in the longitudinal direction of the plate is small in comparison to the other components. With this simplification, there is a fundamental solution for the LNS that relates pressure at the plate surface and the plate's transverse displacement at each cross-section [3]. Evaluation of the fundamental solution at top and bottom surfaces of the plate results in a complex pressure jump over the plate which is linearly and non-locally dependent on the plate's transverse displacement.

Results

As an application example we consider a $300 \times 300 \times 5 \mu\text{m}^3$ silicon micro-plate immersed in water. The micro-plate is clamped on one side and free on the three others, and is excited by an external force at one of the free corners. Fig. 1 shows the displacement spectrum per unit excitation force ϕ/F of the free corner of the plate where the force is applied. Note that some of the peaks in the displacement spectrum are predicted by both KL and EB models. These peaks correspond, evidently, to flexural bending modes. The second peak in KL displacement spectrum corresponds to the first torsional mode. First beam bending mode and first torsional mode are shown in Figs. 2a and 2b, respectively. Roof tile modes in water occur at frequencies 237.4 kHz and 651.8 kHz and are shown in Figs. 2c and 2d. Naturally, note that these modes are predicted only with the KL method. Once the plate spectral displacement is calculated, we can predict the velocity field at any point of the fluid domain by applying once again the fundamental solutions for the LNS. The results of this procedure are shown in Fig. 3, where the velocity field is shown for the plate's vibrational modes shown in Fig. 2. Velocity field associated with the first bending mode exhibits two vortices at the edges of the plate's cross section with opposite directions, with the fluid near the middle being dominated by a normal component. For the torsional mode we see the vortices with opposite directions at the edges, and the fluid moves across the plate's surface dominated by a tangential component. For roof tile modes the fluid moves back and forth across the plate's surface with a pattern that varies with the number of nodal lines of the vibrating mode. Note also that for roof tile modes the velocity field can reach higher velocities near the middle of the plate than at its edges.

Conclusions

We showed that with the KL method we can model non-conventional modes of micro-plates in viscous fluids besides the traditional bending and torsional modes. What is more, we are able to calculate the fluid flow associated to each vibrational mode, which in turn enable novel strategies to further decrease energy losses to the fluid. Future developments include implement 3D fundamental solutions for the LNS and comparison to experimental data.

Modeling of Frequency Locking in a Differential Vibrational Beam Accelerometer

Omer HaLevy and Slava Krylov

*School of Mechanical Engineering, Faculty of Engineering, Tel Aviv University,
Ramat Aviv, Tel Aviv, Israel 69978*

Summary. Nonlinear dynamic behavior of a generic differential vibrating beam accelerometer is studied numerically and analytically with the emphasize on the frequency locking phenomenon. The device incorporates two tuning fork oscillators attached to a proof mass and described as a weakly nonlinear Kirchhoff beam driven through the self-excitation loop. Our numerical results obtained using the reduced order (RO) Galerkin model indicate that the influence of the geometric nonlinearity and inertial coupling on the locking is minor while the role of the structural coupling is dominant. An analytical prediction of the acceleration range where the locking occurs is obtained by considering two coupled Van der Pol oscillators and is found to be in a good agreement with the numerical results.

Introduction

Microelectromechanical (MEMS) accelerometers are among the most widely implemented and commercially successful micro devices. New challenges imposed by emerging applications continue to stimulate intensive research in the inertial sensors area. Among the approaches allowing performance enhancement are resonant accelerometers, which exploit the dependence of the sensing element natural frequency on the inertial (acceleration) force acting on the proof mass. A large variety of resonant accelerometer designs were reported, including beams directly stretched by an inertial force [1], as well as sensors implementing force amplification or electrostatic softening.

In this work, to explore device's dynamics and modeling approaches, we consider the most generic architecture of a vibrating beam accelerometer (VBA). The device consists of two beam-type tuning fork oscillators attached to a proof mass, Fig. 1(a) [1]. Inertial force acting on the mass results in the increase/decrease of the frequencies of the left (L)/right(R) pairs of the beams $f_{L/R} = f_0 \sqrt{1 \pm \gamma Ma/N_E} \approx f_0(1 \pm \gamma Ma/(2N_E))$. Here f_0 is the reference frequency of the unloaded beam, γ is the correction coefficient, M is the proof mass, a is the acceleration and $N_E \gg \gamma Ma$ is the Euler's buckling force. The acceleration is extracted from the measurement of the difference between the two frequencies $\Delta f = (f_L - f_R)$. In the case of nominally identical and uncoupled L and R beams Δf should be zero at $a = 0$. However, as was observed in experiments [2], at small a frequency locking occurs, when two beams oscillate at the same frequency and phase. This phenomenon leads to a "blind zone" in the scale factor curve, limiting the minimal measurable a . As a result, the differential sensing, implemented in these devices to reduce the negative influence of thermal and other environmental effects, cannot be used. Locking (also referred as synchronization) is a well-known phenomenon and the literature on the subject is voluminous [3, 4]. In the MEMS/NEMS area where synchronization can be beneficial, most of the works were focused on the approaches allowing to achieve rather than avoid locking (e.g., see [5] and references therein). However, there is only a limited amount of publications dealing with the modeling of locking in resonant accelerometers [2].

Figure 1: (a) Schematics of a generic vibrational beam accelerometer (VBA). (b) The half-model used in this work.

Model of the device

Due to symmetry only one half of the device is considered, Fig. 1(b). Each of the (assumed to be identical) beams (ties) is clamped at one end and is attached to a proof mass at the other end. The mass moving in the x direction is anchored through the suspension beams. The ties are described in the framework of the nonlinear Kirchhoff beam model, which accounts for a deflection-dependent stretching. By implementing the single-term Galerkin approximation, the beams are described as single DOF oscillators. The dynamics of the device are governed by three coupled nonlinear differential equations in terms of the L and R beams deflections q_L, q_R and the mass displacement u_M

$$\begin{cases} \ddot{q}_L + c\dot{q}_L + (1 + \sigma u_M)q_L + k_{nl}q_L^3 + \alpha(q_L - q_R) = F_L \text{sign}(\dot{q}_L) \\ \ddot{u}_M + c_M\dot{u}_M + k_M u_M = a + \mu((q_R)^2 - (q_L)^2) \\ \ddot{q}_R + c\dot{q}_R + (1 - \sigma u_M)q_R + k_{nl}(q_R)^3 + \alpha(q_R - q_L) = F_R \text{sign}(\dot{q}_R) \end{cases} \quad (1)$$

Here c, c_M are the damping coefficients of the beams and proof mass, σ is the inertial force coefficient, k_{nl} is the nonlinear stiffness coefficient, μ is the inertial coupling coefficient [3], k_M is the effective stiffness of the mass suspension and F

is the driving force amplitude. The overdot represents time derivative. The structural coupling coefficient α is extracted from the results of a three-dimensional finite elements modal analysis. Namely, f_L , f_R were calculated for the beams with slightly detuned parameters and α was obtained by fitting the veering frequency curves in the vicinity of $a = 0$.

Results

Equations (1) completed by zero initial conditions were solved numerically using Runge-Kutta solver. The beam's frequencies were extracted from the steady-periodic time-history using FFT and zero crossing approaches. The phase between the beams was obtained using Hilbert transform. The results presented here correspond to the following parameters: $c = 2.85 \times 10^{-5}$, $c_m = 2.55 \times 10^{-8}$, $k_{nl} = 6.75$, $k_M = 0.0115$, $\alpha = 5.75 \times 10^{-5}$, $\sigma = 2.95 \times 10^{-5}$, $\mu = 1320$, $F = 6.68 \times 10^{-8}$. The relative frequency shifts $\Delta f_{L/R}^{rel} = (f_{L/R} - f_0)/f_0$ are shown in Fig. 2(a). In certain range of a the locking occurs and the curves are indistinguishable. The curve representing the maximal phase difference $\Delta\phi$ between the oscillators, Fig. 2(b), indicates that the locking region (in terms of a) is subdivided into two sub-regions - the strong locking where $\Delta\phi$ is close to zero and the weak locking, where a certain phase difference is apparent. Within the locking region the difference in the amplitudes of the two beams (the "mode localization" effect) is more pronounced than outside of the locking area, Fig. 2(c). Our numerical results suggest that for typically small (compared to the beam's width d) values of vibrational amplitudes, the influence of the geometric nonlinearity and of the nonlinear inertial coupling on the locking region is minor. This allows to consider the deflection of the proof mass as quasi-static, and to reduce the problem to two equations of motion which are coupled only through the stiffness coefficients. An additional simplification, which was made due to a periodic character of motion, is to replace the sign function in the driving force such that $\text{sign}(\dot{q}) \approx \arctan(\dot{q}) \approx \dot{q}(1 - \dot{q}^2/3) \approx \dot{q}(1 - q^2/3)$. As a result, Eqs. (1) are reduced to two coupled Van der Pol equations

$$\begin{cases} \ddot{q}_L + [c - F_L(1 - q_L^2/3)] \dot{q}_L + (1 + \tilde{\sigma} a) q_L + \alpha(q_L - q_R) = 0 \\ \ddot{q}_R + [c + F_R(1 - q_R^2/3)] \dot{q}_R + (1 - \tilde{\sigma} a) q_R + \alpha(q_R - q_L) = 0 \end{cases} \quad (2)$$

where $\tilde{\sigma}$ is the new acceleration force coefficient. The results based on the asymptotic analytical solution of these equations obtained using averaging [6] are shown in Fig. 2(d). Comparison between the analytically predicted locking region (obtained for the realistic device parameters) and the numerical results showed good agreement between the two. Our modeling approach can be useful also for the analysis of other resonant electrostatically or piezoelectrically actuated accelerometers including tilting devices, devices implementing mechanical force amplification or electrostatic softening.

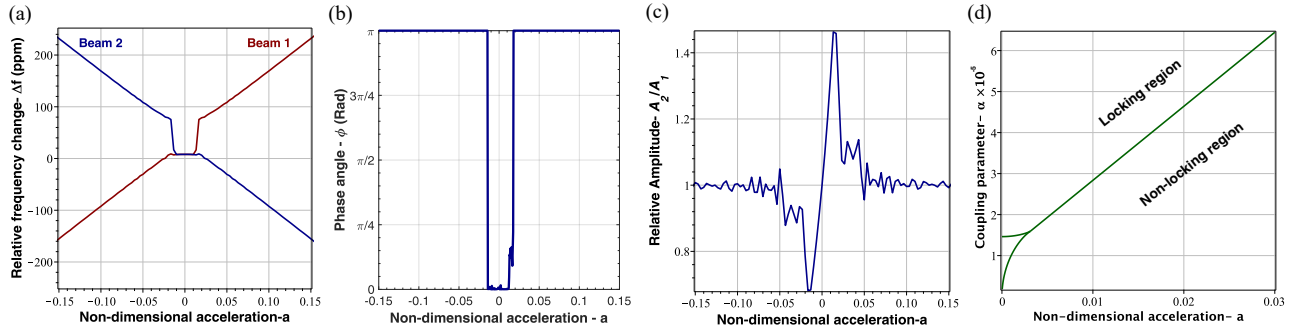

Figure 2: Numerical results obtained by solving Eq. (1) (a) The relative frequency shifts of the each of the beams as a function of the acceleration. In incense of locking the frequency-acceleration dependence curves for each of the beams should cross at $a = 0$. (b) The maximal phase difference between the oscillators as a function of the acceleration. (c) The ratio between the amplitudes of the L and the R beams. (d) Analytical solution - a boundary separating the locked and unlocked regions in the acceleration (detuning)-coupling plane.

Multi-Gas Sensing Design based on Nonlinear Coupled Micromachined Resonators

Zhengliang Fang, Amal Z. Hajjaj and Stephanos Theodossiades

Wolfson School of Mechanical, Electrical and Manufacturing Engineering, Loughborough, LE11 3TU, UK

Summary. Micro-electromechanical (MEMS) gas sensors receive increasing interest thanks to the high demand for environmental monitoring, air quality measurement, chemical process control, and personal safety. Extensive research has been conducted to improve the selectivity and sensitivity of gas sensors. However, there is still no comprehensive study on multi-gas sensing despite its potential. This work proposes a new prototype of gas sensors that can simultaneously detect the concentration of two different surrounding gases using a single structure based on a weakly coupled resonator. This study presents a thorough theoretical investigation on the dynamics of coupled cantilever and bridge resonators to prove its potential for multi-gas sensing. The sensing scheme relies on mass (due to gas absorption) and stiffness (due to cooling/heating) alteration of the cantilever and bridge resonators, respectively. A nonlinear theoretical model is developed using the Euler-Bernoulli beam theory while accounting for the geometric and electrostatic nonlinearities. The sensor's dynamic is explored using the Reduced-Order model and one-mode Galerkin discretization, showing its richness. The results suggest the potential of the nonlinear coupled resonator in performing multi-gas detection.

Manuscript

Over the past decades, several gas-sensing mechanisms have been developed, including resistive/chemical-resistive, electro-chemical, work function, thermal conductivity, optical and surface acoustic wave [1]. One of the most widely used sensor designs is based on sensors coating. These conventional gas sensors rely on special coating materials for selective and sensitive detection [2]. Alternatively, the thermal conductivity-based gas sensors show comparable sensing performance and gains lots of interests. These sensors rely on the thermal energy dissipation of a heated structure due to the alteration of the surrounding gas concentration [3]. This research will present a sensor that combines the thermal conductivity-based gas sensor technique and coating surfaces with micro-electromechanical systems (MEMS) technology. This generates a new kind of multi-gas sensing technology based on micro-gravimetric sensing by mass absorption and the thermal conductivity sensor design. The new sensing approach shows the potential to detect numerous gases and analyze the binary gas mixture.

On the other hand, electrostatically driven MEMS based mass (gas) sensors showed an excellent capability in various potential applications thanks to their easy implementation [4]. A mechanically coupled resonant device is designed to provide a stable sensing performance, as shown in Figure 1. The sensor comprises a weakly coupled resonator including a cantilever and bridge resonators. A thin coupling beam weakly couples both resonators. By changing the coupling position, the moment of inertia and the length of the coupling beam, the coupling strength could be controlled [5]. Both cantilever and the bridge resonators are driven electrostatically by a DC polarization voltage V_{DC} and an AC harmonic voltage of amplitude V_{AC} . The system geometry is optimized to ensure that both the first and second modes are similar.

Physical Parameter (Units)	Value
Gap between the electrodes of bridge, $d_1(\mu m)$	7
Gap between the electrodes of cantilever, $d_2(\mu m)$	7
Length of coupling beam, $L_c(\mu m)$	10

Cantilever actuating AC voltage, V_{ac2}	20

Figure 1: 3D schematic of the weakly coupled micromachined resonator for gas sensing application

Table 1: Geometric parameters of the sensor structure

The multiple gas sensing methodology is demonstrated in two aspects in this sensor structure. The bridge resonator will be heated electrothermally, experiencing convective cooling (or heating) from the ambient gas. The thermal expansion will change the bridge's stiffness and hence its resonance frequency. This technique is promised to detect gases with significant differences in thermal conductivity compared to the air (26.2 mW/mK in 300K), such as Hydrogen (186.9mW/mK in 300K) or Carbon dioxide (16.8 mW/mK in 300K) [3]. At the same time, the cantilever will be coated with a specific material having an affinity to absorb Ammonia (which has a similar thermal conductivity of 24.4 mW/mK with air), causing a mass perturbation and hence frequency shift. Through simultaneous tracking of multiple modes of vibration of the coupled resonator, the change in the surrounding gases' thermal conductivity and the mass perturbation (i.e., due to gas absorption) are shown accurately in the shift in the resonance frequency of the systems.

Results and Discussion

The analytical study is based on nonlinear Euler-Bernoulli beam theory while accounting for the geometric and electrostatic nonlinearities. To simulate the dynamics of the studied system, a reduced-order model and one-mode Galerkin discretization (for each resonator) were used. The geometric parameters of both beams are carefully designed: by adjusting the length of the cantilever, two beams' resonant frequencies are balanced (Figure 2(a)). The theoretical results of eigenvalue problems reveal how mass/stiffness perturbation influences two resonant frequencies (Figure 2(b), 2(c)). The frequency response of two beams' deflection (Figure 2(d), 2(e)) shows several non-linear phenomena of hysteresis and jumps, hence providing the possibilities of high-sensitivity sensing. The results for both stiffness and mass perturbation simulations (Figure 2(f), 2(g), 2(h), 2(i)) present rich dynamics, further prove the influence of both kinds of perturbations on resonant frequencies, which suggests the potential of the proposed design to perform multi-sensing.

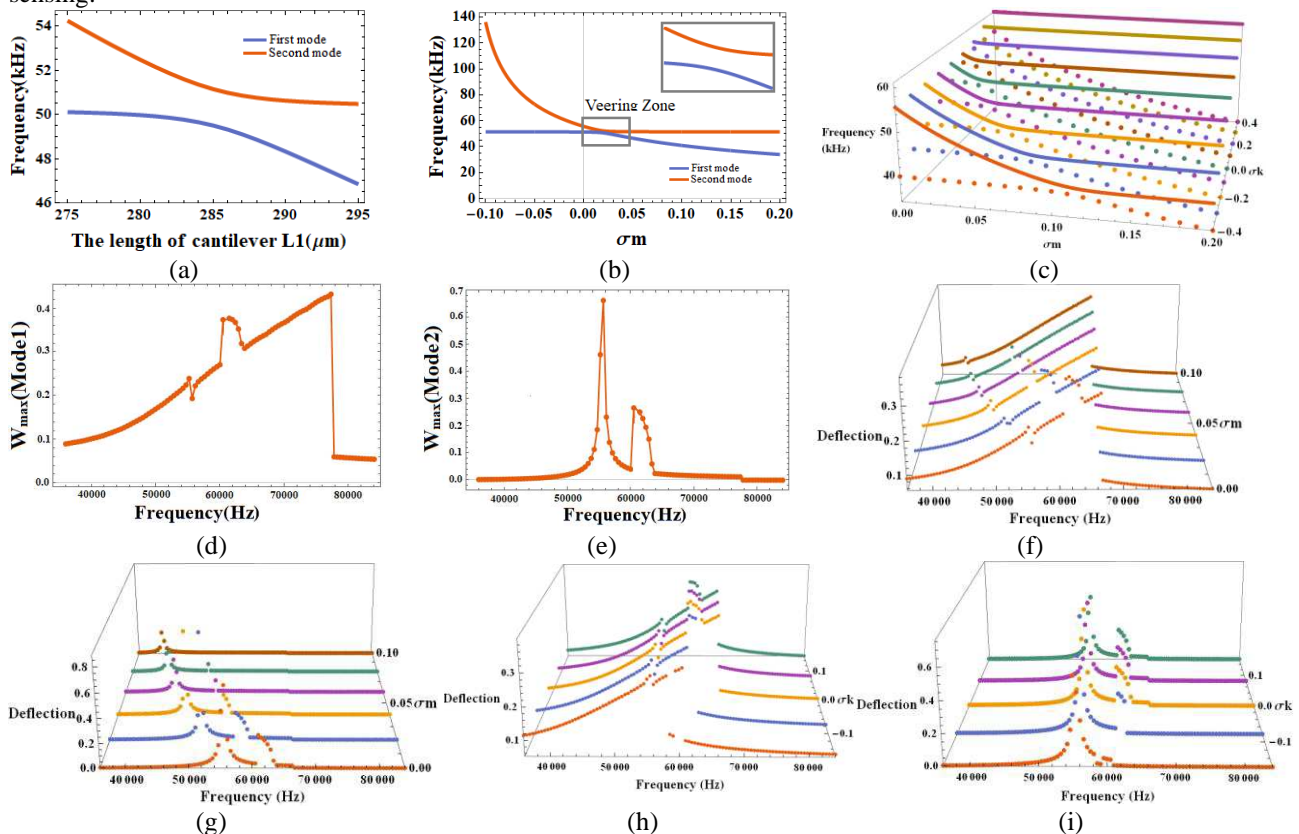

Figure 2: (a) Length of cantilever versus two resonant frequencies. Eigenvalue problems for single mass perturbation (b) and both mass and stiffness perturbation (c). The inset of (b) presents the enlarge view of veering zone.

With the actuating of $V_{dc1} = 50V$, $V_{ac1} = 20V$ on bridge resonator, the frequency response of max deflection for bridge and cantilever without perturbation (d) and (e); with mass perturbation (f) and (g); with stiffness perturbation (h) and (i).

Conclusions

We designed a potential sensor prototype for multi-gas sensing that combined micro-gravimetric sensing technique and thermal conductivity sensing techniques. The dynamics of the proposed design are simulated theoretically and showed promising results for accurate detection of two different surrounding gases simultaneously. The obtained results encourage further experimental and theoretical investigation of the dynamic of the proposed weakly coupled system. This work could reveal a new-generation answer for multi-gas sensing and show potential on different applications.

Nonlinear dynamics of 2D materials

Farbod Alijani, Peter G. Steeneken

**Department of Precision and Microsystems Engineering, TU Delft, The Netherlands*

Summary. Two-dimensional (2D) materials such as graphene are model systems for investigating nonlinear dynamics at the nanoscale. They exhibit phenomena such as intermodal coupling and stochastic switching already at amplitudes that are only a few nanometers with potential applications that are yet to be harnessed. In this talk, I will give an overview of the recent advancements in nonlinear dynamic studies of 2D materials with particular focus on methods for utilizing nonlinearity in ultra-thin mechanical systems.

Introduction

Nanomechanical systems are ubiquitous in a variety of applications in modern technology. The advent of 2D materials, and the ability to fabricate one-atom thick membranes, have made it possible to reach the ultimate sensing capabilities that not so long ago were only dreamed of. But this revolutionary downscaling has been associated with constraints on the linear dynamic range of these mechanical systems since signatures of nonlinearity already emerge at amplitudes that are only a few nanometers [1].

Although the field of nonlinear dynamics dates back several centuries, its implications in atomically thin membranes have remained largely unexplored. In this talk, we present methods and experiments for understanding and utilizing nonlinear dynamic phenomena in 2D material membranes. Our aim is to shed light on the intricate modal couplings and the strong interplay between noise and nonlinearity and discuss the means to harness these effects.

Results

Our experiments are performed on multilayer graphene nanodrums with a diameter of 5 μm , which are transferred over a cavity etched in a layer of SiO_2 with a depth of 285 nm. We use a blue laser to opto-mechanically modulate the tension of the membrane, and a red laser to detect the motion, using interferometry. To control the static deflection of the drum, in some of our experiments we also place a local electrode at the bottom of the cavity. The presence of this electrode will allow us to controllably deflect the membrane downwards and use that as an electromechanical knob to tune the tension and thus resonance frequencies of the drum. Moreover, to reduce the damping from the surrounding air we perform the experiments in a vacuum chamber. A schematic of the setup is shown in Fig. 1a together with microscopic image of the graphene drum in Fig. 1b.

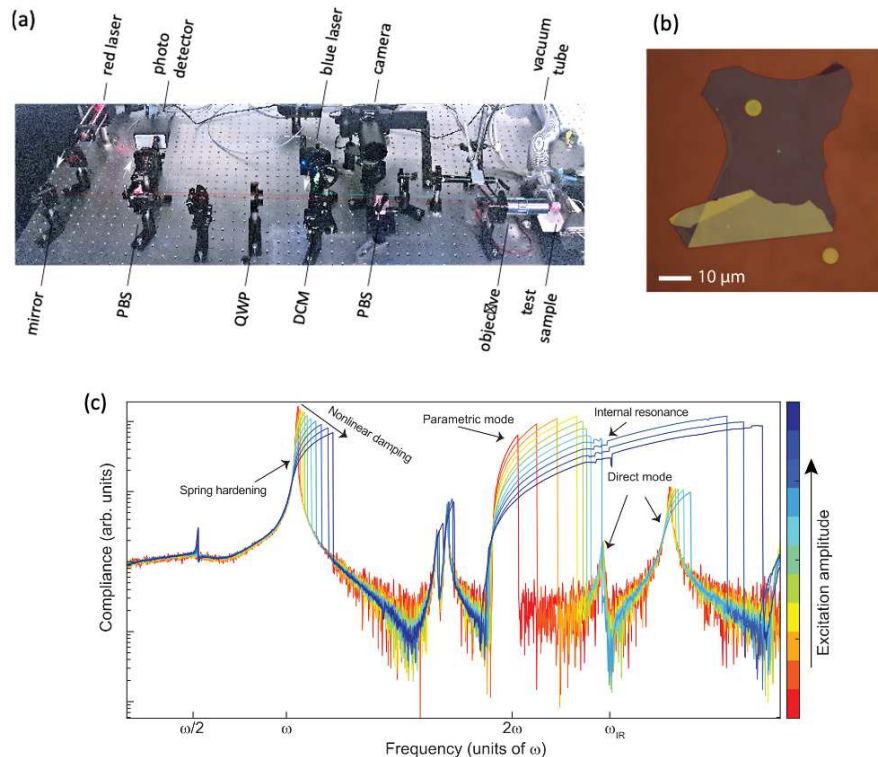

Figure 1: (a) The opto-mechanical set-up for actuating and detecting the motion of the graphene membranes; (b) Microscopic image of the graphene drum [2]; (c) Measurement of the nonlinear dynamic response as a function of the excitation amplitude [3].

By increasing the power of the blue laser, we detect a plethora of nonlinear dynamic phenomena over a wide frequency range. This includes the presence of spring hardening nonlinearity already at forces that are only a few pN, the emergence of nonlinear damping, parametric resonance, parametric -direct internal resonance [2] and a range of direct-direct 2:1 internal resonance. We show that it is possible to make use of these nonlinear effects. For instance, by adding random fluctuations to the drive level, it is possible to obtain stochastic switching rates of 4 kHz between the stable states of the graphene Duffing resonator that are 100 times faster than current state-of-the-art, at effective temperatures 3000 times lower (See Figure 2a and 2b), providing the possibility to transduce weak signals through stochastic resonance. Moreover, by tuning the tension of the membrane using a back gate, we can control internal resonance conditions, obtain quasiperiodic oscillations and thus generate mechanical frequency combs (see Figure 2c).

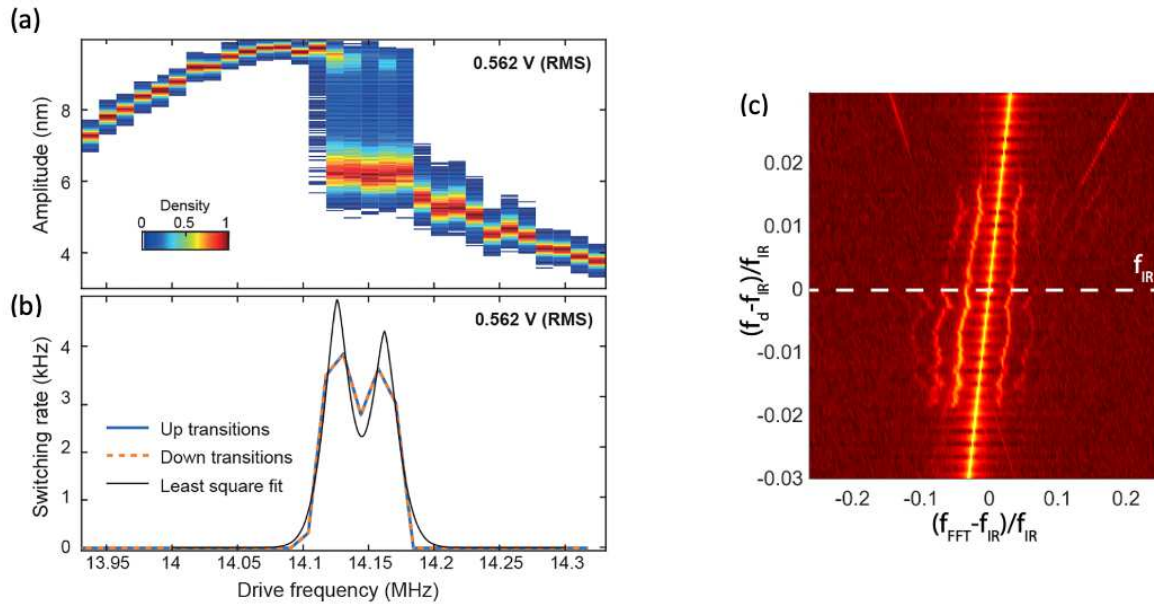

Figure 2: (a) stochastic switching in a graphene resonator close to room temperature [4]; (b) Up and down switching rates as a function of fixed drive frequency [4]; (c) Emergence of frequency combs at internal resonance.

Conclusions

In conclusion we showed that 2D material resonators exhibit a wealth of nonlinear dynamic phenomena and discussed the means to detect them. We showed that these atomically thin membranes provide a platform for investigating a range of modal interactions and the strong interplay between fluctuations and nonlinearities, thus paving the way towards new opportunities for utilizing nonlinear dynamics at smallest length scales and very fast (MHz frequency) time scales.

Summary. In this work, we experimentally measure a relative frequency stability below 10^{-6} for a stress-engineered ≈ 28 MHz nanomechanical resonator by detecting and analyzing its thermodynamic fluctuations at room temperature, without external excitation. We derive the Cramer-Rao lower bound (CRLB) thermodynamic limit for resonance frequency measurement precision for a classical harmonic oscillator subject to dissipation, thermodynamic noise, detection uncertainty and with or without external excitation. We propose a general statistically efficient frequency estimator and experimentally show frequency uncertainty reaching the CRLB on the cavity-optomechanically detected ≈ 1 pg resonator data for up to ≈ 0.1 s averaging. The stress-engineered nanomechanical resonator with high frequency-Quality factor ($fQ \approx 10^{12}$) and considerable frequency stability could be used for frequency-readout displacement sensors with no excitation required.

Introduction and Novelty

The work is related to an earlier report about passive frequency stabilization [1] which uses the same type of high fQ tuning fork resonator [4]. Resonance frequency variance is critical to the performance of nanoresonators. With sufficient motion detection precision, frequency measurement is fundamentally limited by the thermodynamic fluctuations. Lower measured frequency variance is achieved by increasing the driven amplitude. However, as the thermodynamic uncertainty is lowered, the variance becomes limited by frequency drift at ever shorter time scales. Here, we study the frequency variance of a stress-engineered nanomechanical resonator with an effective mode mass of ≈ 1 pg. First, without external excitation, the relative frequency stability is reaching below 10^{-6} , which is better than the average performance of state-of-the-art driven NEMS in such mass range [2]. Second, more importantly, we derive rigorous CRLB, establishing the theoretically lowest limit for the resonance frequency estimation variance. It is applicable to any linear harmonic resonator, including the Micro- and Nano-electron-mechanical systems. Our undriven and driven devices perform at those limits up to the averaging times of ≈ 0.1 s without any extra stabilization [3]. Finally, we present a computationally-fast and statistically efficient frequency estimator—a formula for converting motion records into frequencies with imprecisions at the CRLB. The presented general analysis is applicable to any undriven or harmonically-driven M/NEMs in the linear regime and may be extendable to the nonlinear regime by considering a nonlinear equation of motion, such as a duffing oscillator.

Figure 1: Experimental system introduction. (a) False-colored SEM image of the stress-engineered nanomechanical resonator. (b) Measured optical resonance and the operating principle of the optomechanical detection. (c) Mechanical vibration power spectral density in a vacuum.

Results and Discussion

In this work, stress engineering is applied to increase fQ products of nanoscale Si_3N_4 tuning forks, reaching 10^{12} to 10^{13} range. A false-colored SEM image of the device with a stress tuning bar is shown in Fig. 1(a). The mechanical motion of

the tuning fork modulates the optical resonance frequency of an adjacent microdisk resonator (Fig. 1(b)), generating time-varying optical transmission signals proportional to mechanical displacement. Fig 1(c) shows the mechanical power spectral density of the thermodynamically fluctuating tuning fork mode.

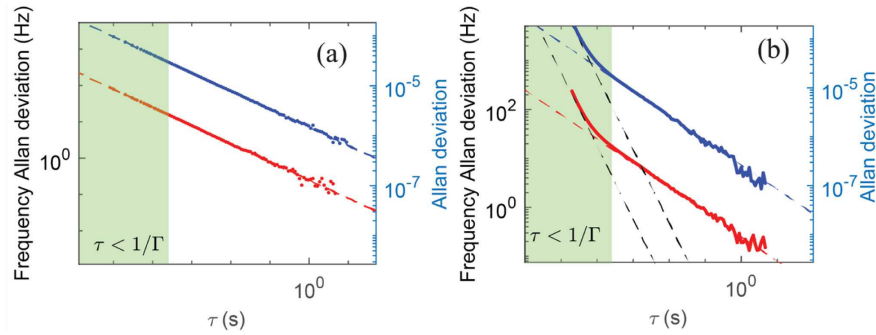

Figure 2: ADEV for simulated data (solid lines) with (a) negligible motion detection noise and (b) experimentally-realistic detection noise added. ADEV without (blue) and with (red) external excitation agrees with theoretical CRLB (dashed lines)

To verify the validity of the derived CRLB and the efficiency of the derived frequency estimator, we first apply the estimator to a simulated motion trace of a fluctuating resonator and calculate the resulting frequency Allan deviation (ADEV). Following the expected $\propto \tau^{-1/2}$, the ADEV quantitatively agrees with the CRLB without any adjustable parameters on all time scale for both the driven and non-driven cases, provided detection noise is negligible (Fig. 2(a)). The maximum-likelihood frequency estimator includes the contributions from both the phase and the phase derivative for the frequency estimation. When artificial motion-detection noise is added to the simulation, the ADEV becomes detection noise limited at the shortest time scales (widest bandwidth), following $\propto \tau^{-3/2}$. The ADEV follows $\propto \tau^{-1/2}$ and quantitatively agrees with the CRLB for the longer time scales, where our CRLB is valid (Fig. 2(b)).

Figure 3: ADEV (solid lines) for experimental data without (blue) and with (red) external excitation. Dashed lines are corresponding theoretical CRLB $\propto \tau^{-1/2}$. Dot-dash lines $\propto \tau^{-3/2}$ are the theoretically expected limits from the detection noise.

The ADEV for experimental data presented in Fig. 3 shows similar features to the simulated data with detection noise, and quantitatively agrees with CRLB without adjustable parameters for $\tau < 0.1$ s. At longer averaging the resonance frequency drift becomes apparent. Remarkably, the resonator without any applied excitation (blue line) shows a low frequency ADEV at the thermodynamic limit of ≈ 7 Hz/Hz^{0.5} below 1 s and (relative) stability of ≈ 10 Hz ($\approx 0.40 \times 10^{-6}$) above 1 s averaging. The undriven and driven devices perform at CRLB up to averaging times of about 1 s and 0.1 s.

Conclusions

In conclusion, we present a statistically efficient resonance frequency estimator and the thermodynamic limit of resonance frequency measurement uncertainty applicable to linear resonator subjects to harmonic drive, thermal fluctuations, and detection uncertainty, on all time scales. After validating them with simulated data, we have implemented the frequency estimator on a stress-engineered nanomechanical resonator. Remarkably, the resonator remained at the thermodynamic limit even for fairly long averaging times, and better than part per million frequency stability has been measured, even though the resonator was driven solely by thermal fluctuations. The stress-engineered nanomechanical resonator with high frequency-Quality factor and considerable frequency stability may be used for developing frequency-readout displacement sensors requiring no excitation.

Summary. We study free ringdown dynamics of a MEMS system with two modes near a 1:3 internal resonance. By separately preparing initial states and measuring the motion of both modes, we demonstrate that dependent on the initial relative phase the modes can either bypass or enter a phase-locked state, which can persist several times longer than the dissipation timescales. The sustained energy transfer between modes in the phase-locked state leads to non-monotonic energy dependence for one of the modes and overall lower dissipation rate for the system. The observations are accurately modeled by the coupled equations of motion, and can be understood by considering the low frequency mode as entering or bypassing a period tripling state under the influence of the periodic force from the high-frequency mode.

Persistent phase-locked state is described by a PTS model.

Nonlinearity in MEMS resonators is widely used in frequency stabilization [1], dissipation engineering [2], and improvement of resonance-based sensing [3] to achieve performance not available in the linear regime. Here, we thoroughly studied the nonlinear dynamics of two coupled MEMS resonators during free ringdown. The two resonators are designed with commensurate 1:3 eigenfrequencies to facilitate fast energy flow at internal resonance (IR). Remarkably, the two modes can get locked during ringdown and persist in this phase-locked state for extended periods of time, much longer than their intrinsic dissipation timescales. During relaxation, the low-frequency mode exhibits striking non-monotonic energy dissipation and negative modal energy dissipation rate (transient energy gain). The rich dynamics observed in the experiment are well explained by an intuitive model that regards the low-frequency mode at period-tripling states (PTS) created by the high-frequency mode, similar to the period-two states in parametric oscillators. In contrast to works at steady states [1,4,5], we demonstrate for the first time the phase lock at the transient states, the non-monotonic dissipation rate, and we provide an intuitive PTS model to describe it, simultaneously and independently from [5]. The observation and the model pave the way to engineering efficient energy flow between coupled nonlinear MEMS, which can be used for frequency stabilization and dissipation engineering.

Results

The two coupled modes are the fundamental in-plane mode (mode1) and torsional mode (mode2) of a clamp-clamp beam, as shown in Figure 1. The two modes are driven electrically with driving frequency $\omega_{1,osc}$ and $\omega_{2,osc}$ via the side gates. The modes are measured electrically and optically by an oscilloscope and a vibrometer, respectively. The eigenfrequencies of mode1 and mode2 are $\omega_1/2\pi \approx 64.6$ kHz and $\omega_2/2\pi \approx 199.9$ kHz ($\omega_1 \approx \omega_2/3$). When the driving force is strong, they exhibit spring hardening and softening effects, respectively, as shown in Figure 2. The dip on mode1's spectrum (orange) corresponds to the IR frequency of $\omega_{1,osc} = \omega_2/3$ where the model coupling is the strongest. In the experiment, we drive the two modes separately to their initial amplitude $A_{1,0}$ and $A_{2,0}$, labeled as red dots. At time $t = 0$, we turn off their drive simultaneously to let them ring down. Following their Duffing trajectory (black arrows in Figure 2), their frequencies shift due to the exponentially decaying amplitude (Fig. 3) and finally get locked at IR (black dots in Figure 2). The locking duration is $\approx 3\times$ of the system intrinsic dissipation time $\approx 1/\Gamma_2$ where $\Gamma_2/2\pi \approx 3.3$ Hz is the intrinsic dissipation rate of mode2. The two modes persist in this state by spontaneously transferring energy from mode2 to mode1, indicated by the energy gain and rapid energy loss of mode1 and mode2 in Fig. 3(b). Their energies are calibrated to the same scale and fitted (black line) based on energy conservation in this system. The coupled two modes system can be regarded as a parametric resonator at PTS (mode1) subject to a period-three harmonic drive (mode 2). Repeating the same ringdown-locking experiment, we find the system exhibits discrete relative phase $n\times 2\pi/3$ shown in Figure 4, similar to period-two parametric oscillators. Following this logic, the non-monotonic and negative energy dissipation rate of mode1 (Γ_1) shown in the inset of Figure 3(b) can be explained by the opposite Duffing coefficients of the two modes: (1) Spring softening effect of mode2 leads to increasing ω_2 during ringdown. (2) Locked by mode2, mode1's amplitude increases at higher frequency following its spring hardening spectrum.

Discussion

More generally, the gain or loss of mode1 can be engineered by altering mode2's Duffing coefficient, i.e. mode1 can either perform gain or rapid loss depending on mode2's parameters. The findings of phase-locking states and tunable dissipation rates are useful for energy dissipation engineering, such as for fast switches or low-dissipation timing/sensing devices. The proposed intuitive model provides a picture to understand the complicated dynamics in coupled nonlinear resonators. More details can be found in our preprint [6].

Figure 1: (a) Measurement schematics and false-colored SEM micrograph of the clamp-clamp beam MEMS. Optical and electrical measurements are performed, simultaneously. (b) Simulated mode shape of the two coupled modes.

Figure 2. Spectrums of mode1 and mode2 are labeled by yellow and green dots. The oscillating frequency of mode2 is divided by 3. The two modes have opposite Duffing coefficients. In ringdown experiments, we set the initial conditions at $A_{1,0}$ and $A_{2,0}$ (red dots), respectively, and turn off the drive simultaneously. They evolve to equilibrium following the black arrows. After locked at the black dots, mode1 experiences frequency and amplitude increase shown as the short black arrow.

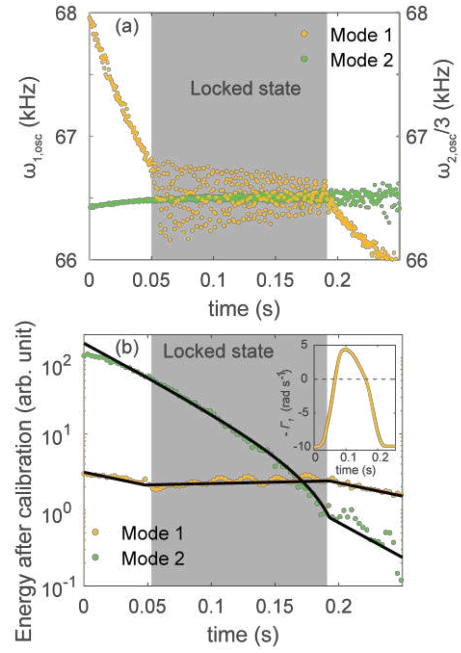

Figure 3. Oscillating frequencies and energy of the two modes are presented in (a) and (b), respectively. The yellow and green dots correspond to mode1 and mode2, respectively. The inset of (b) shows the minors of the measured effective dissipation rate of mode1 ($-I_1$). It indicates that mode1 shows a non-monotonic and negative dissipation rate during locking.

Figure 4. Relative phase of mode1 (ϕ_1) and mode2 (ϕ_2) in 7 repeating experiments. $\phi_1 - \phi_2/3$ exhibits discrete values of $(0, 2\pi/3, 4\pi/3)$ as expected in period tripling states.

Summary. Control-Based Continuation uses feedback control to follow stable and unstable branches of periodic orbits of a nonlinear system without the need for advanced post-processing of experimental data. CBC relies on an iterative scheme to modify the harmonic content of the control target and obtain a non-invasive control signal. This scheme currently requires to wait for the experiment to settle down to steady-state and hence runs offline (i.e. at a much lower frequency than the feedback controller). This paper proposes to replace this conventional iterative scheme by adaptive filters. Adaptive filters can directly synthesize the control target adequately and can operate online (i.e. at the same frequency as the feedback controller). This novel approach is found to significantly accelerate convergence to non-invasive steady-state responses to the extent that the structure response can be characterized in a continuous amplitude sweep. Importantly, the stabilizing effect of the controller is not affected.

State of the art of Control-Based Continuation

A common way to characterize the steady-state behavior of a nonlinear structure consists in identifying its orbits under a monoharmonic excitation. Nonlinear structures can reach different periodic orbits under identical excitation, each one with its own response amplitude, stability and harmonic content. Some of the responses are unstable and cannot be observed experimentally without diverging towards another periodic orbit. Control-Based Continuation (CBC) is an experimental method that stabilizes the structure using feedback control of the displacement to generate the excitation signal and reach these unstable response branches [1][2]. Characterizing the unstable branches is useful to uncover potential hidden branches that, even though stable, cannot be reached by performing standard uncontrolled experiments such as frequency sweeps [3].

Non-fundamental harmonic content of the displacement x is fed back through the controller and must be taken into account to ensure monoharmonic excitation, synonymous with non-invasiveness of the controller [4]. Current implementations of CBC shown in Fig. 1a iterate (e.g. using Newton or fixed-point iterations) on the harmonics of the non-fundamental component of the control target x_{nf}^* until the non-fundamental harmonics of the excitation signal are below tolerance [5][6]. The fundamental component of the target x_f^* determines the fundamental amplitude of the response. Such a method necessitates waiting for steady-state to perform the harmonic decomposition before each target update.

Control-Based Continuation with adaptive filtering

Adaptive filters have been used for online harmonic elimination in the literature [7]. In this work, they are used to estimate the non-fundamental harmonics of the response and synthesize the non-fundamental control target x_{nf}^* . The now fully online strategy is shown in Fig. 1b. No offline iteration is needed to ensure a non-invasive controller. Two continuation procedures can be considered: finite steps like the state of the art lead up to 25% of experimental time reduction; continuous sweep of the target amplitude lead up to 50% time reduction, but high sweep rate can induce transient effects in the system's dynamics, decreasing accuracy. When using an adaptive filter in closed-loop, the structural and filter dynamics are coupled. More research is needed to predict the effect of such a coupling. However, the convergence time of the adaptive filter in open-loop is significantly shorter than the structural transient time.

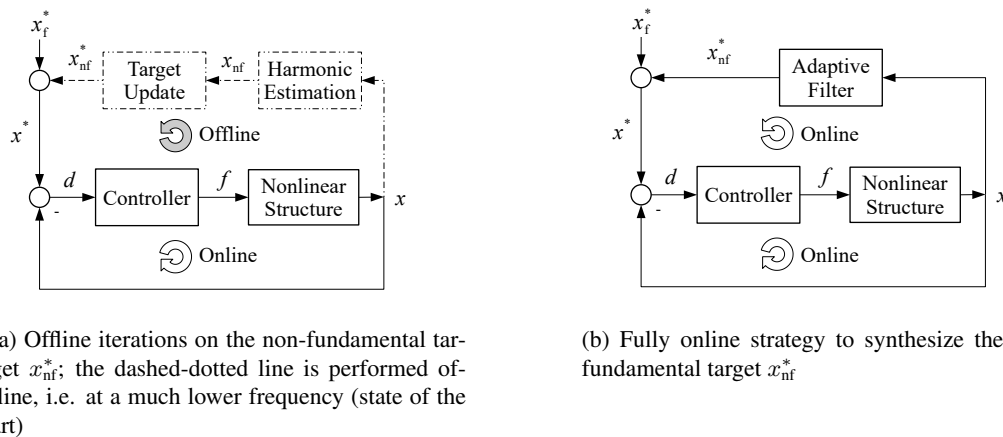

Figure 1: Two methods canceling high harmonic content in the excitation signal f by ensuring that the non-fundamental target x_{nf}^* equals the non-fundamental part of the response x_{nf} , making d monoharmonic; the fundamental target x_f^* drives the amplitude of response

Figure 2: The relationship between excitation and response amplitudes (S-curve) can be obtained by sweeping the target amplitude

Figure 3: S-curves are measured for different frequencies and the manifold is interpolated using a B-spline surface; the interpolated frequency response curves are obtained by slicing the surface in the frequency-response plane for constant excitation amplitudes

The proposed strategy is demonstrated numerically using a Duffing oscillator; the resulting time series and the corresponding S-curves at 7 Hz are shown in Fig. 2. By performing sweeps at different frequencies, the manifold characterizing the structural dynamics can be interpolated, as shown in Fig. 3a. The frequency response curves can then be extracted, they are shown in Fig. 3b.

Conclusion

An online method that identifies stable and unstable periodic orbits of nonlinear mechanical systems is proposed. To ensure non-invasiveness of the controller, an adaptive filter is used to synthesize a target which renders the controller's output monoharmonic. This strategy removes the need for offline iterations on the control target. Therefore, identifying complete frequency response curves with fully-transient sweeps is within reach, significantly accelerating the experimental characterization of nonlinear systems.

Optimal Control of Spin Coating on a Spherical Substrate

Ross G. Shepherd*, Edouard Boujo† and Mathieu Sellier*

Summary. We consider the optimal control of spin coating on a convex spherical substrate. We present a lubrication model for the flow of a thin fluid film on the surface of a rotating sphere, and derive a corresponding adjoint problem to calculate the effects of changes in spin speed on the thickness profile of films produced by spin coating. This was used to determine an optimal time-varying angular velocity throughout the spin coating process in order to produce a uniform coating over section of the substrate. With this we demonstrate that there are circumstances in which spinning can allow for greater control of coating thickness than gravitational draining, but even the best performance achieved by optimal spinning showed up to a 10% deviation from the desired coating thickness.

Introduction

Spin coating has been used in a wide range of industrial applications since the early 20th century as a technique to deposit thin liquid films onto flat substrates [1]. Today, it is used to apply functional and protective coatings in the manufacturing of printed circuit boards, solar panels, light-emitting diode displays, chemical sensors, and optical components [2]. Current spin coating methods are limited, however, to flat substrate geometries and cannot reliably produce uniform thin films over curved substrates. A novel spin coating process for curved substrates could enable the development of new technologies in consumer electronics, medicine, and optics, among many other fields. Building on the seminal work of Emslie et al. [3], spin coating on flat substrates has been extensively studied, however the problems associated with coating curved surfaces have received relatively little attention despite being identified as early as this original paper. Feng and Sun [4], Chen et al. [5], and Liu et al. [6] have all developed models for spin coating on spherical substrates and validated these against experimental measurements, but the question of how to improve coating performance on curved substrates has yet to be addressed. Here, we investigate whether the spin speed used throughout the process can be manipulated to improve coating performance on a convex spherical substrate.

Model Development

We consider the flow of an axisymmetric thin liquid film on the surface of a rotating spherical substrate, parameterised by the zenith angle ϕ from the top of the sphere. Let h be the film thickness measured normal to the substrate, let R be the substrate radius, and let Ω be the angular velocity of the substrate around the vertical axis. Choosing the average film thickness \bar{h} and drainage time $t_d = \mu_0 \bar{h} / \varepsilon \gamma$ as characteristic length and time scales (where $\varepsilon = \bar{h} / R$ and μ_0, γ are the initial viscosity and surface tension of the fluid), we derive a dimensionless 4th-order partial differential equation (PDE) describing the evolution of the film, with hats denoting rescaled dimensionless variables and subscripts denoting partial derivatives:

$$0 = \frac{\partial \hat{h}}{\partial \hat{t}} + \frac{1}{\sin \phi} \left(\frac{\hat{h}^3}{3\hat{\mu}} \sin \phi \left[\varepsilon^2 \hat{\kappa}_\phi + Bo \left(\sin \phi - \varepsilon \hat{h}_\phi \cos \phi + \varepsilon Ga \hat{\Omega}^2 (\sin \phi \cos \phi + \varepsilon \hat{h}_\phi \sin^2 \phi) \right) \right] \right)_{\phi}. \quad (1)$$

Here, $Bo = \rho g \bar{h}^2 / \gamma$ is the Bond number, $Ga = \gamma^2 / \mu_0^2 \bar{h} g$ is the Galileo number characterising the relative strength of gravity and centrifugal force, and $\hat{\kappa}_\phi = \hat{h}_{\phi\phi\phi} + \hat{h}_{\phi\phi} \cot \phi + \hat{h}_\phi (2 - \csc^2 \phi)$ is the derivative of the dimensionless curvature of the free surface. We incorporate the effects of increases in viscosity due to curing or evaporation following the method of Lee et al. [7] by introducing the coefficient:

$$\hat{\mu}(t) = \begin{cases} \exp(\beta t), & t \leq t_c \\ \hat{\mu}_1 t^\alpha, & t > t_c \end{cases} \quad (2)$$

so that the time-varying viscosity may be written as $\mu = \mu_0 \hat{\mu}(t)$, with a characteristic curing time t_c after which the film becomes essentially solid. Here, $\hat{\mu}_1 = \exp(\beta t_c) t_c^{-\alpha}$ is chosen to ensure continuity. An example film evolution under the effects of gravity alone is shown in figure 1 (left panel) using the same fluid properties and substrate dimensions as [7]. We see that beginning from a non-uniform initial condition concentrated around the top of the sphere, the fluid drains over the entire upper half before hardening, leaving a non-uniform coating with thickness of approximately $\hat{h} \approx 2.5$.

Optimal Control Methodology

We now wish to determine how the angular velocity $\hat{\Omega}$ can be changed as a function of time throughout the spin-coating process in order to achieve a more even coating. We begin by choosing (as a proof of concept) the region of the substrate surface $\phi \in D = [0, \pi/4]$ over which we want to produce a uniform coating. We also choose $\hat{h}_{\text{opt}} = 2$ as a desired coating

Figure 1: (Left panel) Example evolution of a film under gravitational draining alone with $\hat{\Omega} = 0$, $Bo = 5.7 \times 10^{-3}$, $Ga = 6.9 \times 10^{-10}$, $\varepsilon = 2.6 \times 10^{-3}$, and $\hat{t}_c = 0.2421$ in order to match [7]. (Right panel) The optimal angular velocity distribution over time by the adjoint method with the same parameters, compared with an optimal constant angular velocity with comparable performance.

thickness, corresponding to the thickness of a uniform coating over the entire upper-half sphere. The uniformity of the final film $\hat{h}_f = \hat{h}(\phi, \hat{t}_f)$ at the time $\hat{t}_f = 2\hat{t}_c$ can then be characterised by:

$$\mathcal{J}(\hat{h}, \hat{\Omega}^2) = \int_D (\hat{h}_f - \hat{h}_{\text{opt}})^2 \sin \phi \, d\phi, \quad (3)$$

where small values of \mathcal{J} correspond to good coating performance. We determine the optimal $\hat{\Omega}(\hat{t})$ using the same method as Boujo and Sellier [8] by considering the constrained minimisation of (3) subject to (1). We then introduce an adjoint variable λ as a Lagrange multiplier for \hat{h} and derive a terminal value PDE which can be solved for λ . The adjoint variable then allows for the calculation of the gradient $d\mathcal{J}/d\hat{\Omega}$ and the use of a simple gradient-descent optimisation algorithm.

Results and Conclusions

The optimal control methodology described above was implemented using COMSOL Multiphysics and MATLAB for two cases: (i) with no restrictions on the angular velocity distribution over time $\hat{\Omega}(\hat{t})$, and (ii) with the additional constraint that $\hat{\Omega}$ is constant over time, similar a typical speed profile currently used in spin coating. The angular velocity profiles resulting from the optimisation are shown in figure 1 (right panel). We see that the optimal angular velocity is greatest early in the coating process, then decreases as the viscosity increases and the film hardens. The final film uniformities produced using adjoint optimised and constant angular velocities are $\mathcal{J}_{\text{adjoint}} = 7.55 \times 10^{-4}$ and $\mathcal{J}_{\text{constant}} = 8.17 \times 10^{-4}$, respectively, compared to $\mathcal{J}_0 = 0.0159$ if the film drains under gravity alone ($\hat{\Omega} = 0$). However, following optimal spinning the final film thickness still varied by up to 10% from \hat{h}_{opt} over the domain $D = [0, \pi/4]$. This shows that spin coating offers significantly improved control of film thickness over simple gravitational draining, but a constant angular velocity is able to achieve almost the same coating performance as the optimal time-varying velocity profile. We can conclude from this that spin coating cannot, in general, be used to uniformly coat a curved substrate even with optimised angular velocity. We also see that the use of an adjoint-optimised time-varying angular velocity cannot produce a significantly more uniform coating than the constant speeds typically used in spin coating. This suggests that new coating processes designed specifically for curved surfaces will be required if we wish to produce uniform spin-coated films on non-planar substrates.

Non-smooth inverted pendulum swing-up control optimization using a novel, Fourier series based numerical method

Marek Balcerzak*, Sandra Zarychta*, Volodymyr Denysenko* and Andrzej Stefanski*

*Division of Dynamics, Lodz University of Technology, Lodz, Poland

Summary. Swing-up control of an inverted pendulum is one of the classical tasks in dynamics and control theory. Optimization of the pendulum's trajectory and the corresponding control function is not trivial, particularly when the controlled object is non-smooth (for example, due to presence of dry friction). This short paper contains a concise description of a novel, Fourier series based numerical method of control optimization, which is able to successfully solve such problem. It is expected that this algorithm will enable progress in control optimization of systems, for which typical approaches cannot be utilized.

Introduction

Optimal control is the one that minimizes the cost of performing a desired action [1]. In the case of systems described by a set of ordinary differential equations (ODEs), the necessary conditions for control optimality have been described by Pontryagin [2] in terms of variational calculus. Another classical approach to solving optimal control problems is the dynamic programming method, introduced by Bellman et al. [3]. However, the former cannot be utilized in non-smooth and discontinuous systems, whereas the latter requires significant computing power even in simple cases [1]. Therefore, there is a need for a simple method which solves optimal control problems in non-smooth systems. In this paper authors present a novel, Fourier series based numerical algorithm [4] applied in optimization of the swing-up control of an inverted pendulum [5] with a dry friction discontinuity.

System description

Figure 1: Scheme of the inverted pendulum system

The inverted pendulum system [5], whose scheme is presented in Fig. 1, consists of the controlled cart, able to move along the x axis, with a mathematical pendulum of the mass m and the length l attached to it. Dry and viscous friction torque in the pendulum's bearing is taken into account, i.e. $T_f = c_v \dot{\varphi} + c_d \text{sgn } \dot{\varphi}$. The swing-up control means moving the cart in such a manner that the pendulum stands up from the initial state $\varphi = \dot{\varphi} = x = \dot{x} = 0$ (pendulum hanging vertically downwards) to the final one $\varphi = \pi, \dot{\varphi} = x = \dot{x} = 0$ (pendulum standing vertically upwards). Defining the dimensionless time $\tau = \omega t$ with $\omega = \sqrt{\frac{g}{l}}$, transforming the derivatives $\dot{\varphi} = \frac{d\varphi}{d\tau} \frac{d\tau}{dt} = \varphi' \omega$, $\ddot{\varphi} = \omega^2 \varphi''$, $\dot{x} = \omega^2 x'$ and introducing dimensionless parameters $z = \frac{x}{l}$, $\zeta = \frac{c_v}{2m\omega l^2}$, $\mu = \frac{c_d}{m\omega^2 l^2}$ yield the following dimensionless form of the model.

$$\varphi'' = -\sin \varphi - z'' \cos \varphi - 2\zeta \varphi' - \mu \text{sgn } \varphi'$$

The quantity $u = z' = \frac{\dot{x}}{\omega l}$, a dimensionless counterpart of the cart's velocity, is the controlled variable in the system. Obviously, velocity and acceleration of any physical drive are bounded. Moreover, the space in which the cart moves may be restricted. Therefore, the following constraints are assumed: $-z_{\max} \leq z \leq z_{\max}$, $-v_{\max} \leq z' \leq v_{\max}$, $-a_{\max} \leq z'' \leq a_{\max}$, where $z_{\max} > 0$, $v_{\max} > 0$, $a_{\max} > 0$.

Optimization method

Assume that the goal is to minimize two factors in parallel, motion time T and drive usage - the integral of u'^2 . Therefore, the cost functional can be defined as follows: $J = \int_0^T (\lambda + u'^2) d\tau$, where λ is a positive, real parameter. The proposed optimization method assumes that the control function $u(\tau)$ to be optimized is described using a finite number of harmonics of the Fourier series.

$$u(\tau) = \frac{a_0}{2} + \sum_{i=1}^K [a_i \cos(i\omega\tau) + b_i \sin(i\omega\tau)]$$

Bearing in mind that $u(\tau) = z'$ and taking into account the boundary conditions $z(0) = z'(0) = z(T) = z'(T) = 0$, it can be easily shown that $a_0 = 0$, $a_K = -\sum_{i=1}^{K-1} a_i$, $b_K = -\sum_{i=1}^{K-1} \frac{b_i}{i}$. Consequently, the control function $u(\tau)$ depends on $(2K - 2)$ independent parameters, which can be collected in a vector $\mathbf{H} = [a_1, b_1, a_2, b_2, \dots, a_{K-1}, b_{K-1}] \in \mathbb{R}^{2(K-1)}$. Taking a large enough value K enables to approximate $u(\tau)$ with arbitrarily high accuracy. Now an important fact must be noticed: the *direction* of the vector \mathbf{H} in $\mathbb{R}^{2(K-1)}$ is responsible for the *shape* of the function $u(\tau)$, i.e. signs of its derivatives of all degrees, locations of local extrema and inflection points etc., whereas the *length* of \mathbf{H} determines the *span*, i.e. the set of values and the global extrema of $u(\tau)$ [4]. Therefore, the *shape* of the function $u(\tau)$ for a fixed ω can be uniquely defined by a *direction* \mathbb{R}^{2K-2} , which in turn can be described by a point on a unit hypersphere immersed in \mathbb{R}^{2K-2} , i.e. on S^{2K-3} , a $(2K - 3)$ –dimensional one. Location of any point on such hypersphere depends on $2K - 3$ angular coordinates, which uniquely define the *shape* of $u(\tau)$ [4]. Assume that this *shape* is already known. Now, as the continuous function $z' = u(\tau)$ is constrained by $-z_{\max} \leq z \leq z_{\max}$, $-v_{\max} \leq z' \leq v_{\max}$, $-a_{\max} \leq z'' \leq a_{\max}$, there exists the smallest number $Q > 0$ such that at least one of the constraints is violated by $q * u(\tau)$ if $q > Q$. Consequently, as the shape of $u(\tau)$ is fixed, then $p * Q * u(\tau)$ with a parameter $p \in (0, 1]$ define all the admissible functions $u(\tau)$ of the shape defined by a point on S^{2K-3} . Summing up, K -harmonics approximation of any Dirichlet control function $f: [0, T] \subset \mathbb{R} \rightarrow [-v_{\max}, v_{\max}] \subset \mathbb{R}$ can be described using $(2K - 3)$ angular coordinates on S^{2K-3} and the parameters ω, p . Global optimization of all these parameters, for example using Differential Evolution method [6], leads to optimization of the control function $u(\tau)$ itself. When the proposed approach is utilized, smoothness of the controlled system is not required as long as the required trajectories exist and are unique.

Results and conclusions

The shape of the function $u(\tau)$ was optimized for $K \in \{2, 3\}$ parametrized in terms of spherical coordinates on S^{2K-3} along with the parameters $\omega \in [0.1, 10], p \in (0, 1]$ using the Differential Evolution method [6]. The results are presented in the graphs below.

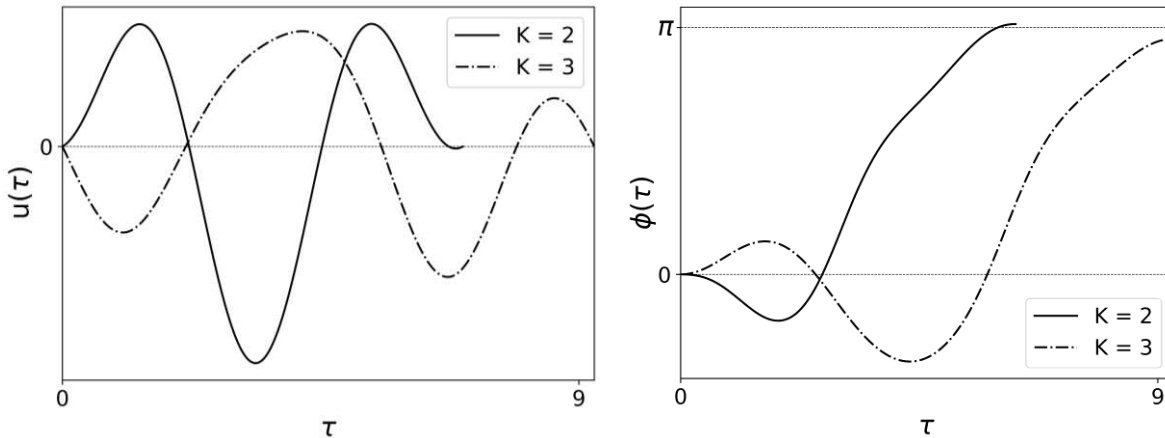

Figure 2: Results of optimizing the control function $u(\tau)$ with respect to the cost functional J .

The optimized values of the cost functional $J = \int_0^T (\lambda + u'^2) d\tau$ were approximately equal 13.93 (optimization with 2 harmonics, i.e. $K = 2$) and 12.62 (optimization with 3 harmonics, i.e. $K = 3$). Therefore, it can be noticed that increasing number of harmonics in the optimized function $u(\tau)$ from $K = 2$ to $K = 3$ increases accuracy of control optimization. It is expected that larger values of K lead to better approximations of the optimal control. As it can be noticed, the method works successfully in the discontinuous system. Authors hope that this algorithm will enable progress in control optimization of systems, for which typical approaches cannot be utilized.

Summary. Classical PID control is exploited widely in industrial motion systems suffering from dry friction. This is motivated by the easy-to-use design tools available. However, friction-induced limit cycling (i.e., *hunting*) is observed when integral control is employed on frictional systems that suffer from the Stribeck effect, thereby compromising setpoint stability. In addition, the resulting time-domain behavior, such as, e.g., rise-time, overshoot, settling time, and positioning accuracy, highly depends on the particular frictional characteristic, which is typically unknown or uncertain. On the other hand, omitting integral control can lead to constant non-zero setpoint errors (i.e., *stick*). To achieve superior setpoint performance for frictional motion systems in a repetitive motion setting, we propose a PID-based feedback controller with a *time-varying* integrator gain design. To ensure optimal setpoint positioning accuracy, a data-based sampled-data extremum-seeking architecture is employed to obtain the optimal time-varying integrator gain design. The proposed approach does not rely on knowledge on the friction characteristic. The effectiveness of the proposed approach is evidenced experimentally by application to an industrial nano-positioning motion stage set-up of a high-end electron microscope.

Introduction

The vast majority of the high-precision industry employs classical PID control, since control practitioners are often well-trained in linear control design (loop-shaping). Moreover, it is well-known that integral action in PID control is capable of compensating for *unknown* static friction in motion systems. However, friction-induced limit cycling (i.e., *hunting*, see [1]) is observed when integral control is employed on systems where the friction characteristic includes the velocity-weakening (Stribeck) effect, so that stability of the setpoint is lost. Even if stability can be warranted, rise-time, overshoot, settling time (see [2]), and positioning accuracy depend on the particular friction characteristic, which is highly uncertain in practice. Hence, despite the popularity of the PID controller in industry, friction is a performance- and reliability-limiting factor in PID-controlled motion systems.

In this work, we propose a PID-based learning controller in order to achieve a high setpoint accuracy for repetitive tasks in motion systems subject to unknown static and velocity-dependent friction, including the Stribeck effect. The PID-based learning controller consists of two elements. First, a PID control architecture with a *time-varying integrator gain* design is proposed, facilitating a tailored design such that friction-induced limit cycles can be avoided, and high accuracy repetitive setpoint positioning can be achieved instead. In addition, similar robustness properties as for the classical PD control at the desired setpoint can be achieved. Second, a sampled-data extremum-seeking architecture (see [3]) is proposed, in order to iteratively find the optimal time-varying integrator gain, in the presence of unknown friction. The effectiveness of the proposed approach is evidenced experimentally by application to an industrial nano-positioning motion stage set-up of a high-end electron microscope

Control problem formulation for frictional motion systems

Consider a single-degree-of-freedom motion system, consisting of a mass m sliding on a horizontal plane, with measurable position x_1 , velocity x_2 , control input u_c , and subject to a friction force F_f . The friction force F_f takes values according to the set-valued mapping of the velocity $x_2 \mapsto \Phi(x_2)$. The set-valued friction characteristic Φ consists of a Coulomb friction component with (unknown) static friction F_s , a viscous contribution γx_2 (where $\gamma \geq 0$ is the viscous friction coefficient), and a (unknown) nonlinear velocity-dependent friction component f , encompassing the Stribeck effect, i.e.,

$$F_f \in \Phi(x_2) := -F_s \text{Sign}(x_2) - \gamma x_2 + f(x_2), \quad (1)$$

The dynamics are governed by the following differential inclusion:

$$\dot{x}_1 = x_2, \quad m\dot{x}_2 \in \Phi(x_2) + u_c. \quad (2)$$

We focus on achieving high-accuracy positioning for frictional motion systems that perform a *T-repetitive* motion. We consider, for the position x_1 , a desired repetitive reference r , defined on the time interval $[0, T]$, where the system starts and ends at rest and define two particular time intervals; 1) the interval $t \in [0, T_B]$ during which the system is allowed to move from 0 to r , and 2) the interval $t \in [T_B, T]$, during which standstill at r is required. The time interval $[T_B, T]$ is typically used by the industrial machine, of which the motion system is part, to perform a certain machining operation, for which accurate positioning is required. We address the following setpoint control problem: *Design a PID-based control strategy for motion systems of the form (2), (1), that perform a repetitive motion profile and are subject to unknown static and velocity-dependent friction, such that high-accuracy setpoint positioning during the standstill time window is achieved.*

Figure 1: Nano-positioning motion stage set-up: ① Maxon RE25 DC servo motor, ② spindle, ③ coupling, ④ nut, ⑤ carriage, ⑥ linear Renishaw encoder, ⑦ bearings, ⑧ coiled spring.

Figure 2: Experimental results that show the error and corresponding $k_i(t)$ and u_c after the initial parameter setting $u_0 = [0.85, 0.175]^T \cdot 10^8$ (—), the 2nd (—), 4th (—), and 7th (—) extremum seeking controller update, leading to an achieved setpoint accuracy of about 4 – 6 nm.

A time-varying integrator gain design for PID-based control of frictional motion systems

Limit-cycle behavior present in the case of PID control with *constant* integrator gain is caused by the build-up of integrator action (during transients and the stick phase) in interplay with the friction characteristic, see, e.g., [1]. This observation motivates the design of a novel *time-varying* integrator gain $k_i(t)$ for point-to-point motion, namely: 1) the presence of integrator action still allows the system to escape undesired stick phases, 2) overcompensation of friction due to, e.g., a severe Stribeck effect, can be avoided, by altering $k_i(t)$ during the slip phase, and 3) zero integral action can be enforced at the setpoint when standstill of the system is required, such that robustness against other force disturbances is provided by the static friction. The resulting controller is then given by $u_c = k_p e + k_d \dot{e} + k_i(t)x_3$, $\dot{x}_3 = \varsigma(t)e$, with $\varsigma(t) \in \{0, 1\}$ a to-be-designed switching function that prevents uncontrolled growth of x_3 . We are able to 1) escape undesired stick phases by enabling $k_i \neq 0$ and $\varsigma(t) = 1$ during $t \in [0, T_B]$, and 2) create robustness to other force disturbances close to the setpoint, by enforcing $k_i = 0$ and $\varsigma = 0$ during $t \in [T_B, T]$. Thereto, we parametrize $k_i(t) = \sum_{j=1}^6 [v^{(j)} v^{(j+1)}] \Psi^{(j)}(t)$ by linear spline basis functions $\Psi^{(j)}(t)$, with $v^\top = [1 \cdot 10^8 \ u_0^\top \ 0^{1 \times 4}]$, and u_0 a to-be-optimized parameter vector.

PID-based learning control for an industrial nano-positioning motion stage

The working principle and the effectiveness of the proposed PID-based controller are demonstrated on an industrial nano-positioning stage, representing a sample manipulation stage of an electron microscope, exhibiting significant and unknown frictional effects. The experimental setup and a schematic representation are presented in Fig. 1. A sampled-data extremum-seeking architecture (see, [3]) is used to iteratively find a time-varying integrator gain design $k_i(t)$, ultimately leading to a position error in the range of 4 – 6 nm, depicted by (—) in Fig. 2. In contrast, the classical PID controller for this particular set-up yields an absolute error of about 100 nm on the same time interval, and does not provide robustness during the standstill time window. This clearly illustrates the performance benefits of the proposed PID-based learning controller in terms of the ability to cope with Stribeck friction and achieving superior setpoint positioning accuracy.

Conclusions

We have presented a novel time-varying integrator gain design for motion systems with unknown Coulomb and velocity-dependent friction, capable of achieving a high positioning accuracy, in contrast to classical PID control, which often leads to limit cycling. The optimal time-varying integrator gain is iteratively obtained by employing a sampled-data extremum-seeking architecture. The superior performance of the proposed control architecture over classical PID control is experimentally demonstrated on a nano-positioning stage of an electron microscope.

Summary. The development of electronics in general, in particular integrated circuits, allowed accurate and stable clock signal - or phase and frequency - distribution. The PLL is the fundamental component of clock signal distribution networks, and consists of a closed-loop control system that synchronizes a local oscillator, or clock, to a reference signal. The Phase-Locked Loop (PLL) is the basic element of clock signal distribution networks that is a fundamental part of digital communications networks. In many cases One-Way Master-Slave (OWMS) chain networks is used for clock signal distribution due to its reliability and low cost. Due to the nonlinear behavior of PLLs the design of the networks is a difficult problem, therefore, numerical simulations play important role. In this paper, a parallel computing strategy is used to simulate OWMS chain networks aiming to develop a more efficient simulation strategy, and to study the nodes interaction effects on the network due to parallel computing and distribution of the clock signal.

Index Terms — Clock distribution, phase-locked loop, synchronization, OWMS chain networks and parallel computing.

Introduction

PLLs (Phase-Locked Loops) are part of numerous applications in Electrical Engineering, control systems, and especially in communication networks. A time synchronization signal distribution network is defined by the connection of a certain clock oscillators whose purpose is to organize a temporal coordination. Synchronization networks are characterized by the fact that several oscillators (clocks) operate with the same frequency and phase. The basic element in these networks are PLL circuits [1, 2]. The PLL is a control system that synchronizes a local oscillator to an input signal. If properly designed the PLL tracks the input signal and filter phase and frequency fluctuations (jitter and wander) [3, 4, 5, 6].

The PLL block diagram shown in Fig. 1 is composed of a Phase Detector (PD), of a Low-Pass Filter (LPF) and of a Voltage Controlled Oscillator (VCO). The multiplier type PD compares the input signal v_i (Eq. 1) with the output v_o (Eq. 2) of the VCO and generates the phase error signal v_d with the same sign of the phase difference. The LPF filters the phase and frequency fluctuations and also provide the control signal v_c that controls the VCO frequency and phase (Eq. 3) around the free-running frequency ω_M .

Figure 1: PLL block diagram.

$$v_i(t) = v_i \sin(\omega_M t + \theta_i(t)) \quad (1)$$

$$v_o(t) = v_o \cos(\omega_M t + \theta_o(t)) \quad (2)$$

$$\frac{d}{dt} \theta_o(t) = k_o v_c(t), \quad (3)$$

Considering a multiplier type PD in Fig. 1 with the input and output signals in Eqs. 1 and 2, and that the VCO control signal 3, the mathematical model of a PLL is given by

$$L[\theta_o(t)] + GQ[\sin(\theta_o(t) - \theta_i(t))] = GQ[\sin(2\omega_M t + \theta_i(t) + \theta_o(t))], \quad (4)$$

where $G = \frac{1}{2} k_m k_o v_i v_o$ is the loop gain and the operators L and Q depend on the LPF transfer function. In addition, the nonlinear differential equation in 4 is of order $p + 1$ given that the LPF order is p [1, 5].

Network Synchronization

The clock signal distribution in synchronous networks requires that the frequencies and phases are common to all network elements. Many methods have been proposed for synchronization of spatially distributed clocks, such as mutually connected networks or master-slave networks. In mutually connected networks, see Fig. 2(a), all the PLLs (clocks) contribute to the phase and frequency scales. On the other hand, in Master-Slave networks, see Fig. 2(b), the master clock dictates

the phase and frequency scales. Due to simplicity and low cost, the Master-Slave strategy is frequently used for clock signal distribution. In OWMS (One-Way Master-Slave) networks, the master node has its own time base and is independent the others while slave nodes have their time base depends on a single node, may come from the master node or from another slave node. The master clock has its own and independent time basis. Slave clocks have their basis depending on a unique node, the master or another slave. Besides, these networks are classified according to the topology in chain and star.

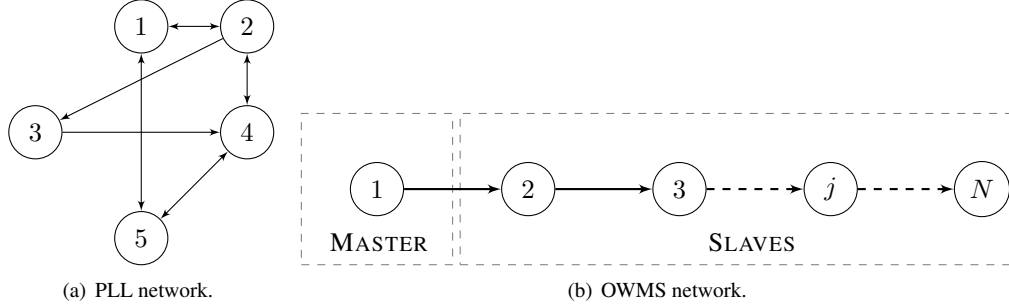

Figure 2: Clock signal distribution networks.

Considering an OWMS network with N nodes, as shown in Fig. 2(b), and the PLL model of the previous section, the OWMS network model of the slave nodes is given by

$$L^{(j)} \left[\theta_o^{(j)}(t) \right] + G^{(j)} Q^{(j)} \left[\sin \left(\theta_o^{(j)}(t) - \theta_o^{(j-1)}(t) \right) \right] = G^{(j)} Q^{(j)} \left[\sin \left(2\omega_M t + \theta_o^{(j-1)}(t) + \theta_o^{(j)}(t) \right) \right] \quad (5)$$

for $j = 2, 3, \dots, N$. As it can be noticed, the master clock's phase and frequency scales do not instantaneously spread throughout the network given that it depends on the dynamics of each slave node. In addition, noise, jitter and wander impair the quality of the clock signal distribution. The nonlinear and interaction of the slave nodes generate complex dynamics, and in this case numerical simulation is an important tool to study the qualitative behavior of the synchronization.

Parallel Programming

With the development of computational resources and multicore processors, it is possible to build faster computational systems with higher precision and stability using parallel programming techniques [7]. A program is considered sequential programming when it is viewed as a series of sequential instructions that must be executed on a single processor. A program is considered parallel programming when it is seen as a set of parts that can be solved concurrently. Each part also consists of a series of sequential instructions, which together can be executed simultaneously on several cores of the multicore processor, as depicted in Fig 3. Traditionally, parallel programming was motivated by the resolution of fundamental engineering problems of great scientific and economic relevance, called Grand Challenge Problems (GCPs). Typically, GCPs simulate phenomena that cannot be measured by experimentation, such as: climatic, physical, chemical and biological phenomena and in telecommunications, mainly in the propagation of signals. Two main reasons for using parallel programming are: to reduce the time needed to solve a problem and to solve more complex and larger issues [7].

Figure 3: Instructions will be executed simultaneously on multiple processor cores [7].

Today, applications that require the development of faster and faster computers are everywhere. These applications require a lot of computing power or require the processing of large amounts of information. Same idea can be applied for the simulation of synchronization networks. A computer program is considered parallel when it is organized as a set of parts that can be solved concurrently, reducing the time needed for complex computational solutions. Each part is also composed of a series of sequential instructions, but as a whole they can be executed simultaneously in several processors or processing cores, as depicted in Fig. 4.

In this paper the parallel programming is used to build and simulate the nodes of OWMS network. The target is developing an efficient simulation strategy, that allows to study the interaction of the nodes running in parallel in a distributed computation system.

Figure 4: Distributed processing system for a network [7].

Parallel Programming in Matlab

With parallel computing, Matlab can help solve large computing problems in different ways. The software provides an interactive programming environment where it can vectorize tasks and use parallel computing support through distributed matrices, allowing you to perform multiple calculations simultaneously. Big problems can often be broken down into smaller ones, which are then solved at the same time (in sync). The main reasons to consider parallel computing in Matlab are: optimization of simulation time when distributing tasks with simultaneous execution, solving big data problems and simulating signal propagation in telecommunications and electronics [8].

Workers in Matlab are the cores of the multicore processor and are thought of as computational engines that automatically execute smaller tasks (threads) in the background when triggered by parallelism commands. Here, the PARFOR loop was used, which executes the sequence of instructions of the loop in parallel, analogously synchronous counter.

Figure 5: Interactively run a loop in parallel using PARFOR [9].

Each loop execution is an iteration where the workers perform in any order and independently of each other. If the number of workers is equal to the number of iterations of the loop, each one performs one iteration, as depicted in Fig. 5. If there are more iterations than cores, some will run more than one, receiving multiple threads at once to reduce processing time. When using parallelism commands, consideration must be given to the parallel overhead, which includes the parameterization of the processor cores, the time required for communication, coordination and data transfer (sending and receiving data) [9].

Steps to simulate a OWMS chain network

To design the mathematical simulation some steps were followed:

- 1 - Simulation parameters: number of PLLs, start and end time, integration math step, time vector and number of integration points;
- 2 - PLL parameters: input and output sinusoids amplitudes, phase detector and VCO gains, free-running angular frequency and excitation signal input;
- 3 - Declaration of 2 auxiliary variables to handle parallel processing. Its necessary cause the processing output of each core is given by a matrix that indexes each line corresponds to a processor core;
- 4 - Designing the OWMS network: making a selector to identify the condition of PLL1 (Master) and the others PLLs (Slaves), that identify the blocks that should receive feedback signal (previous PLL);
- 5 - Run the Network in parallel processing (PARFOR Loop);
- 6 - Receive the calculated values from the simulating, compile results and call the graphics function.

Simulation graphics

The simulation was performed with 4 PLLs OWMS chain network and phase angle step excitation input $\theta_i(t) = u(t)$.

Let $v_i(t)$: input signal, $v_o(t)$: output signal; $v_d(t)$: output of detector phase; $v_c(t)$: control signal; $\theta_i(t)$: reference phase and $\theta_o(t)$: output phase (or lagged phase).

First PLL node (Master)

Conclusions

Dynamic Systems Simulation is a very useful tool for this type of problem, providing conditions of existence and stability for the synchronous state of networks, relating circuit parameters, delays and deviations. An OWMS chain network was modeled with order $P + 1$ PLLs as slave nodes, taking into account the jitter from the phase detector. Notes that if it is not properly mitigated, network performance can be seriously degraded. It was shown that amplitude on the control signal depends on the node gain and on the filter frequency response. Using several processing cores to build a synchronization network gives flexibility to the simulation, however, parallel interactions of the nonlinear nodes, including jitter and wander dynamics, can lead to complex dynamics and, probably, to a more realistic model of synchronization networks. While parallel computing can be more complex and have a higher upfront cost, the advantage of being able to solve a problem more quickly outweighs any difficulties.

Nonlinear oscillations of a beam-like model of pipe with deformable cross-sections

Arnaldo Casalotti and Daniele Zulli and Angelo Luongo

Department of Civil, Construction-Architectural and Environmental Engineering, University of L'Aquila, Italy

Summary. Nonlinear dynamics of a beam-like model of pipe are considered here. The mechanical model allows change in shape of the cross-sections of the pipe under bending, through a nonlinear and coupled response function for the hyperelastic materials, which is outcome of a homogenization procedure. The coupling between global bending and change in shape of the cross-sections is addressed, and large amplitude vibrations are analyzed under harmonic loading, including different internal resonance conditions.

Introduction

Pipes are widely used structures in civil and industrial applications, and the evaluation of their strength represents a key point for structural engineers to be addressed in the design process. Usually, their thin-walled nature introduces some peculiar features to be considered during structural analysis, like possible occurrence of local effects as well as change in the transversal shape. In this framework, the use of beam-like models for their analysis can, on the one hand, allow one to deal with (moderately) handy equilibrium or dynamic equations; on the other hand, they may not avoid to include specific aspects which are commonly discarded for slender beams, like cross-section change in shape and warping. For instance, it is well known that ovalization of the cross-section, taking place when pipes are bent over, may lead to instability phenomena, with consequent loss of carrying capacity of the whole structure. This phenomenon is explained by the occurrence of a limit point in the bending moment-curvature relationship, as a consequence of the softening nature of such a law, and is known as Brazier effect [1]. This specific effect is analyzed in [2] in case of anisotropic materials. In case of multi-layered structures, a one-dimensional beam-like, which is derived from a corresponding three-dimensional continuum, is proposed in [3], distinguishing the case of open and closed cross-sections and accounting for the Vlasov theory. Theories of multi-layered beams and cross-sectional models are addressed in [4], where use of the Variational Asymptotic Method is made to obtain the equations of motion. In [5], a homogeneous beam-like coarse model is adopted to describe the mechanics of thin-walled beams with possibility of cross-section distortion. In [6], static and free dynamic analysis of a homogeneous beam-like model is performed, after an identification procedure from a companion three-dimensional continuum. The same model is then extended in [7], where further parameters are introduced in order to take into account shear deformations in the multi-layered case, and in [8], where inertial contributions are identified in order to take into account dynamical effects.

In some cases, a soft core realized with structural foam may be introduced to improve the performance of the pipes under bending. For instance, in [9], the contribution of soft elastic cores is analyzed in thin-walled cylindrical structures, letting inspiration from nature where, e.g., plant stems or hedgehog spines have their mechanical efficiency increased by soft cores. In [10] the optimum design of thin-walled cylindrical shells with compliant cores, subjected to uniaxial compression and bending, is theoretically addressed and experimentally proved. In [11], an internally constrained beam model is proposed to deal with foam filled tubes, and equilibrium analysis is then performed in order to forecast and reproduce typical phenomena.

Here, the one-dimensional non-standard beam-like model presented in [7, 8] is used to address nonlinear oscillations under specific internal resonance conditions between global (bending) and local (ovalization) modes, also in presence of a resonant external load which expends work on cross-section flattening.

Equations of motion

A nonlinear beam-like model is used to analyze nonlinear dynamics of an elastic pipe. The beam model is shown in Fig. 1a, where the axis-line, spanned by the abscissa s running from 0 to l , and the generic cross-section are sketched. Besides the classical kinematic descriptors of planar Timoshenko beams, which are the longitudinal and transversal displacements of the axis line (u, v) and the cross-section bending rotation (ϑ), two further s - and time-functions are used, referred to as a_p and a_w and related to the cross-section change in shape, in its plane and out of its plane, respectively. The kinematic equations are posed and the dynamic equilibrium equations of the beam evaluated from the consequential use of the virtual power theorem. The constitutive relations are evaluated by means of a process of homogenization from a corresponding 3D model, shown in Fig. 1b, where the pipe is assumed as realized by longitudinal rods and transversal ribs. For the homogenization purposes, the change in shape of the cross-section is described as in the GBT theory [12], namely the kinematic variables a_p and a_w multiply assumed functions, as shown in Fig. 1c. The equations of motion are written

Figure 1: (a) The one-dimensional beam-like model; (b) the three-dimensional model with fibers and ribs; (c) the assumed functions and amplitudes for the change in shape of the cross-section.

below, where the nonlinear terms are related to elastic and inertial contributions:

$$\left[c_1 \left(v' - \vartheta - \left(\frac{\vartheta^2}{2} - \vartheta v' \right) \vartheta + \frac{1}{6} (\vartheta^3 - 3\vartheta^2 v') \right) - \frac{1}{2} c_1 a_w \vartheta' \right]' + p_v - m_1 \ddot{v} - \left\{ \frac{c_1 (v' - \vartheta) \vartheta^2}{2} - \vartheta \left[c_1 (v' - \vartheta) \vartheta + \int_s^l \left(p_u - m_1 \int_0^\xi \left(\frac{\vartheta^2}{2} - \vartheta v' \right) d\zeta \right) d\xi \right] \right\}' = 0 \quad (1)$$

$$\left[c_2 \vartheta' + c_3 a_p \vartheta' + c_4 a_p^2 \vartheta' - \frac{1}{2} c_1 a_w (v' - \vartheta) + \frac{1}{2} c_1 a_w \vartheta' \right]' + c_1 \left(v' - \vartheta - \left(\frac{\vartheta^2}{2} - \vartheta v' \right) \vartheta + \frac{1}{6} (\vartheta^3 - 3\vartheta^2 v') \right) - \frac{1}{2} c_1 a_w \vartheta' + (\vartheta - v') \left(c_1 (v' - \vartheta) \vartheta + \int_s^l \left(p_u - m_1 \int_0^\xi \left(\frac{\vartheta^2}{2} - \vartheta v' \right) d\zeta \right) d\xi \right) + c - m_2 \ddot{\vartheta} - m_3 \dot{a}_p \dot{\vartheta} - m_3 a_p \ddot{\vartheta} - m_4 \dot{a}_p a_p \dot{\vartheta} - m_1 a_w \dot{a}_w \dot{\vartheta} - m_5 a_p^2 \ddot{\vartheta} - m_6 a_w^2 \ddot{\vartheta} = 0 \quad (2)$$

$$[c_7 a_w + c_8 a_w^3 + \frac{1}{4} c_1 a_p']' - c_5 a_p - c_4 a_p \vartheta'^2 - c_6 \vartheta'^2 + q_p - m_4 \ddot{a}_p + \frac{5}{8} m_6 a_p \dot{\vartheta}^2 - m_7 \dot{\vartheta}^2 = 0 \quad (3)$$

$$c_{12} a_w'' - c_9 a_w - c_7 a_p' - c_{11} a_w^2 a_p' - \frac{1}{2} c_1 a_w \vartheta'^2 - c_{10} a_w^3 + \frac{1}{2} c_1 (v' - \vartheta) \vartheta' + q_w - m_6 \ddot{a}_w + m_6 a_w \dot{\vartheta}^2 = 0 \quad (4)$$

Boundary conditions are combined to Eqs. (1)-(4), prime indicates s -derivative and dot t -derivative, whereas p_v , c , q_p and q_w are external load components. It is worth noticing that the bending problem (variables v , ϑ) and the cross-section problem (variables a_p , a_w) are uncoupled in their linear part, while coupling occurs only due to nonlinear terms. Solutions are obtained both via perturbation methods and pure numerical approach, in case of internal resonance conditions among modes involving the bending and cross-section problems. Discussion on the effect of change in shape of the cross-sections during bending vibrations is provided, highlighting the resulting softening behavior related to reduction of bending stiffness of the pipe due to the cross-section flattening.

Conclusions

Nonlinear dynamics of a thin pipe is analyzed here. A homogeneous beam-like model is used, where specific kinematic functions describe the change in shape of the cross-section. Dynamic interaction between bending of the beam and change in shape of the cross-sections is addressed, leading to a softening behavior of the cantilever and related to the reduction of the bending stiffness as the cross-sections flatten.

Analysis of parametric instabilities of two-oscillator bi-linear model through the resonant order reduction in the vicinity of similar nonlinear normal modes

Anish Kumar* and Yuli Starosvetsky†

*Department of Mechanical Engineering, JK Lakshmipat University, Jaipur, Rajasthan, India

†Department of Mechanical Engineering, Technion-Israel Institute of Technology, Haifa, Israel

Summary. Present study is devoted to analysis of fundamental problem of parametric instability of damped-driven bi-linear two-oscillator model, given to the low-amplitude parametric forcing. Assuming the resonant excitation in the vicinity of similar NNMs, we derive the reduced order model. Further, applying the method of isolated resonance we analyze asymptotically the most significant family of sub-harmonic (m:1) resonance regions which reveal their peculiar properties.

Introduction

Response of bi-linear oscillatory systems subject to various types of forcing has become a subject of immense theoretical and experimental research. These models are broadly applied for mathematical modeling of the response of various engineering problems such as mooring towers [1], interlocking structures [2], suspension bridges [3], beams with breathing cracks [4] and many more. Numerous analytical and numerical works have been devoted to the analysis of externally forced, single bi-linear oscillator. Shaw and Holmes [5] were the first to develop the semi-analytical methods for the analysis of stability and bifurcation structure of periodic orbits emerging in the harmonically forced piece-wise linear oscillator (PWLO). In the same year, a thorough computational study of sub-harmonic orbits, bifurcations of periodic solutions and chaotic motion of harmonically forced piece-wise linear oscillator has been reported by Thomson et al. [6]. Some initial experimental work by Shaw [8] has shown the superharmonic and sub-harmonic steady state regimes in the experimental setup, mimicking the damped-forced response of piece-wise linear oscillator. We bring here some most fundamental theoretical works which considered the parametric instability phenomena arising in the various damped-driven piece-wise linear setups [9, 10, 11].

Model

In the present study we consider the damped-driven system of two coupled identical, bi-linear oscillators which assume the parametric excitation on the first oscillator. The non-dimensional equations of motion of the system under consideration read,

$$\xi_1'' + \epsilon \lambda \xi_1' + [1 + \alpha \mathcal{H}(-\xi_1)] \xi_1 + \beta (\xi_1 - \xi_2) + \epsilon P \cos(\Omega t) \xi_1 = 0, \quad (1a)$$

$$\xi_2'' + \epsilon \lambda \xi_2' + [1 + \alpha \mathcal{H}(\xi_2)] \xi_2 + \beta (\xi_2 - \xi_1) = 0, \quad (1b)$$

. Here ϵ is a formal, small non-dimensional system parameter. Where $\lambda, P, \alpha, \beta$ stand for the damping, forcing, bi-linear nonlinearity and coupling parameters. The formal small system parameter $0 < \epsilon \ll 1$ is introduced for scaling the magnitude of damping and forcing terms. This system can model the low amplitude vibrations of two linearly coupled, damped pendulums where one out of the two pendulums, performs the prescribed vertical oscillatory motion on its point of suspension.

It can be easily seen that OP NNM belongs to the special family of NNMs of similar type. Further setting the OP NNM to be the resonating mode, we define the two auxiliary coordinates $\xi_1 - \xi_2 = \eta$ and $\xi_1 + \xi_2 = \zeta$. It is reasonable to assume that in the resonant motion of the system being parametrically excited in the resonant region of OP NNM, the newly defined η variable, dominates over ζ . Applying some rather simple algebraic manipulation and using the same resonant assumption, one readily arrives at the following, reduced order model (ROM) i.e. the damped-driven, bi-linear oscillator which recovers the entire resonance structure of resonating OP NNM.

$$\eta'' + \epsilon \lambda \eta' + (1 + \alpha \mathcal{H}(-\eta) + 2\beta) \eta + \epsilon \frac{P}{2} \cos((m\Omega_N + \epsilon\sigma)t) \eta = 0. \quad (2)$$

Results

We rewrite Eq. (2) in the phase space form, as follows:

$$\dot{q} = p, \quad \dot{p} = -\epsilon \lambda p - (1 + \alpha \mathcal{H}(-q) + 2\beta) q + \epsilon \frac{P}{2} \cos((m\Omega_N + \epsilon\sigma)t) q, \quad (3)$$

It is worthwhile noting that the asymptotic analysis applied in the present work is valid up to $\mathcal{O}(\epsilon)$ order. Therefore, the terms of the higher asymptotic order are omitted in the following part of analysis. To derive the asymptotic approximation for transition curves corresponding to the special family of (m:1) resonant tongues, we introduce the action-angle variables [11, 12]

$$I(E) = \frac{1}{2\pi} \oint p(q, E) dq, \quad \text{and} \quad \Theta = \frac{\partial}{\partial I} \int_0^q p(q, I) dq. \quad (4)$$

and using the method of isolated resonance derive the averaged flow in the neighborhood of $(m:1)$ resonance tongues. Further analysis of the averaged flow, reveals the closed form asymptotic approximations for the transition curves for different resonance conditions (see e.g. [12]). Please note that $\epsilon\sigma$ stands for the small detuning parameter, while the excitation frequency in the vicinity of $m:1$ resonant neighborhood is taken as $\Omega = m\Omega_N + \epsilon\sigma$. Here Ω_N is a natural frequency of the out-of-phase NNM. In Figure. 1 we present the stability charts for the three resonant cases. It can be readily seen that the analytical approximation of transition curves (shown by black solid lines) are in very good agreement with the results of numerical simulations of the full model (Eqs. (1a) and (1b)). In Figure.2 (left panel) we present the evolution of transition curve w.r.t damping. In the limiting case of zero damping transition curves become straight lines whose slopes change w.r.t the system parameter α . As is shown in 2 (right panel) the width of the instability regions, varies w.r.t the change in the parameter of non-linearity, such that the well-known, fundamental, 2:1 parametric resonance tongue can become narrower than the 1:1 tongue.

Figure 1: Stability chart for resonance conditions (a) 1 : 1, (b) 2 : 1, and (c) 3 : 1. Here green and red colours represent stable and unstable regions, respectively obtained numerically from exact model in Eqs. (1a) and (1b) and black solid lines represent instability boundaries obtained using A-A method. Parameters are $\alpha = 2$, $\beta = 0.5$, $\lambda = 0.005$ and $\epsilon = 0.1$.

Figure 2: (a) Variations of the instability tongues with damping coefficient λ for resonance condition 2 : 1. (b) Variations of the slope corresponding to each resonance condition with α .

Concluding Remarks

Present study has concerned the resonant parametric excitation of the symmetric system of two coupled bi-linear oscillators. To derive the relatively simple analytical approximation to transition curves, we derive the reduced order model which mimics the response of resonantly excited two-oscillator model in the vicinity of out-of-phase NNM. Boundaries of the transition regions emerging in the original, parametrically forced system are approximated asymptotically. Transition curves emerging from the analysis of effective bi-linear, parametric oscillator are in very good agreement with numerical results of the original system. In this talk, we will also present the alternative analytical treatment for the case of resonant system reduction in the vicinity of NNMs of the general type. This part of the talk is currently a work in progress.

On the Nonreciprocal Dynamics of Bilinearly Coupled Oscillators

Ali Kogani, Hooman Zoka and Behrooz Yousefzadeh
*Department of Mechanical, Industrial and Aerospace Engineering,
 Concordia University, Montreal, QC, Canada*

Summary. This work explores nonreciprocity in the dynamic response of oscillators that are coupled by a bilinear elastic force and subject to external harmonic drive. The conditions for breaking reciprocity and the influence of different parameters on the steady-state nonreciprocal dynamics of the system are described. The manifestation of nonreciprocity in the time profile of the response is discussed in terms of the amplitudes of oscillation, phase differences and time-independent shifts. While the main focus is on the frequency-preserving response regime, the nonreciprocal response beyond the weakly nonlinear regime is also addressed.

Introduction

There has been an incredible interest in the recent years to explore scenarios in which reciprocity theorems do not hold [1]. A main motivation is that deviation from reciprocity can lead to asymmetric propagation of elastic waves for opposite directions. Reciprocity theorems generally apply to linear, time-invariant systems [2]. The breakdown of reciprocity may take place, for example, in systems with time-dependent (active) [3] or nonlinear (passive) [4] material properties. The focus of this work is on nonreciprocity caused by nonlinearity. In particular, the nonreciprocal dynamics that results from bilinear elasticity is studied. A bilinear spring exhibits two different values of stiffness with a transition occurring at a critical strain. Bilinear stiffness is used, among other problems, for modeling systems involving contact and friction. A system with bilinear elasticity, due to its non-smooth character, can exhibit complex nonlinear dynamic behavior [5]. This work studies the conditions that lead to the emergence of nonreciprocal dynamics in bilinearly coupled oscillators subject to external harmonic excitation.

Bilinearly Coupled Oscillators

The following normalized equations govern the dynamics of the system considered here

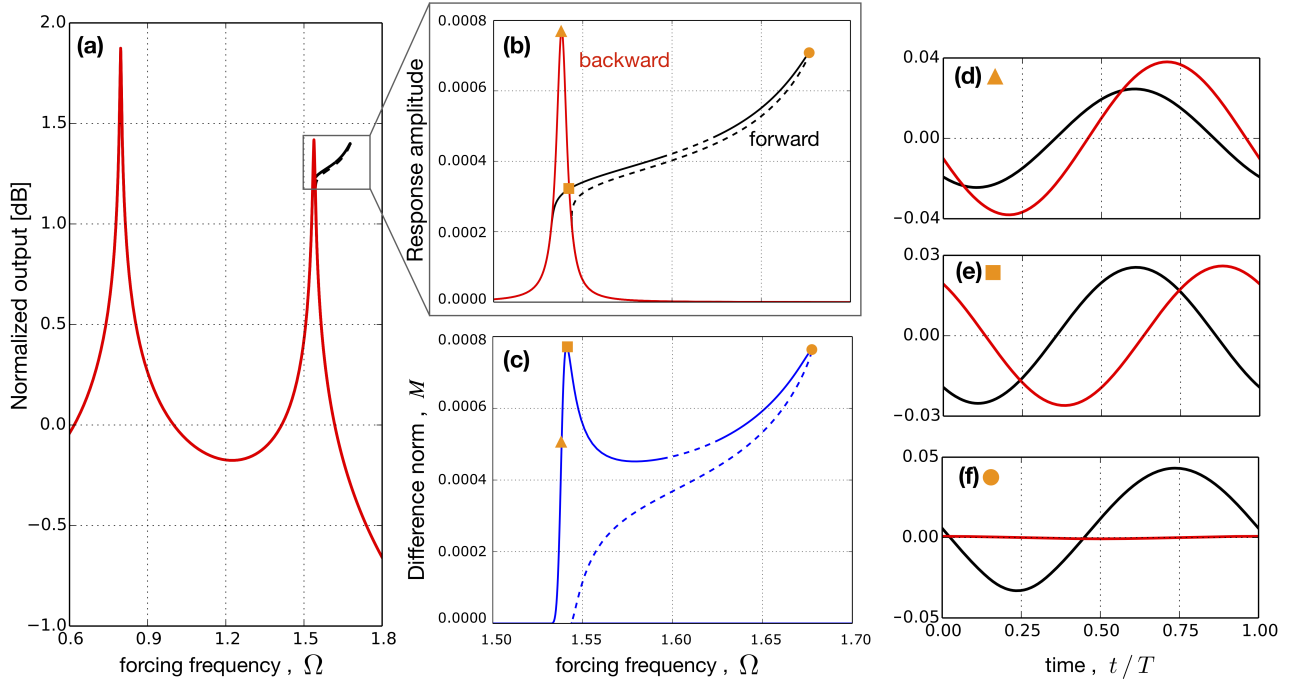

$$\begin{cases} \ddot{x}_1 + c\dot{x}_1 + x_1 + k_c(x_1 - x_2) = F_1 \cos(\Omega t) \\ (1 + \mu)\ddot{x}_2 + c\dot{x}_2 + x_2 + k_c(x_2 - x_1) = F_2 \cos(\Omega t) \end{cases}, \quad k_c = \begin{cases} 1 + b, & x_1 - x_2 > d \\ 1, & x_1 - x_2 < d \end{cases} \quad (1)$$

where d is the offset above which bilinearity is triggered. The steady state dynamic response is computed as the periodic orbits of Eq. (1) using the numerical continuation software package AUTO [6]. The bilinear stiffness is regularized using a hyperbolic tangent function to maintain smoothness. A very large coefficient is used for regularization to ensure the results are representative of the bilinear system.

To investigate reciprocity, two configurations need to be considered: (i) *forward*, where $F_1 = P$, $F_2 = 0$ and the steady response of x_2 is monitored; (ii) *backward*, where $F_1 = 0$, $F_2 = P$ and the steady response of x_1 is monitored. A reciprocal response is characterized by $x_2^f = x_1^b$, where the superscripts f and b denote the response in the forward and backward configurations, respectively. To better analyze the results, the steady time-periodic response of each oscillator is decomposed into a constant (time-independent) and oscillating component: $x_i(t) = C_i + y_i(t)$, where $C_i = (1/T) \int_0^T x_i(t) dt$ with T denoting the period of oscillations. Furthermore, the amplitude of oscillations is defined as A_i , where $A_i^2 = (2/T) \int_0^T y_i^2(t) dt$. A difference norm M is used as a quantitative measure of nonreciprocity: $M = (1/T) \int_0^T (x_2^f - x_1^b)^2 dt$.

Nonreciprocal Dynamics

Fig. 1 shows the steady response of the system for $\mu = 1$ and $b = 1$. A damping coefficient of $c = 0.008$ is chosen. A non-zero value of $d = 0.1$ is chosen for the offset; accordingly, the response of the system is linear for very small values of the driving amplitude. The driving amplitude $P = 0.0015$ is just high enough to trigger the transition into bilinearity (i.e., $x_1 - x_2 > d$) for one of the configurations. Panel (a) shows the normalized amplitude of oscillations $\log_{10}(A_i/P)$ as a function of Ω for the forward and backward configurations. As expected, the first appearance of nonlinear behavior occurs near the out-of-phase mode because $(x_1 - x_2)$ has a larger value there. The inspection of A_i near this resonance in panel (b) shows that while the system is behaving linearly in the backward configuration, the response of the forward configuration has clearly entered the nonlinear regime. The initial effect of bilinearity is to increase the frequency of the second mode (because $b > 0$). Panel (c) shows the difference norm M for the same frequency range as in panel (b). The time profile of three points are shown in panels (d)-(f), with the corresponding points marked by a triangle, square and circle in panels (b) and (c). Panel (d) corresponds to the peak oscillation amplitude of the backward configuration. Panel (e) corresponds to equal oscillation amplitudes for the forward and backward configuration. Note, however, that it corresponds to a large phase difference between the two configurations, which is responsible for the large value of M ; see [7] for a detailed discussion. Panel (f) corresponds to the peak oscillation amplitude of the forward configuration. The backward configuration is off-resonance at this point, explaining the large difference between the amplitudes.

 Figure 1: The steady-state dynamic response of the system for $\mu = 1$ and $b = 1$.

The bilinear nature of the coupling force causes nonreciprocity in the system, manifested by a large difference in the amplitude of oscillations (panel (f)), as well as a significant phase difference between the backward and forward configurations (panel (e)). The bilinear response may also exhibit a time-independent component (a DC shift). In particular, the shift in the response is different for the forward and backward configurations, contributing to the nonreciprocity of the response. This shift can be seen in panel (f) for the forward configuration. In the weakly nonlinear regime, the DC shift in the response is less significant than the shift in the resonance frequencies (i.e., it appears in a higher order of correction). It is important to note the significant influence of b and μ on nonreciprocity. b controls the degree of nonlinearity and its type (softening or hardening). In the limit of very large b , the coupling force is effectively modeling an impact problem [5]. Having a non-zero value for μ is essential for violating reciprocity because it is the parameter that breaks the symmetry; nonlinearity and asymmetry are both needed for breaking reciprocity in a passive dynamical system. The values used here for b and μ (as well as for c and d) can be realized in experiments.

At larger driving amplitudes (equivalently, at higher values of b or lower values of d), the backward configuration also exhibits nonlinear behavior in the out-of-phase mode. Beyond the weakly nonlinear response, we also observe some of the typical bifurcations in a bilinear system such as period doubling and subharmonic resonances. A period-doubling bifurcation is already detectable in Fig. 1(b), though it is not further explored here. As expected, these nonlinear behaviors are more readily accessible through the out-of-phase mode of the system.

Conclusions

Bilinearly coupled oscillators can exhibit steady nonreciprocal dynamics when subject to external harmonic drive. The nonreciprocal regime can be reached at relatively small values of driving amplitude, degree of bilinearity and asymmetry, making the mechanical system a good candidate for experiments. The nonreciprocal behavior manifests in the time domain as different amplitudes of oscillation, phases and time-independent shifts. Typical instabilities such as period-doubling bifurcations may be observed and further exploited for nonreciprocity. This work highlights the potential of bilinear elasticity in realizing passive nonreciprocity in mechanical systems.

Parametric excitation of an asynchronous Ziegler's column with a piezoelectric element

Carlos Mazzilli and Guilherme Franzini

Department of Structural and Geotechnical Engineering, Escola Politécnica,
University of São Paulo, São Paulo, Brazil

Summary. The paper addresses the use of a piezoelectric element for energy-harvesting purposes in a 2 DOF Ziegler's column subjected to a harmonically varying follower force. Hence, two different destabilizing mechanisms are potentially present in this problem, namely the follower-force-driven flutter and the parametric instability. The system parameters are chosen in such a way that the column is tuned into the principal parametric resonance with respect to an asynchronous vibration mode. The initial voltage applied to the piezoelectric element is a key variable which either favours vibration control – as a result of the structural stiffening associated to the inverse effect, inherent to piezoelectric coupling – or energy harvesting. For brevity reasons, only small initial voltages will be considered herewith, focusing the case of enhanced vibrations to a stable post-critical steady state, which is suitable for energy harvesting. Due to the similarity of this problem to that of pipes carrying fluids or gases in harmonic flows, it is expected that similar behaviour could also appear there.

Introduction

The 2 DOF model of a column with a follower force P , forming an angle θ_2 with the vertical direction, as represented in Fig. 1, is the classic model studied in [1,2]. In this paper, it is further assumed that the follower force varies harmonically with time, so that $P(t) = P_0 + P_1 \cos \Omega t$. When $L_1 = L_2 = L$, $M_1 = 2M_2 = 2M$, $K_1 = K_2 = K$, $C_1 = C_2 = 0$ and also $\bar{p} = \frac{P_0 L}{K} = 2$, the system displays a stable asynchronous (in the sense it is *localised*) vibration mode $\mathbf{u}_1 = \{\theta_1 \ \theta_2\}^T = \{0 \ 1\}^T$ with natural frequency $\omega_{10} = \frac{1}{L} \sqrt{\frac{K}{M}}$. By the way, this value of $\bar{p} = 2$ is *slightly smaller* than the critical load $\bar{p}_{cr0} = \frac{7-2\sqrt{2}}{2}$ that causes instability of the trivial solution for the undamped model, as seen in [3]. At \bar{p}_{cr0} a supercritical Hopf bifurcation takes place and a stable periodic attractor appears. It is worth noting that there is also a subcritical Hopf bifurcation at \bar{p}_{cr0} , indicating that if $\bar{p} < \bar{p}_{cr0}$, which happens to be the case, the basin of attraction of the stable trivial solution is very small due to the proximity to the critical load. It is further known that even an infinitesimal damping $C_1 = C_2 = \mu$ is capable of finitely reducing the critical load of the model to $\bar{p}_{cr\mu} = \frac{41}{28}$, as seen in [3]. Hence, the load $\bar{p} = 2$ that tunes the system into a *stable* asynchronous mode, which is *smaller* than the critical load for the undamped system, becomes *larger* than the critical one for the damped one.

Figure 1: 2 DOF Ziegler column with follower force

A single piezoelectric element is inserted in parallel with spring K_2 , with the following constitutive properties: electro-mechanical coupling term e_θ and capacitance C_p . Two dimensionless quantities associated with the piezoelectric parameters are introduced, namely $\sigma_1 = \frac{e_\theta^2}{C_p M L^2 \omega^2}$ and $\sigma_2 = \frac{1}{R C_p \omega}$, $\omega = \frac{1}{L} \sqrt{\frac{K}{M}}$ being the chosen reference frequency. The energy harvesting circuit is composed of an electrical resistance R . It is worth mentioning that if a new modal analysis is performed for the enlarged 3 DOF electro-mechanical model, in which the piezoelectric element voltage v is added as the third generalized coordinate, the previously found structural vibration mode \mathbf{u}_1 will not be practically affected, i.e. it will be *nearly-asynchronous*, provided σ_1 and σ_2 are *small*, which happens to be the case for $\sigma_1 = \sigma_2 = 0.01$. Yet, a slightly different natural frequency appears for the nearly-asynchronous mode, namely $\omega_1 = 1.02 \frac{1}{L} \sqrt{\frac{K}{M}}$. Further, a free-body mode $\mathbf{u}_0 = \{\theta_1 \ \theta_2 \ v\}^T = \{-0.817 \ -0.408 \ 0.108\}^T$ will also appear, coinciding with the quasi-static deformed configuration due to an applied initial voltage to the piezoelectric element, known as the *inverse effect*.

Parametric excitation

In addition to the follower force scenario, already explained, parametric excitation is applied to the column by means of a harmonic variation of load $P(t) = P_0 + P_1 \cos \Omega t$, with $\Delta p = \frac{P_1 L}{K} = 0.20$ about $\bar{p} = \frac{P_0 L}{K} = 2$. The forcing frequency Ω is assumed to be twice the natural frequency $\omega_1 = 1.02 \frac{1}{L} \sqrt{\frac{K}{M}}$ of the nearly-asynchronous mode, so that the system is subjected to the *principal parametric instability* of the trivial configuration. Nevertheless, due to the kinematic and piezoelectric nonlinearities, it may be stabilised in a post-critical fluttering pattern. The piezoelectric element plays the role of an energy harvester. Fig. 2 illustrates the time histories for $\theta_1(t)$, $\theta_2(t)$ and $v(t)$ for a mechanically undamped ($\zeta = \frac{\mu}{2\sqrt{ML^2K}} = 0$) or a damped system ($\zeta = \frac{\mu}{2\sqrt{ML^2K}} = 0.01$). The assumed initial conditions were $\theta_1(0) = 0$, $\theta_2(0) = 0.01$ and $v(0) = 0$.

Figure 2: time histories for $\theta_1(t)$, $\theta_2(t)$ and $v(t)$

Although the follower-force-driven pattern alone *is not* characterised by localised vibrations, the parametric-instability pattern *does favour* localisation. It is seen that, for sufficiently large values of Δp , which happens to be the case here, the parametric instability pattern *prevails*, as seen in Fig.2, since $\theta_1(t) \approx 0$. The undamped case leads to a *post-critical amplitude-modulated nearly-asynchronous response*, whereas the damped one indicates a well-defined *stable periodic steady state nearly-asynchronous response*, in which $\theta_2(t)$ and $v(t)$ are in *anti-phase*.

Conclusions and final remarks

The two mechanical DOF Ziegler column model has been addressed in a scenario characterised by the coupling of four phenomena, namely: follower-force-driven flutter, parametric instability, modal asynchronicity and energy harvesting using a piezoelectric element. The paper is still the result of on-going research. The high system-parameter-space dimension didn't allow yet for an exhaustive study of all possible response regimes, such as those related to vibration control and the influence of the inverse-effect phenomenon provided by the piezoelectric constitutive properties. Future work will also look at the three mechanical DOF model of the Ziegler's column and the continuous model of the Beck's column. As already mentioned, the problem of pipes carrying fluids or gases in harmonic flows, due to common characteristics with the model studied herewith is of the author's interest.

Summary. Braking systems of modern cars require a high speed contact between a rotating and a stationary part, with material flows taking place in between for optimal functioning. During those situations, self-excited vibrations can lead to squeals phenomena which can be of high intensity. A high speed contact test rig was developed to recreate various contact conditions occurring in a road profile. Thermal and mechanical instrumentation were used in each test, coupled with surface observations and numerical modeling. Establishing an understanding of thermo-mechanical phenomena and tribological behavior of the contact to guide machine learning models allows to develop a more accurate, physics-based estimation of the squeal occurrence in a frictional contact.

Pin-on-disk interaction

The self-excitation of friction-induced vibrations has a long history in tribology and vibrations research, and still today lacks a full-explanatory framework of mechanisms, driving factors and instability conditions [1, 2]. Most uncertainty stems from the frictional interface, which is notoriously difficult to access, measure and characterise in practice [3]. However, data retrieved from the interface carry information representative of the whole system (state of materials, vibrations from all scales...). In this work an experimental study of frictional contact between a pin and a rotating disk is conducted (Fig. 1), with self-excited vibrations and squeal sound emissions. The set-up is heavily-instrumented at the system and contact scales. Particularly, along thermomechanical characterization from sensors on the pin and disk, surface observations such as profilometry are realised on both parts between solicitations to track the interface evolution. Cross-checking those pieces of information allows for the deduction of which phenomena will be in play during the contact and to establish a better understanding of their influence on vibrations and squeal. Tests are realised with various contact parameters (in term of normal load, rotating speed of the disc, contact duration and duration between each contact) to represent different road profiles.

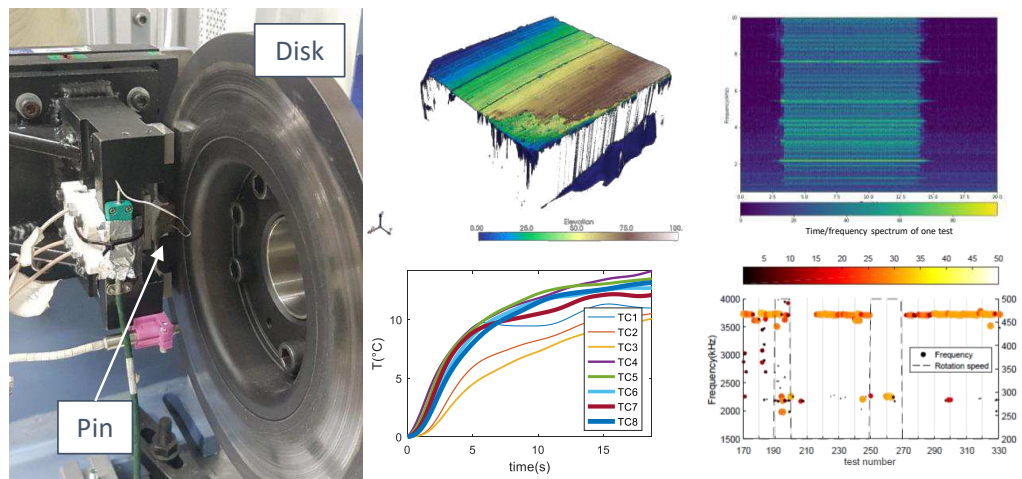

Figure 1: Pin and disk assembled on the test bench - sample recordings of temperatures, frequencies and surface observation.

Data analysis

The aim of this work is to establish the relation between phenomena involved at the interface and the propensity of high-amplitude self-excited vibrations for the system at hand. In order to further reveal the relation of effect and cause, a data analytics perspective is taken. Machine learning models are set up to replicate the dynamical system in the sense of a digital twin model, and recognize patterns in the high-dimensional space of loading conditions acting in the interface and the structural response [4]. Based on the extensive experimental measurements and with the help of appropriate processing algorithms the study of correlations between physics expected to be responsible of self-excited vibrations and squeal occurrence is investigated [5]. Deep learning methods, namely recurrent and convolutional neural architectures, are employed to approximate the functional relationship of external loads (frictional contact loads), internal states (interface

temperatures and friction), and the vibrational response of the structure at hand. A multivariate sequence classification task is set up to predict a binary target indicating linear instability and the resulting nonlinear high-amplitude vibrations. Neural architecture search is performed upfront for selecting proper model hyperparameters and results are reported in terms of binary classification metrics with an intentional correction of imbalanced data sets. Correlations are identified, for example, between heating and squealing events, which are signs of variations in load-bearing area [6] and in the contact interface morphology.

Conclusion

Post-mortem observations of the surfaces (profilometry, camera) allows the identification of various material flows through the contact, which are used to establish a phenomenological model of the third body at the interface. Thermo-mechanical characterisation realised during tests allows to better understand the mechanisms underlying those material flows and to locate them in time and place. The influence of contact parameters is investigated to guide machine learning models, which highlight the relationships between the identified phenomena and the occurrence of self-excited vibrations. The treatments also show the importance of considering the history effects corresponding to the evolution of the tribological situation. This study shows the contribution of machine learning models in the prediction of non-linear vibrations from frictional contact.

Free Vibration Analysis of Functionally Graded Plates with Crack or Slit by the R-Functions Method

Jan Awrejcewicz^{*}, Lidiya Kurpa^{**}, Tetyana Shmatko^{**}, Aleksandr Shmatko^{**}

^{*}Lodz University of Technology, Poland

^{**}National Technical University "KhPI", Kharkov, Ukraine

Summary. The proposed approach applies the Ritz method combined with the R-functions theory to analyze the free vibrations of cracked functionally graded material (FGM) plates of an arbitrary planform and different boundary conditions. Material properties are assumed to be temperature-independent and varying along the thickness direction according to Voigt's law. The paper proposes a new set of admissible functions in order to describe the effect of cracks on the frequencies and mode shapes of vibrations. The admissible functions constructed by the R-functions theory take into account discontinuous of deflection. A comparison of the obtained results with available ones for rectangular plates confirms validation of the proposed approach. The present method is employed to obtain the frequencies and mode shapes for FGM plates with complex form and internal cracks, having various locations and length. Effects of the gradient index, crack location, crack length and orientation on frequencies and mode shapes of FGM plates are studied.

Introduction

Free vibration analysis of cracked functionally graded materials (FGM) plates with complex planform is a difficult mathematical problem, but it is very important for investigation of the nonlinear dynamical behavior of many modern thin walled construction. Number of publications devoted to this problem is quite limited and concerns only rectangular plates [1-3]. In this study we propose to apply the R-functions theory to construct the corresponding admissible functions which take into account the discontinuous behavior of the deflection of FGM plates with complex planforms. The developed approach is tested on linear vibration problems, what is important for solving nonlinear vibration problems.

Problem formulation

Assume that a plate is made from a mixture of ceramics (top of the plate) and metal (bottom). Below a power-law distributions (Voigt's model) of the volume fractions of the metal and ceramics is employed. Then the effective material properties $P_{ef}(z)$ such as Young's modulus E , Poisson's ratio ν , and mass density ρ can be expressed as [1-4]:

$$P_{ef}(z) = (P_c(T) - P_m(T)) \left(\frac{z}{h} + \frac{1}{2} \right)^k + P_m(T). \quad (1)$$

Mechanical characteristics of ceramic P_c and metal P_m depend on temperature T . This dependence is defined by known formula presented in work [4]. Stress and strain resultants in matrix form are as follows:

$$\{N\} = [A] \{\varepsilon^0\} + [B] \{\chi\}, \quad \{M\} = [B] \{\varepsilon^0\} + [D] \{\chi\}, \quad (2)$$

where $\{N\} = \{N_{11}, N_{22}, N_{12}\}^T$ are forces per unit edge length in the middle surface of a plate, $\{M\} = \{M_{11}, M_{22}, M_{12}\}^T$ are bending and twisting moments per unit edge length, whereas the components of the vectors $\{\varepsilon^0\} = \{\varepsilon_{11}^0, \varepsilon_{22}^0, \varepsilon_{12}^0\}^T$ and $\{\chi\} = \{\chi_{11}, \chi_{22}, \chi_{12}\}^T$ are defined in the following way

$$\begin{aligned} \varepsilon_{11}^0 &= u_{,x} & \varepsilon_{22}^0 &= v_{,y} & \varepsilon_{12}^0 &= u_{,y} + v_{,x}, & \varepsilon_{13} &= \delta(w_{,x} + \psi_{,x}), & \varepsilon_{23} &= \delta(w_{,y} + \psi_{,y}), \\ \chi_{11} &= \delta \psi_{,x} - (1 - \delta) w_{,xx}, & \chi_{22} &= \delta \psi_{,y} - (1 - \delta) w_{,yy}, & \chi_{12} &= \delta (\psi_{,x,y} + \psi_{,y,x}) - 2(1 - \delta) w_{,xy}. \end{aligned} \quad (3)$$

where u , v are middle surface displacements along the axes Ox and Oy respectively, w is the transverse deflection of the plate along the axis Oz , $\psi_{,x}$, $\psi_{,y}$ are angles of rotations of the normal to the middle surface about the axes Ox and Oy . Symbol $\delta = 1$ stands for first order shear deformation theory (FSDT) and $\delta = 0$ is associated with the classical theory (CLT). Elements of the matrixes $[A]$, $[B]$, $[D]$ have the following form:

$$([A], [B], [D]) = \int_{-\frac{h}{2}}^{\frac{h}{2}} E(z) [C] (1, z, z^2) dz, \quad [C] = \frac{1}{1 - \nu^2} \begin{bmatrix} 1 & \nu & 0 \\ \nu & 1 & 0 \\ 0 & 0 & \frac{1 - \nu}{2} \end{bmatrix}. \quad (4)$$

The proposed method of investigation of free vibration of FGM plates is based on an application of the R-functions theory and the Ritz method [5, 6]. Variational statement of the vibration problem is reduced to determine the stationary point of the following functional

$$J = U - \omega^2 P, \quad (5)$$

where U and P are maximum potential and kinetic energies [3] relatively:

$$U = \frac{1}{2} \iint_{\Omega} (N_{11}\varepsilon_{11} + N_{22}\varepsilon_{22} + N_{12}\varepsilon_{12} + M_{11}\chi_{11} + M_{22}\chi_{22} + M_{12}\chi_{12} Q_x\varepsilon_{13} + Q_y\varepsilon_{23}) d\Omega, \quad (6)$$

$$P = \frac{1}{2} \iint_{\Omega} I_0 (\dot{u}_t^2 + \dot{v}_t^2 + \dot{w}_t^2) + 2I_1 (\dot{u}_t \dot{\psi}_{x,t} + \dot{v}_t \dot{\psi}_{y,t}) + I_2 (\dot{\psi}_{x,t}^2 + \dot{\psi}_{y,t}^2) dx dy, \quad (7)$$

where

$$(I_0, I_1, I_2) = \int_{-\frac{h}{2}}^{\frac{h}{2}} \rho(z) (1, z, z^2) dz. \quad (8)$$

Construction of admissible functions

Let us construct admissible functions for FGM plates clamped on part of the border and free on remain part of the border. Suppose that a crack or a slit is located on the straight line directed from the free plate part to inside domain. Equation of the clamped part of the border $\omega_1(x, y) = 0$ can be constructed by the R-functions theory. Normalized equation of the crack or slit $\omega_2(x, y) = 0$ can be also constructed using tools of the R-functions theory. If crack or slit lies on the line l with the normalized equation $l = 0$ and the function $\varphi(x, y) \geq 0$ describes the area, separating the part of the line coinciding with length and position of the crack or slit, then the function $\omega_2(x, y) = 0$ takes the following form

$$\omega_2(x, y) = \sqrt{l^2 \vee_0 \varphi}, \quad (9)$$

where \vee_0 is a sign of the R-disjunction [6]. The R-function theory allows to construct an equation of the free part of the border $\omega_3(x, y) = 0$. It is possible to prove that solution structure with an account of crack on free part of the boundary plate has the following form

$$W = \frac{\omega_1^2}{\omega_1^2 + \omega_3} (\Phi_1 q_1 + \Phi_2 q_2 + (1 + \omega_3) \Phi_1), \quad (10)$$

where Φ_1, Φ_2, Φ_3 are indefinite components of the solution structure. Functions $q_1(x, y), q_2(x, y)$ are defined as

$$q_1(x, y) = (1 + D_1^{(l)} \omega_2(x, y)) / 2, \quad q_2(x, y) = (1 - D_1^{(l)} \omega_2(x, y)) / 2, \quad (11)$$

where $D_1^{(l)} \omega_2 = l_{,x} \omega_{2,x} + l_{,y} \omega_{2,y}$. It is possible to show that $D_1^{(l)} \omega_2 = \pm 1 + O(\omega_2)$.

The corresponding structures can be constructed for the functions u, v and ψ_x, ψ_y in a similar way. In order to get admissible functions, indefinite components Φ_1, Φ_2, Φ_3 are expanded into series over some complete system of functions $\{\varphi_i^{(k)}\}, k = 1, 2, 3$.

Conclusions

A new approach is proposed to study free vibrations of FG plates with cracks or slits. System of basic functions, which takes into account the shape of a crack and the discontinuous behavior of the deflection, is constructed by the R-functions theory. The proposed approach is validated against available results for the linear frequencies of cracked isotropic and FGM plates with various boundary conditions and rectangular planform. The comparison was made for simply supported square plate with center crack and cantilevered plate with a side crack. The obtained results are found to be in a good agreement with the known solutions. In order to demonstrate the possibilities of the proposed method and developed software, we have analyzed influence of the location, crack length on natural frequencies of the FGM plates with complex planform.

Summary: The paper gives further development of methods for reducing a system of partial differential equations (PDEs) to a system of ordinary differential equations (ODEs). Iterative methods are proposed which at each loading step for static problems and at each time step employ suitable approximating functions. The Bubnov-Galerkin method was considered as a basis for further consideration. The effectiveness of the developed methods were demonstrated by solving the problems of the theory of plates and shells. The proposed approaches allow us to solve a wide class of problems in linear/nonlinear formulation for both full-sized and nanoscale structures. The problems were solved taking into account the temperature field, geometric and physical nonlinearities, contact interaction between structures, as well as the Casimir and Van der Waals effects. The convergence theorems of solutions for some iterative methods were proved. Software packages for solving problems of statics/dynamics were developed. The exact solutions regarding plates were given taking into account the nanoscale parameter and constant load. Then exact solution was compared with solutions obtained by two iterative methods.

Introduction

Such problems are usually solved using the following methods: finite difference methods (FDM), finite element method (FEM) and in result a system of linear or nonlinear algebraic equations is obtained, which bounds application of these methods.

Mathematical models and solution methods

Iterative methods for reducing PDEs to a system of ODEs were constructed. These methods are based on the Bubnov-Galerkin method, and the method of Kantorovich–Vlasov (MKV) [1]. The latter method, by its ideology, match the Fourier method (MF) based on the variables separation and the Bubnov-Galerkin method (MBG), which gave impetus to a number of modifications (Fig. 1) including the following modifications: the Vaindiner method (MV)[2], the variational iteration method (MVI) [3] or extended Kantorovich method (EKM) [4], the Agranovsky – Baglai – Smirnov method (MABS) [5-6] and their combinations [7-10]. These articles provide evidence of convergence and a comparative analysis of the results can be applicable for full-sized structures. The method of variational iterations (MVI) eliminates the need to construct a system of approximating functions in the procedure of employment of the Bubnov-Galerkin method. The functions initially specified in an arbitrary way (obviously satisfying certain well-known smoothness conditions) were refined in the process of calculations by MVI based on the solutions of the original system of PDEs. The resulting system of functions was given and the Bubny-Galerkin method was used to obtain a system of ODEs with respect to another variable. This iterative process continues to obtain a solution with a given accuracy. In this paper, these methods are implemented to solve a class of problems in the mechanics of a continuous deformable medium. The nanostructures are described using the modified couple stress theory [11] and the classical theory of shallow shells. Contact interaction is investigated using the theory of Kantor. Physical nonlinearity is taken into account according to the deformation theory. The temperature field is determined from the solution of a three-dimensional heat PDE. The relationship between the strain fields and temperature is not taken into account

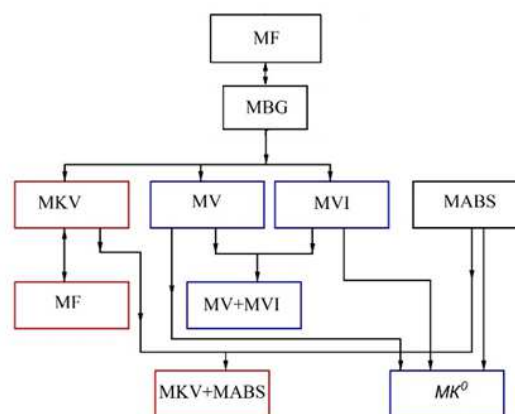

Fig.1 Interrelation of the Bubnov-Galerkin method, the Fourier method, the method of Kantorovich-Vlasov and their modifications

The effects of Casimir [12], Van der Waals are taken into account as well as a geometric non-linearity based on the von Kármán theory. The governing partial differential equations, boundary and initial conditions are obtained from the Hamilton principle and the calculus of variations. For a number of approaches (Fig. 1), theorems were formulated and proved for the existence and uniqueness of solution for the equations of nanostructures of rectangular shells in terms of geometric nonlinearity.

Results

As a numerical example, the results of a study of the static problem of a square in terms of a nanoplate are presented. The load is uniformly distributed over the plate area. Plate material is isotropic and elastic with Poisson's ratio $\nu=0.3$. The solution is obtained for two types of boundary conditions. The problems are solved in a linear formulation for a size dependent parameter $\gamma=0$ and $\gamma=0.5$. Exact solutions have been obtained.

Table 1.

Boundary condition	Exact solution	γ	MVI	MVI+MABS
Hinge	0.2028	$\gamma=0$	0.2030	0.2028
Rigid jamming	0.0661		0.0653	0.0661
Hinge	0.1064	$\gamma=0.5$	0.1073	0.1065
Rigid	0.0381		0.0376	0.0383

The solutions are obtained by a combination of MVI and MVI + MABS. These solutions practically coincide with the exact solution of the considered problems. This indicates the effectiveness of these methods. These two approaches have their advantages: there was no need to build an initial approximation that satisfies the given boundary conditions of the problem. The methods (MV) and (MV+MABS) have the same property. To analyze the problems of nonlinear dynamics, the methods of the theory of differential equations are used including analyses of signals, phase portraits, Fourier power spectra and wavelets. In addition, the Lyapunov exponents are numerically estimated using the Wolf, Kantz, and Rosenstein methods. Static problems are obtained from dynamic solutions using the set up method.

Remark. The approach proposed in Fig. 1 applies to elliptic equations. It is possible to extend it to linear and nonlinear hyperbolic equations. Then the solution can be represented as a product of three functions, each of which depends on one variable t, x, y . B Reducing the PDE's to ODE's regarding t at each time step, it was proposed to use the methods described in Fig. 1.

Summary. The sandwich conical shell with three layers is considered. The middle layer of the structure consists of honeycomb core, which is manufactured by FDM additive technology from ULTEM 9085 material. Top and bottom faces are produced from the carbon fiber-reinforced composite. The self-structure vibrations are observed due to structure interactions with supersonic gas flow. The assumed mode method is used to obtain the system of nonlinear ordinary differential equations for the structure motions. The combination of the shooting technique and the continuation algorithm is used to study the structure periodic vibrations. The periodic and quasiperiodic self-sustained vibrations are discussed. The quasiperiodic vibrations are born due to the Naimark-Sacker bifurcation.

Introduction

Honeycomb sandwich structures are commonly used in aircrafts and launch vehicle structures because of their superior strength and stiffness. Honeycomb sandwich shell can be used to make rocket and missile head shell, engine tail nozzle, spacecraft fairing, solar cell shell and so on. Therefore, many efforts were made to study the mechanical properties of the honeycomb sandwich structures. Now the nonlinear vibrations of the honeycomb sandwich structures are treated. The nonlinear vibrations of smart viscoelastic composite doubly curved sandwich shell with flexible core and magnetorheological layer with different distribution patterns are treated in [1]. The nonlinear vibration analysis of composite sandwich doubly curved shell with a flexible core integrated with a piezoelectric layer is considered in [2]. The nonlinear dynamic behavior of the double curved shallow shells with negative Poisson's ratios in auxetic honeycombs on elastic foundations subjected blast is treated in [3]. A geometrically nonlinear forced vibration analysis of circular cylindrical sandwich shells with cellular core using higher-order shear deformation theory is presented in [4]. The paper [5] studies the nonlinear free and forced vibration of the sandwich cylindrical panel on Pasternak foundations in thermal environment under the action of blast load. The sandwich cylindrical panel consists of the auxetic honeycombs core and two carbon nanotube reinforced composite face sheets. The nonlinear dynamics of a double curvature sandwich shell with honeycomb are studied in [6].

Figure 1: Truncated conical shell and honeycomb core

Problem formulation and main equations

The sandwich conical shell with three layers is shown on Fig.1. The middle layer of the structure consists of honeycomb core, which is manufactured by FDM additive technology (Fig.1) from ULTEM 9085 material. Top and bottom faces are produced from the carbon fiber-reinforced composite. The main geometrical parameters of the honeycomb cell (Fig.1) are the following: l_1, l_2, h_c, ψ , where h_c is thickness of the cells.

The dynamic instability and the self-sustained vibrations of the sandwich conical shell are treated. These nonlinear vibrations are take place due to interaction of the supersonic gas flow with the sandwich conical shell. The growth of

vibrational amplitudes of thin-walled structures is observed due to the system dynamic instability. Then the geometrical nonlinearity contributes essentially to the nonlinear mathematical model of the sandwich structure. This geometrical nonlinearity limits of the vibrational amplitudes grow. This limitation results in the self-sustained vibrations. Therefore, the geometrical nonlinearity is taken into account. The faces composite material and the honeycomb materials satisfy the Hooke's law. The shell initial imperfections are not accounted here.

As the sandwich structure self-sustained vibrations are expanded by the eigenmodes, the linear vibrations of the sandwich structure are considered in this paper too.

The stress-strain state of the sandwich conical shell is studied in the curvilinear coordinate system. Three curvilinear coordinate systems, which are connected with the layers middle surfaces, are used. The curvilinear coordinate systems of the top, core and bottom layers are denoted as: (s_t, θ, z_t) , (s_c, θ, z_c) , (s_b, θ, z_b) , where s_t, s_c, s_b are longitudinal coordinates directed along the generating line of the layer middle surface; θ is curvilinear coordinate (Fig.1); z_t, z_c, z_b are lateral coordinates of the layers.

Results of numerical analysis

The data of the self-sustained vibrations numerical simulations, which are observed due to interaction of supersonic gas flow with the sandwich conical shell is considered accounting geometrical nonlinear deformations. The nonlinear autonomous dynamical system of the structure vibrations has 21 degrees-of-freedom. This dynamical system is analyzed numerically by the algorithm, which combines the shooting technique and the continuation approach. Fig. 2 shows the result of the dynamical systems steady states. The dependences of the vibrational amplitudes $\max(q_1/h_c)$ on the pressure p_∞ is shown on the figure. The stable and unstable steady states are shown by solid lines and dotted lines, respectively.

The dynamical behavior of the structure, which are shown on Fig.2, are considered. The trivial equilibriums, which are described by the straight line (AB) (Fig.2), are observed at any value of p_∞ . The Hopf bifurcation is taken place in the H point. The stable equilibriums (AH) are transformed into the unstable equilibriums (HB) and the stable self-sustained vibrations are born. These vibrations are described by the curve (HN_S) . The Naimark-Sacker bifurcation is observed in the point N_S . Then the stable self-sustained vibrations are transformed into unstable ones and stable quasiperiodic vibrations are born. The amplitudes of such quasiperiodic vibrations are shown by the curve $(N_S D)$.

Summary. Dynamic models of geometrical nonlinear deformations of functionally graded carbon nanotubes reinforced composite thin-walled structures are obtained. Reddy higher-order shear deformation theory is used to derive this model. The nonlinear system of high dimension ordinary differential equations, which describes the structure nonlinear vibrations, is obtained using the assumed-mode method. The linear piston theory is used to describe the supersonic flow. The losses of the cylindrical shell dynamic stability owing to the Hopf bifurcations are analyzed. The self-sustained vibrations, which describe the circumferential traveling waves flutter, occur due to this bifurcation. The harmonic balance method is applied to analyze these self-sustained vibrations. The properties of the circumferential traveling waves are analyzed. The dynamic instability of conical-cylindrical thin-walled nanocomposite structure is treated.

1. Introduction

Intensive researches in advanced materials, which have been widely used in aerospace engineering, are carried out in recent years. The extraordinary stiffness and tensile strength of carbon nanotubes (CNTs) make them well-suited as reinforcing components of composites. Computational approaches play a significant role in the development of the CNT reinforced composites by providing simulations results, which help to understand the behavior of nanocomposite structures. Effective elastic properties of CNTs are obtained in [1]. These properties are used to obtain effective elastic parameters of nanocomposites by the Mori-Tanaka methods. The effective mechanical properties of CNT reinforced composites are evaluated by 3D nanoscale representative volume element method by Liu, Chen [2]. The technique for developing constitutive models of CNTs reinforced polymer composite materials is proposed by Odegard and others [3].

The mechanical characteristics of the nanocomposites are analyzed experimentally by several researchers. The tensile tests of dog-bone shaped specimens were performed by Allaoui and others [4]. They obtained, that the Young's modulus and the yield strength have been doubled and quadrupled for composites with respectively 1 and 4 wt.% CNT in comparison with the pure resin matrix samples. Ci and Bai [5] systematically evaluate the stiffness of nanocomposite, when the CNTs reinforcement is used. The ultimate stresses experimental analysis of rubbery epoxy with CNTs reinforcement is treated by Richard and others [6].

The geometrical nonlinear vibrations of functionally graded CNTs reinforced composite cylindrical shell is analyzed by using the higher-order shear deformation theory. The self-sustained vibrations of the cylindrical shell interacted with the supersonic flow are analyzed numerically. The piston theory is applied to describe the supersonic flow.

The assumed-mode method is used to analyze the nonlinear vibrations of functionally graded CNTs reinforced composite cylindrical shell. The high dimension nonlinear system of the ordinary differential equations is obtained. The harmonic balance method with monoharmonic approximation of the self-sustained vibrations is applied to analyze the self-sustained vibrations. The system of the nonlinear algebraic equations with respect to the self-sustained vibrations amplitudes is derived.

The dynamic instability of the shell with different types of composite CNTs reinforcement is analyzed. As follows from the numerical analysis, the type of composite reinforcement affects essentially on the system parameters, when the flutter occurs. If the type of composite reinforcement is changed, the system parameters of the flutter origination can be changed twice.

The effect of the composite reinforcement type on the self-sustained vibrations is investigated. As follows from the data of the numerical simulations, the CNTs reinforcements of the composite shell affect essentially on the amplitudes of the self-sustained vibrations.

2. Problem formulation and main equations

The cylindrical shell with constant thickness h in supersonic flow is treated. The dynamic stress-strain state of the cylindrical shell is analyzed in curvilinear coordinate system (x, θ, z) . Three projections of the middle surface displacements and rotations of the middle surface normal are chosen as the main unknowns. The dynamic instability of the cylindrical shell in supersonic flow is analyzed. This instability results in an increase of the vibrations amplitudes. In

this case, the shell geometrical nonlinear deformations occur. This growth of the amplitudes is limited due to the shell geometrical nonlinear behavior. Then three projections of the middle surface displacements u, v, w are moderate and shell strains are small. The Hooke's law is true.

The material of the shell is functionally graded CNTs reinforced composite. CNTs are assumed to be uniaxially aligned. Five types of CNTs reinforced are considered. UD denotes uniform CNTs reinforced in the transverse direction of the cylindrical shell. The rest types of CNTs reinforced are FGV, FGA, FGX and FGO. They have variable CNTs dispersion. The shell material is functionally graded. The part of the volume for uniform distribution, which is occupied by CNTs, is denoted by V_{CNT}^* .

As the shell material is functionally graded and composite, shear is taken into account. The shear modulus takes the form: $G_{13}(z) = G_{12}(z)$; $G_{23}(z) = G_{12}(z)$. The Hooke's law is the following:

$$\begin{aligned} \begin{bmatrix} \sigma_{xx} \\ \sigma_{\theta\theta} \end{bmatrix} &= \begin{bmatrix} Q_{11}(z) & Q_{12}(z) \\ Q_{12}(z) & Q_{22}(z) \end{bmatrix} \begin{bmatrix} \varepsilon_{xx} \\ \varepsilon_{\theta\theta} \end{bmatrix}; \\ \sigma_{\theta z} &= G_{23}(z) \gamma_{\theta z}; \\ \sigma_{xz} &= G_{13}(z) \gamma_{xz}; \\ \sigma_{x\theta} &= G_{12}(z) \gamma_{x\theta}. \end{aligned} \quad (1)$$

The projections of the shell points displacements, which are placed on the z distance from the middle surface, are denoted by $u_x(x, \theta, t, z)$, $u_\theta(x, \theta, t, z)$ and $u_z(x, \theta, t, z)$. The higher-order shear deformation theory is used to describe the shell displacements:

$$\begin{aligned} u_x(x, \theta, t, z) &= u(x, \theta, t) + z\phi_1(x, \theta, t) + z^2\psi_1(x, \theta, t) + z^3\gamma_1(x, \theta, t); \\ u_\theta(x, \theta, t, z) &= \left(1 + \frac{z}{R}\right)v(x, \theta, t) + z\phi_2(x, \theta, t) + z^2\psi_2(x, \theta, t) + z^3\gamma_2(x, \theta, t); \\ u_z(x, \theta, t, z) &= w(x, \theta, t), \end{aligned} \quad (2)$$

where R is radius of the cylindrical shell; ϕ_1 and ϕ_2 are the rotations of the middle surface normal about the θ and x axes, respectively.

3. Results and discussions

As a result of the numerical analysis, the bifurcation diagram is calculated (Fig.1). The self-sustained vibrations are originated as a result of the Hopf bifurcation. The influence of the types of CNTs reinforced is analyzed.

Figure 1: The response diagram of the self-sustained vibrations. The amplitudes $A_1 h^{-1}$ versus the free stream static pressure p_∞ is shown

Resonance Steady State and Transient in the Non-Ideal System having the Pendulum Absorber

Yuri V. Mikhlin* and Yana O. Lebedenko*

*Dept. of Applied Mathematics, National Technical University "KhPI", Kharkiv, Ukraine

Summary. Resonance behavior of the system with a limited power-supply (or non-ideal system) having the pendulum as absorber is considered. The multiple scales method is used to describe the system dynamics near the resonance. It is shown that the essential reduction of the resonance vibration amplitudes can be obtained by choose of the system parameters. Transient in the non-ideal system under consideration is effectively constructed using the rational Padé approximation. Tending of the transient to the resonance steady state is shown. It is shown that the amplitudes of resonant oscillations of the elastic subsystem can be essentially reduced by choosing some system parameters.

Introduction. The basic model.

The systems with limited power supply are characterized by interaction of the source of energy and elastic sub-system which is under action of the source. Such systems are named also as non-ideal systems (NIS). For the NIS the external excitation depends on the excited elastic sub-system dynamics. The most interesting effect appearing in non-ideal systems is the Sommerfeld effect [1], when in the elastic sub-system the large amplitude resonance regime is appeared, and the big part of the vibration energy passes from the energy source to the resonance behavior. Resonance dynamics of the systems with limited power supply is first analytically described by V.Kononenko [2]. Then investigations on the subject were continued by Kononenko [3] and other authors [4-7]. Reviews of numerous studies of the NIS dynamics can be found in [8-10]. We can note that different types of the NIS behaviour were considered, including forced and parametric oscillations, self-oscillations, transient, chaotic oscillations, interaction of the NIS with energy sources of different physical characteristics, and so on.

It is known that nonlinear vibration absorbers can significantly reduce the amplitudes of resonant elastic vibrations. We consider here the resonant behaviour of the non-ideal system with three DOF (Fig.1), having the pendulum-type absorber, by the multiple scales method. Both the resonance steady state and the transient are constructed. The transient is effectively presented using the rational Padé approximants [11] containing exponents. It is shown that amplitudes of the resonant oscillations of the elastic subsystem can be reduced by changing some system parameters.

Figure. 1. The model under consideration

Resonance steady state solution. Influence of the system parameters to resonance dynamics of the system

Equations of motion of the system under consideration with respect to variables x , φ and θ are the following:

$$\begin{cases} (M + m)\ddot{x} + (c_0 + c_1)x = c_1 r \sin \varphi - ml(\ddot{\theta} \cos \theta - \dot{\theta}^2 \sin \theta); \\ I\ddot{\varphi} = a - b\dot{\varphi} + c_1 r(x - r \sin \varphi) \cos \varphi; \\ ml(l\ddot{\theta} + g \sin \theta + \ddot{x} \cos \theta) = 0. \end{cases} \quad (1)$$

Here I is the moment of inertia of rotating masses; $(c_0 + c_1)$ is the rigidity of the elastic subsystem having the mass M ; the combination $L = a - b\dot{\varphi}$ describes both the driving moment of the energy source and the moment of the forces of resistance to the rotation that is the so-called characteristics of the engine. From equations (1) it is seen that the moment $c_1 r x \cos \varphi$ is the part of the motor excitation that depends on the oscillations of the elastic subsystem.

Construction of a stationary resonant solution.

In the first place, we use some transformations. Namely, the functions $\cos \theta$ and $\sin \theta$ are expanded in the McLaren series, and terms remain to the third degree. Then a small parameter ε , introduced into the equations of motion, characterizes the small mass of the absorber with respect to the mass of the elastic part of the system, $m \rightarrow \varepsilon m$, and the smallness of vibration components in variability in time of the angle φ velocity with respect to its main constant component. Terms $\varepsilon h \dot{x}$ and $\varepsilon h \dot{\theta}$ describe the small dissipation. Considering a region of the resonance between frequencies of the motor rotation and the elastic sub-system vibrations, we introduce the small frequency detuning as $\varepsilon \Delta = \omega_x^2 - \dot{\varphi}^2$, where $c_0 + c_1 = M \omega_x^2$. We also assume that in the resonance region the external excitation of the elastic subsystem is small. A relatively not large nonlinear part of the elastic subsystem response is represented by the term $\varepsilon \tau x^3$, which is included in the first equation of the system (1). As a result, we consider the following equations of motion instead of the equations (1):

$$\begin{cases} (M + \varepsilon m) \ddot{x} + \omega_x^2 x + \varepsilon h \dot{x} + \varepsilon \tau x^3 = \varepsilon c_1 r \sin \varphi - \varepsilon m l \left(\ddot{\theta} \left(1 - \frac{1}{2} \theta^2 \right) - \left(\theta - \frac{\theta^3}{6} \right) \dot{\theta}^2 \right) \\ I \ddot{\varphi} = \varepsilon (a - b \dot{\varphi} + c_1 r (x - r \sin \varphi) \cos \varphi) \\ \varepsilon m l \left(l \ddot{\theta} + g \left(\theta - \frac{\theta^3}{6} \right) + \ddot{x} \left(1 - \frac{1}{2} \theta^2 \right) \right) + \varepsilon h \dot{\theta} = 0 \end{cases} \quad (2)$$

The multiple scales method [12] is used to describe the behaviour of the system in the field of resonance. According to this method, we write the following representations of solutions:

$$x(t, \varepsilon) = x(t, \varepsilon t, \varepsilon^2 t, \dots; \varepsilon); \quad \varphi(t, \varepsilon) = \varphi(t, \varepsilon t, \varepsilon^2 t, \dots; \varepsilon); \quad \theta(t, \varepsilon) = \theta(t, \varepsilon t, \varepsilon^2 t, \dots; \varepsilon) \quad (3)$$

In addition, the following transformations are used:

$$\begin{aligned} \frac{d}{dt} &= \frac{\partial}{\partial T_0} + \varepsilon \frac{\partial}{\partial T_1} + \varepsilon^2 \frac{\partial}{\partial T_2} + \dots \\ \frac{d^2}{dt^2} &= \frac{\partial^2}{\partial T_0^2} + 2\varepsilon \frac{\partial}{\partial T_0} \frac{\partial}{\partial T_1} + \varepsilon^2 \left(\frac{\partial^2}{\partial T_1^2} + 2 \frac{\partial}{\partial T_0} \frac{\partial}{\partial T_2} \right) + \dots \end{aligned} \quad (4)$$

Here $T_0 = \omega t$, $T_1 = \varepsilon \omega t$ and $\omega = \omega_x$. The representations (3) are decomposed in the form of the power series by the small parameter. Substituting the power series into the system (2), we distinguish the terms of zero and first degrees by the small parameter. As a result, the following system of differential equations can be obtained:

$$\varepsilon^0 : \frac{\partial^2 x_0}{\partial T_0^2} + \Omega^2 x_0 = 0, \quad (5)$$

$$\frac{\partial^2 \varphi_0}{\partial T_0^2} = 0, \quad (6)$$

$$\begin{aligned} \varepsilon^1 : 2M \frac{\partial^2 x_0}{\partial T_0 \partial T_1} + M \frac{\partial^2 x_1}{\partial T_0^2} + m \frac{\partial^2 x_0}{\partial T_0^2} + \Delta M x_0 + M \Omega^2 x_1 + h \frac{\partial x_0}{\partial T_0} + r \tau x_0^3 = c_1 r \sin(\Omega T_0) - \\ - m l \frac{\partial^2 \theta_0}{\partial T_0^2} + \frac{1}{2} m l \frac{\partial^2 \theta_0}{\partial T_0^2} \cdot \theta_0^2 + m l \theta_0 \left(\frac{\partial \theta_0}{\partial T_0} \right)^2 - m l \frac{\theta_0^3}{6} \cdot \left(\frac{\partial \theta_0}{\partial T_0} \right)^2, \end{aligned} \quad (7)$$

$$2 \frac{\partial^2 \varphi_0}{\partial T_0 \partial T_1} + \frac{\partial^2 \varphi_1}{\partial T_0^2} = K - N \Omega \frac{\partial \varphi_0}{\partial T_0} + q x_0 \cos \varphi_0 - \frac{q r}{2} \sin 2 \varphi_0, \quad (8)$$

$$l \frac{\partial^2 \theta_0}{\partial T_0^2} + g \theta_0 - g \frac{\theta_0^3}{6} + \frac{\partial^2 x_0}{\partial T_0^2} - \frac{\theta_0^2}{2} \frac{\partial^2 x_0}{\partial T_0^2} + \tilde{h} \frac{\partial \theta_0}{\partial T_0} = 0 \quad (9)$$

Here $\tilde{h} = h/(ml)$, Ω is the frequency of the motor rotation, depending on the time scale T_1 . The solutions of equations of the zero approximation by the small parameter (5) and (6) are presented as follows:

$$\begin{cases} x_0 = A \cos(\Omega T_0) + B \sin(\Omega T_0) \\ \varphi_0 = \Omega T_0 \end{cases} \quad (10)$$

We assume that in the resonance between the engine speeds and the oscillations of the elastic subsystem, the amplitudes of the pendulum oscillations are small. Therefore, we assume that in equation (9) all members with a degree greater than one have the order of the small parameter ε . As a result, from equation (9) we have the following:

$$\theta_0 = C \cos \Omega T_0 + D \sin \Omega T_0, \quad \text{where} \quad C = \frac{A\Omega^2}{g - l\Omega^2}, \quad D = \frac{B\Omega^2}{g - l\Omega^2}. \quad (11)$$

The solution of the zero approximation (10) is substituted to the equation (7). To avoid the appearance of secular terms the following modulation equations are obtained:

$$2 \frac{\partial A}{\partial T_1} \Omega + \mu B \Omega^2 - \Delta B + \frac{hA\Omega}{M} - \frac{3\tau A^2 B}{4M} - \frac{3\tau B^3}{4M} + \sigma + \mu l D \Omega^2 = 0, \quad (12)$$

$$-2 \frac{\partial B}{\partial T_1} \Omega + \mu A \Omega^2 - \Delta A - \frac{hB\Omega}{M} - \frac{3\tau AB^2}{4M} - \frac{3\tau A^3}{4M} + \mu l C \Omega^2 = 0, \quad (13)$$

$$\left(\mu = \frac{m}{M}, \sigma = \frac{c_1 r}{M} \right)$$

To avoid the appearance of secular terms in the solution of the equation (8) we use the following relation:

$$-2 \frac{\partial \Omega}{\partial T_1} + K - N \Omega^2 + \frac{qA}{2} = 0, \quad \text{where} \quad K = \frac{a}{I\omega_x^2}, \quad N = \frac{b}{I\omega_x}, \quad q = \frac{c_1 r}{I\omega_x^2}. \quad (14)$$

Together, all three equations (12-14) give variables A , B and Ω , which correspond to the resonant state. Considering the steady state, we assume that the values of A , B and Ω are constant. In this case, equations (12-14) are transformed into a system of nonlinear algebraic equations for these values, which is solved by the Newton's numerical method. Thus, constants can be obtained for a stationary solution $\tilde{A}_0, \tilde{B}_0, \tilde{\Omega}_0$. In particular, from equation (14) we have that

$$\tilde{\Omega}_0 = \pm((2a + c_1 r \tilde{A}_0)/2b)^{1/2} \quad (15)$$

Note that in the resonance region, the frequencies Ω and ω_x differ by an order of magnitude of the small parameter ε . Thus, if in the coefficients K , N the variable frequency Ω changes by ω_x , then we can find the following solution of equation (14):

$$\Omega = \tilde{\Omega}_0 + \rho(\eta + 1), \quad \text{where} \quad \rho = C_2 = \frac{\tilde{\Omega}_0}{10}, \quad \eta = e^{\frac{N}{2} T_1} - 1. \quad (16)$$

The last relation shows the approach of the motor frequency to the stationary value of $\tilde{\Omega}_0$ with increasing time.

Construction of the transient using the Padé approximants.

The expression (16) is substituted to equations (12) and (13), preserving the terms of zero and first degree by the variable η . To solve the obtained differential equations, the following representations of functions A and B in the form of the following power series:

$$A = A_0 + A_1 \eta + A_2 \eta^2 + \dots, \quad B = B_0 + B_1 \eta + B_2 \eta^2 + \dots \quad (17)$$

Here the magnitudes A_0 and B_0 selected to match the corresponding values for stationary mode, namely, the values \tilde{A}_0, \tilde{B}_0 . Next, we need to select equations that contain members of the order η^0, η, \dots . The zero approximation solutions with respect to η , which is not presented here, permits to obtain A_1 and B_1 , namely

$$A_1 = \frac{\mu B_0 \Omega_0}{2\beta} + \frac{\mu B_0 \rho}{2\beta} - \frac{\omega_x^2 B_0}{2\beta(\Omega_0 + \rho)} + \frac{B_0 \Omega_0}{2\beta} + \frac{B_0 \rho}{2\beta} + \frac{h A_0}{2\beta M} - \frac{3\tau A_0^2 B_0}{8\beta M(\Omega_0 + \rho)} - \frac{3\tau B_0^3}{8\beta M(\Omega_0 + \rho)} + \frac{\sigma}{2\beta(\Omega_0 + \rho)} + \frac{\mu l B_0 (\Omega_0 + \rho)^3}{2\beta G}; \quad (18)$$

$$B_1 = -\frac{\mu A_0 \Omega_0}{2\beta} - \frac{\mu A_0 \rho}{2\beta} + \frac{\omega_x^2 A_0}{2\beta(\Omega_0 + \rho)} - \frac{A_0 \Omega_0}{2\beta} - \frac{A_0 \rho}{2\beta} + \frac{h B_0}{2\beta M} + \frac{3\tau B_0^2 A_0}{8\beta M(\Omega_0 + \rho)} + \frac{3\tau A_0^3}{8\beta M(\Omega_0 + \rho)} - \frac{\mu l A_0 (\Omega_0 + \rho)^3}{2\beta G}. \quad (19)$$

Here $\beta = \frac{N}{2}$, $G = g - l(\Omega_0 + \rho)^2$. From the equations of the first approximation, i.e. equations containing members of the order η , the constants A_2 and B_2 can be found, which are not presented here. Then we introduce the following expansions of functions A and B in power series:

$$A = A_{0in} + A_1 \eta + A_2 \eta^2 + \dots \quad B = B_{0in} + B_1 \eta + B_2 \eta^2 + \dots \quad (20)$$

Here (A_{0in}, B_{0in}) these are here arbitrary values of the amplitudes of oscillations, which are determined by the initial conditions. For further research, we also introduce the following parameter:

$$\psi = \frac{e^{-\beta T_1} - 1}{e^{-\beta T_1}} = \frac{\eta}{\eta + 1}, \quad \text{then} \quad \eta = \frac{\psi}{1 - \psi} \quad (21)$$

Substituting the relationship (21) to the power series (20) and decomposing these expressions into McLaren series by the parameter ψ , corresponding to the case $T_1 \rightarrow 0$, one has the following:

$$A = A_{0in} + A_1 \psi + (A_1 + A_2) \psi^2 + \dots \quad (22)$$

$$B = B_{0in} + B_1 \psi + (B_1 + B_2) \psi^2 + \dots$$

We introduce the Padé approximants for values ψ , varying it from zero to infinity, corresponding to change of the time scale T_1 also from zero to infinity, as:

$$A_p = \frac{\alpha_0 + \alpha_1 \psi + \alpha_2 \psi^2}{1 + \beta_1 \psi + \beta_2 \psi^2}; \quad (23)$$

$$B_p = \frac{\tilde{\alpha}_0 + \tilde{\alpha}_1 \psi + \tilde{\alpha}_2 \psi^2}{1 + \tilde{\beta}_1 \psi + \tilde{\beta}_2 \psi^2}.$$

Then we compare expressions (23) with series (22). In addition, to describe the approximation of the transition process to the stationary regime, we consider the boundary of expressions (23) when $\psi \rightarrow \infty$ (that is, when $T_1 \rightarrow \infty$) and equate this limit to the values of the amplitudes \tilde{A}_0 and \tilde{B}_0 , previously obtained for stationary mode, i.e. $\frac{\alpha_2}{\beta_2} = \tilde{A}_0$, $\frac{\tilde{\alpha}_2}{\tilde{\beta}_2} = \tilde{B}_0$. All this makes it possible to obtain coefficients of the Padé approximants (23) from a system of linear algebraic equations.

Comparative characteristics of the transition and stationary modes. Resonant behaviour of the system when changing system parameters.

Here we consider a comparison of the stationary solution and the transient of the system at small and time values. Then we consider also the influence of the system parameters on the amplitude of elastic oscillations in the resonant region.

This applies to the change of the parameters of the pendulum mass m and the parameter of nonlinearity in the elastic force τ . The corresponding numerical simulation was performed for the basic system (2) using the 4th order Runge-Kutta procedure. Change of the driving moment coefficient a and the length of the pendulum l leads to a slight decrease in the amplitude of elastic oscillations, thus graphical representations corresponding to changes in these parameters are not given. From numerical simulations it can be concluded that the amplitudes of resonant elastic oscillations can be significantly reduced with the parameters m and τ . We will consider the solutions at different time intervals, as at small values of time, $t \in (0; 5)$, and for significant values of time, $t \in (220; 225)$. Note that in the pictures a),c) the variable $x(t)$, and in the pictures b),d) the variable $\theta(t)$ are presented. In all Figs. the following fixed parameters are given: $a = 0,37261$; $l = 1$. In Fig. 2 the comparison of the stationary solution and the transient at $t \in (0; 5)$ is presented for $\tau = 0,05$. In Fig. 2. a,b the parameter $m = 0.07$ and in Fig. 2. c,d one has $m = 0.11$. Fig. 3 shows the comparison of the stationary solution and the transient at $t \in (220; 225)$ for the same fixed parameters a, l, τ as in Fig. 2. In Fig. 3a,b the parameter $m = 0.07$, and in Fig. 3c,d one has $m = 0.11$. Fig. 4 presents the comparison of the stationary solution and the transient at $t \in (0; 5)$, for $m = 0.05$. In Fig. 4a,b the parameter $\tau = 0,01$, and on Fig. 4c,d one has $\tau = 0,05$. In Fig. 5 the comparison is shown at $t \in (220; 225)$ for the same fixed parameters a, l, τ as in Fig. 4. In Fig. 5a,b the parameter $\tau = 0,01$, and in Fig. 5c,d one has $\tau = 0,05$.

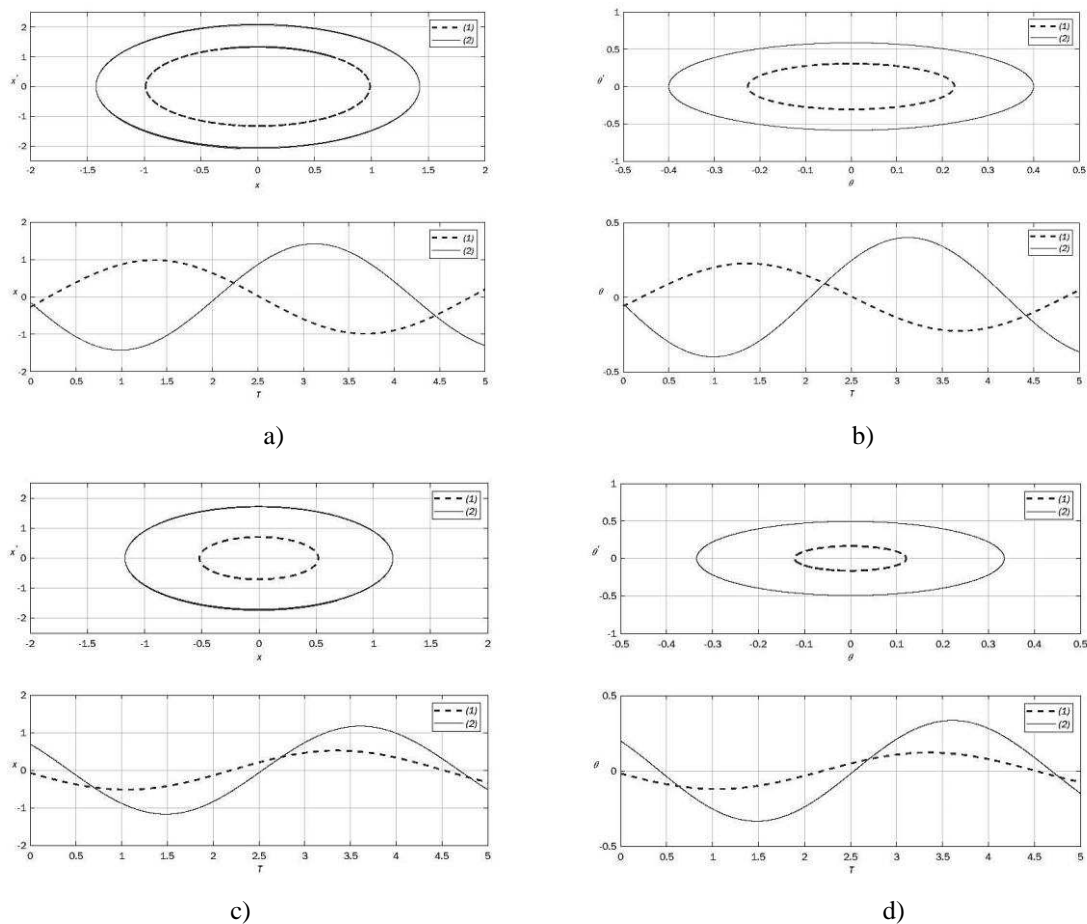

Figure 2. Comparison of the stationary solution (1) and the transient (2) at $t \in (0; 5)$: a) variable x for $m = 0.07$; b) variable θ for $m = 0.07$; c) variable x for $m = 0.11$; d) variable θ for $m = 0.11$.

Conclusions

Analyzing the obtained results, we can obtain the following conclusions. First, it is fashionable to obtain the resonance steady state effectively by the multiple scales method. Secondly, we can see a good coincidence of the transient represented by the Padé approximants to the stationary regime with increasing time values. Thus, the proposed Padé approximants having exponents are very effective for the transient presentation. Finally, the numerical simulation demonstrates a significant decrease in the amplitudes of elastic oscillations with increasing the pendulum mass and the nonlinearity in the elastic force.

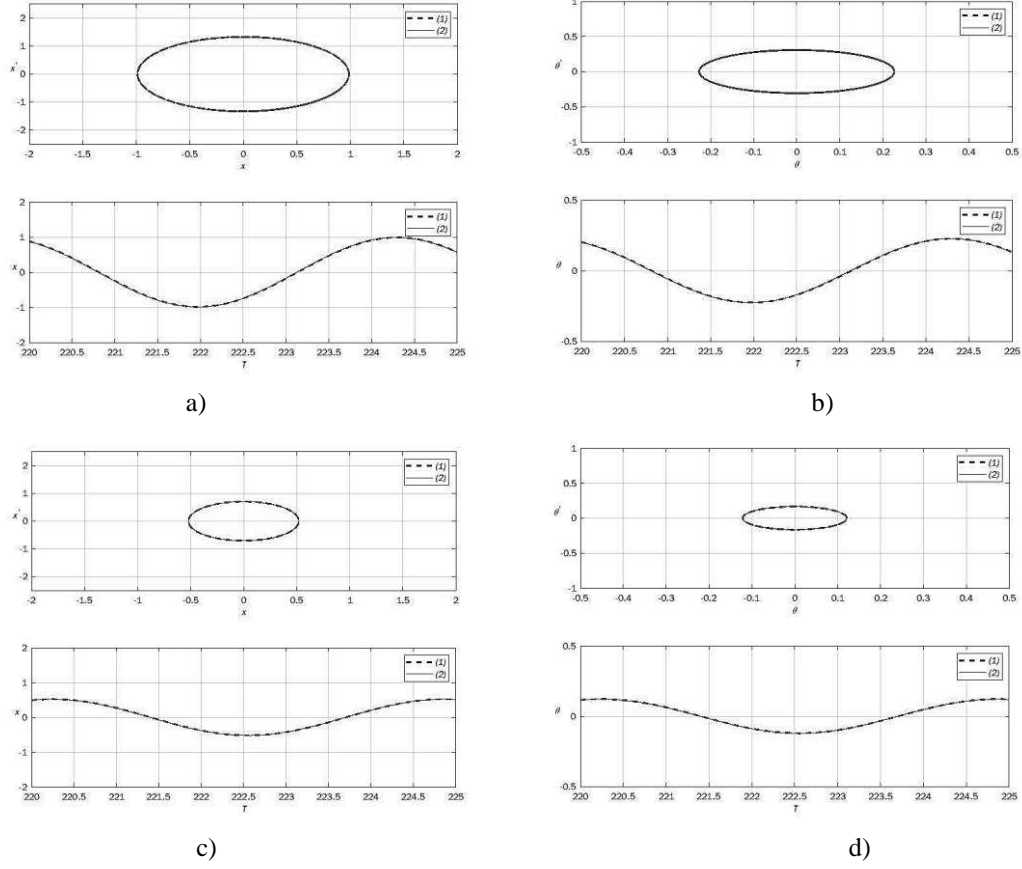

Figure 3. Comparison of stationary solution (1) and transient (2) at $t \in (220; 225)$: a) variable x for $m = 0.07$; b) variable θ for $m = 0.07$; c) variable x for $m = 0.11$; d) variable θ for $m = 0.11$.

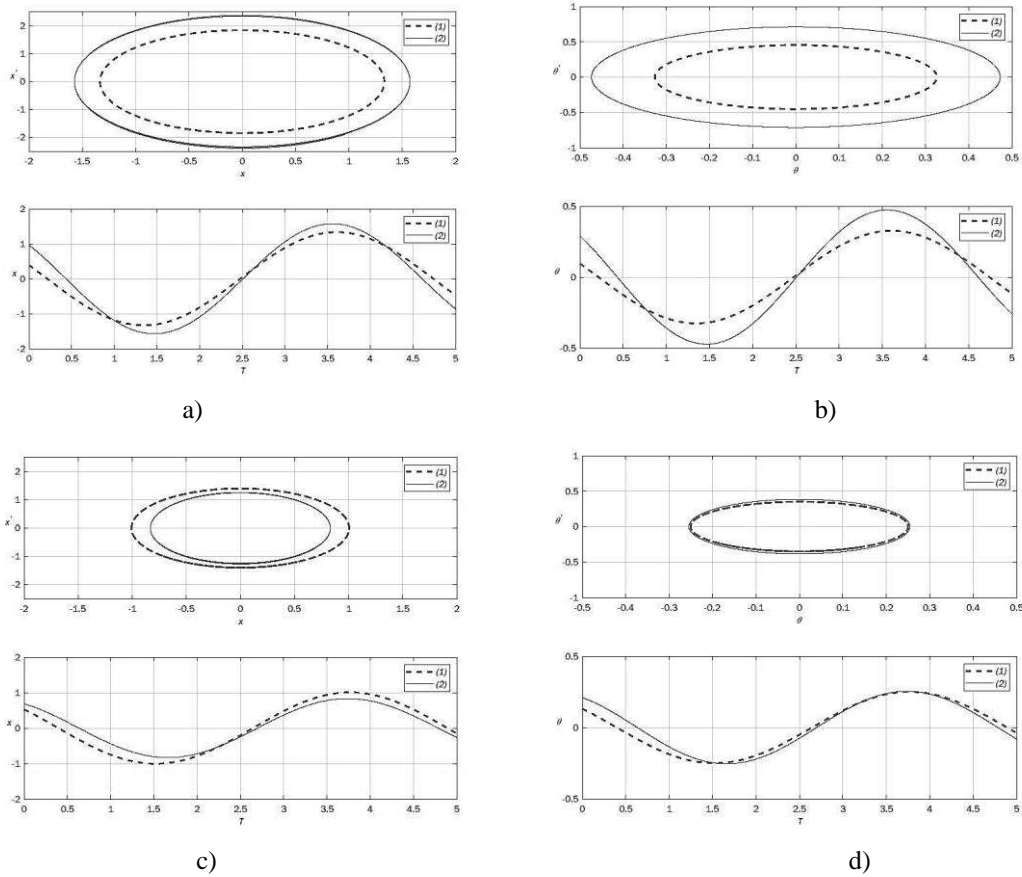

Figure 4. Comparison of the stationary solution (1) and the transient (2) at $t \in (0; 5)$: a) variable x for $\tau = 0,01$; b) variable θ for $\tau = 0,01$; c) variable x for $\tau = 0,05$; d) variable θ for $\tau = 0,05$.

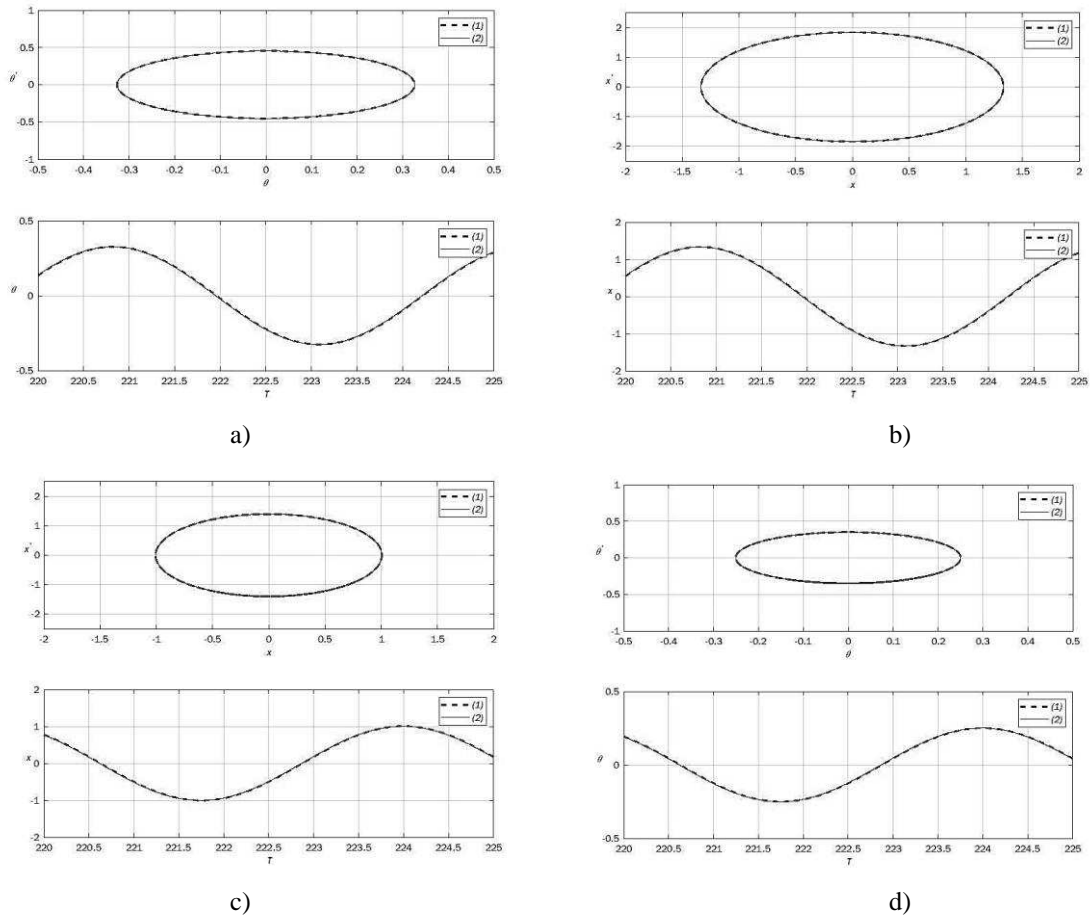

Figure 5. Comparison of the stationary solution (1) and the transient (2) at $t \in (220; 225)$: a) variable x for $\tau = 0,01$; b) variable θ for $\tau = 0,01$; c) variable x for $\tau = 0,05$; d) variable θ for $\tau = 0,05$.

Summary. A mechanical model of a beam subjected to impact velocity is analyzed. It consists of a beam with additional mass-spring systems. We investigate the distribution of the axial stress along the beam, and the effect of different parameters (masses and their distribution, spring's stiffness) on the stability of the beam.

Introduction

In industrial safety, dynamic buckling is one of the most important considerations to design structures subjected to sudden loadings. For instance, spacer grids in nuclear fuel assembly should have sufficient buckling strength in case of major accidents as earthquakes. Several studies using finite elements models with experimental validation for static buckling and post-buckling of spacer grids were conducted [1]. In literature, most studies focus only on inner characteristics of the spacer grid components without a fully dynamic analysis of the fuel rods movements [2]. Dynamic buckling of structural elements (columns, plates, shells...) under impulsive axial loading has been studied using different approaches. It has been widely investigated for imperfection-sensitive structures with neglected axial inertia forces [3]. For nearly perfect structures, other studies have shown that the axial inertia forces must be considered, particularly in the case of high impact velocities [4].

Mechanical model

We propose a simplified beam model to reproduce the effect of fuel rods, as lumped masses, on the dynamic buckling of the spacer grid. In the present study, we conduct a stability analysis based on eigenvalues evolution for the systems shown in figure 1 and figure 2. The occurrence of buckling and its characteristics (time to buckling, evolution of eigenvalues) are affected by additional masses due to axial stress waves. This effect is illustrated through the impact response of the system with an initial velocity for different configurations. Each configuration is defined by a specific distribution of mass-spring systems and by their frequencies.

Figure 1: Model of a beam with additional masses

Figure 2: Model of a beam with additional mass-spring systems

To predict a potential buckling of the beam, we solve the wave equation by considering the additional masses

$$E \frac{\partial^2 u}{\partial x^2} = \rho \frac{\partial^2 u}{\partial t^2} \quad (1)$$

To obtain the geometric stiffness matrix at each time step, we consider the first nonlinear term in transverse direction in the axial strain of the beam

$$E I \frac{\partial^4 v}{\partial x^4} + \frac{\partial}{\partial x} \left(E A \frac{\partial u}{\partial x}(x, t) \cdot \frac{\partial v}{\partial x} \right) + \rho A \frac{\partial^2 v}{\partial t^2} = 0 \quad (2)$$

Then an eigenvalue problem is obtained at each time step

$$[K_{\text{elas}} + K_{\text{geom}}(t)]. X + M. \ddot{X} = 0 \quad (3)$$

In fact, the system is instable if one eigenvalue of the system is positive.

Results

The study is carried out for several configurations with multiple distributions of the masses or the mass-spring systems. Herein we present the results obtained for two configurations. The first configuration consists of a beam with three masses characterized by the mass ratio: $r_m = \frac{m_i}{M_{\text{beam}}}$, with M_{beam} is the beam's mass. The second one consists of a beam with three mass-spring systems characterized by the frequency ratio: $r_f = \frac{f_i}{f_{\text{beam}}}$ where f_{beam} is the first natural longitudinal frequency of the beam and f_i is the frequency of the mass-spring system. The distribution of the axial stress along the beam at each time step is shown in figures 3 and 4 for the first and the second configurations, respectively. As shown in figure 5 the beam tends to buckle for heavy additional masses. Furthermore, for a given additional mass, the frequency of the mass-spring system needs to be smaller than the natural frequencies of the beam to avoid buckling (figure 6).

Figure 3: axial stress in the beam with masses for $r_m = 1$

Figure 4: axial stress in the beam with mass-spring systems for $r_f = 1$

Figure 5: Evolution of the maximum real part of eigenvalues of the beam with masses for different mass ratios

Figure 6: Evolution of the maximum real part of eigenvalues of the beam with mass-spring systems for different frequency ratios

Conclusion and comparison with experimental data

In this study we highlight the importance of considering the compression wave in the prediction of the buckling of a beam with an impact velocity. A further study considering non-linear springs is currently carried out to investigate their effect on the axial wave motion.

For the beam model with mass-springs, the validation of this analysis is considered by setting up a prototype of a structure with rigid point mass inclusions and an adapted experimental protocol under impact conditions.

The Bifurcation Structure of a Self-Excited Inertia Wheel Double Pendulum

Y. Levi and O. Gottlieb

Department of Mechanical Engineering, Technion-Israel Institute of Technology, Haifa, Israel.

Summary. We construct the bifurcation structure of a self-excited inertia wheel double pendulum. The dynamical system exhibits stable equilibria, periodic limit cycle oscillations and nonstationary rotations. We investigate several configurations documented in literature which exhibit internal resonances and compare their bifurcation structure demonstrating similarities in periodic oscillations and distinct differences in patterns of chaotic rotations.

Introduction

Self-excitation of restrained and freely oscillating rigid bodies are encountered in a variety of engineering applications including friction induced vibration, aeroelastic limit cycle oscillations and fluid-structure interaction. Stabilization of limit cycle oscillations has been proposed by several approaches including boundary feed forward control of a multi-tethered lighter-than-air sphere [1] and digital delayed feedback control of an aero-pendulum [2]. Of particular importance is the capability of an inertia wheel (or reaction wheel) with linear and nonlinear feedback to obtain stable and robust limit-cycle oscillations in underactuated dynamical systems [3,4]. We thus investigate the self-excited dynamics of an autonomous dynamical system which consists of a planar double pendulum augmented with a rotating inertia wheel (see Fig.1-left). We consider double pendulum configurations documented in literature which exhibit conditions near a 1:1 [5], 2:1 [6] and 3:1 [7] internal resonances. Stability analysis of the zero-angle equilibrium position under a partial-state feedback scheme yields a stability map of feedback gains (Fig.1-right) that includes a distinct region (green) of possible self-excited limit cycles that is bounded by Hopf and Saddle-Node bifurcations denoting the transitions from stable equilibria to periodic limit-cycle oscillations (solid blue line) and the transition to rotations (dashed red line), respectively.

Figure 1. Definition sketch (left) and stability map of the inertia wheel feedback gains for a 2:1 configuration depicting regions of stable zero equilibrium (grey), possible limit-cycles (green) and rotations (white).

Results

We perform a numerical investigation of the dynamical system near a 1:1 internal resonance where the states include the angles (X_1, X_3) and angular velocities of the pendula and wheel (X_2, X_4, X_5), respectively. The bifurcation diagram (Fig.2-left) depicts the maximal state oscillation amplitude as a function of the wheel velocity feedback gain (Γ_3) and includes two regions of periodic oscillations (about the stable zero equilibrium and about the unstable upper equilibrium) and two regions of nonstationary oscillations and rotations. Examples of a periodic limit cycle (Fig.2-center) and a chaotic rotation (Fig.2-right) include state space projections of the system conjugate momenta ($P_i, i=1,2,3$) and the bottom pendulum position ($Y(X)$) overlaid with their corresponding Poincare' maps (sampled every positive zero crossing of the bounded wheel velocity).

Discussion

We numerically integrate the dynamical system using the conditions of the above noted 2:1 and 3:1 internal resonances and normalize their bifurcation structures by their respective Hopf thresholds ($\Gamma_3/\Gamma_{3\text{Hopf}}$). We portray the normalized bifurcation structures (Fig.3-left) demonstrating a distinct similarity of the periodic

self-excited limit cycles between the configurations of the 1:1 (blue), 2:1 (red) and 3:1 (green) internal resonances.) However, the Poincaré maps of the nonstationary rotations for the 2:1 (Fig.3-center) and 3:1 (Fig.3-right) configurations reveal a distinctly different chaotic pattern than the one obtained for the configuration near a 1:1 internal resonance (Fig.2-right). Furthermore, while all the considered cases reveal similar behavior of the inertia wheel velocity (X_5), the velocities of the two pendulum elements (X_2 , X_4) exhibited a distinctly different behavior between the region of periodic limit cycle oscillations and nonstationary rotations.

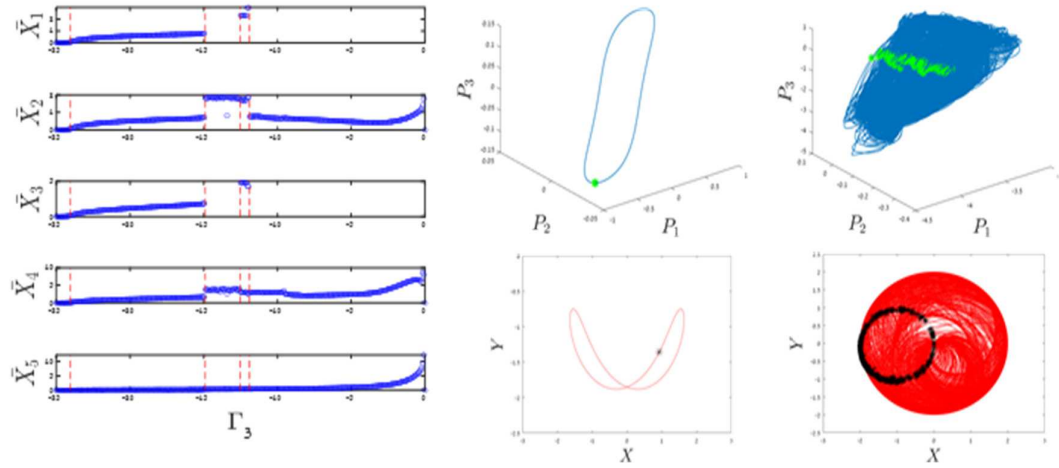

Figure 2. Bifurcation diagram (left), and overlaid state space with Poincaré map for periodic limit cycle oscillations (center) and nonstationary rotations (right).

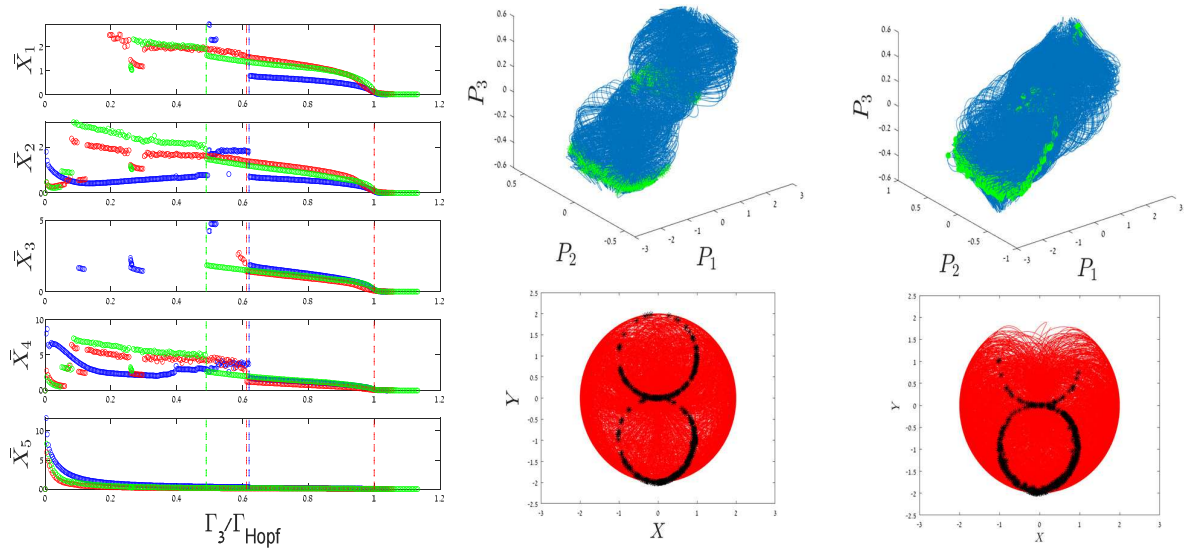

Figure 3. Normalized bifurcation diagram (left) depicting the configurations of the 1:1 (blue), 2:1 (red) and 3:1 (green) internal resonances and overlaid state space and Poincaré map for nonstationary rotations of the 2:1 (center) and 3:1 (right) internal resonances.

Switching from primary to subharmonic resonances in nonlinear systems

Ghislain Raze*, Samer Houry* and Gaëtan Kerschen*

*Aerospace and Mechanical Engineering Department, University of Liège, Liège, Belgium

Summary. This work proposes a simple method to switch between the primary and subharmonic resonances of nonlinear systems. For a primary resonance harmonically excited at a specific forcing amplitude, there exists another forcing amplitude at an integer multiple of the fundamental frequency allowing for the excitation of the corresponding subharmonic resonance having the same amplitude and frequency. Using an energy analysis, it is possible to determine the necessary forcing amplitude change to switch to the targeted subharmonic resonance. The proposed method is numerically illustrated with a transition from a 1:1 to a 1:3 resonance of a Duffing oscillator.

Introduction

Nonlinear systems feature rich dynamics, such as multistability, modal interactions, isolated responses, quasiperiodic oscillations under harmonic forcing, and chaos. Furthermore, the nonlinearities of the system generate harmonics of the forcing frequency. This leads to the appearance of different families of resonances in addition to the primary one, such as superharmonic, subharmonic, ultra-subharmonic and combination resonances [1]. Among these, subharmonic resonances are unique in that they occur when the excitation frequency is an integer multiple of a resonance frequency. Subharmonic resonances have attracted attention in various physics and engineering research areas, such as energy harvesting [2, 3], micro-electromechanical systems [4] and metamaterials [5]. An inherent difficulty associated with their characterization is that they usually appear as isolated branches with respect to the main nonlinear frequency response [1, 6]. Exciting them thus generally requires time-consuming stochastic approaches to bring the state of the system under test into the basin of attraction of the sought resonance [3].

This work proposes a method to excite subharmonic resonances when the corresponding primary resonance is known. If the system is excited at one of its primary resonances, and we wish to seamlessly transition to a subharmonic resonance while maintaining the same motion in terms of amplitude, frequency and phase, then an explicit relation between the forcing amplitudes in these two cases can be derived using an energy method. By performing an adequate change in excitation frequency and amplitude, it is thus possible to change a primary resonance into a subharmonic one.

Energy analysis of resonances

The following equations of motion are considered:

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) + \mathbf{f}_{nl}(\mathbf{x}(t), \dot{\mathbf{x}}(t)) = f_\nu \mathbf{f}_{ext} \sin(\nu\omega t), \quad (1)$$

where \mathbf{M} , \mathbf{C} and \mathbf{K} are structural mass, damping and stiffness matrices, respectively, \mathbf{f}_{nl} is the vector of nonlinear forces, and f_ν and \mathbf{f}_{ext} are the external forcing amplitude and spatial distribution, respectively. It is assumed that the structure responds periodically with an angular frequency ω to the external forcing at angular frequency $\nu\omega$ (with ν a strictly positive integer number). The response can thus be expressed by the Fourier series

$$\mathbf{x}(t) = \frac{\mathbf{x}_{c0}}{\sqrt{2}} + \sum_{n=1}^{\infty} \mathbf{x}_{sn} \sin(n\omega t) + \mathbf{x}_{cn} \cos(n\omega t). \quad (2)$$

We now look for the conditions under which a primary resonance $\mathbf{x}_{1:1}(t)$ can be switched to a subharmonic one $\mathbf{x}_{1:\nu}(t)$, where $\mathbf{x}_{1:1}(t)$ and $\mathbf{x}_{1:\nu}(t)$ represent the solution of Equation (1) for $\nu = 1$ and $\nu \neq 1$, respectively. It is thus assumed that $\mathbf{x}(t) := \mathbf{x}_{1:1}(t) \approx \mathbf{x}_{1:\nu}(t)$. A justification of this hypothesis can be found in [6] if lightly-damped systems are considered, because primary and subharmonic resonances can both be seen as perturbations of the same periodic orbit of the underlying conservative system. The premultiplication of Equation (1) by $\dot{\mathbf{x}}^T(t)$ (where superscript T denotes transposition) and subsequent integration over one period of motion T feature the dissipation \mathcal{D} and the work done by the external forcing over one period $\mathcal{W}_{ext,\nu}$

$$\mathcal{D} = \int_0^T \dot{\mathbf{x}}^T(t) (\mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{f}_{nl}(\mathbf{x}(t), \dot{\mathbf{x}}(t))) dt = \int_0^T \dot{\mathbf{x}}^T(t) f_\nu \mathbf{f}_{ext} \sin(\nu\omega t) dt = \mathcal{W}_{ext,\nu} = -\nu\pi \mathbf{x}_{c\nu}^T \mathbf{f}_{ext} f_\nu, \quad (3)$$

where the last equality is obtained thanks to Equation (2). \mathcal{D} depends only on the motion $\mathbf{x}(t)$ and is therefore identical for the primary and subharmonic resonances by assumption. It then follows that $\mathcal{W}_{ext,1} = \mathcal{W}_{ext,\nu}$, and hence from Equation (3) the forcing amplitudes of the primary (f_1) and subharmonic (f_ν , $\nu \neq 1$) resonances must satisfy a relation given by

$$f_\nu = \frac{\mathbf{x}_{c1}^T \mathbf{f}_{ext}}{\nu \mathbf{x}_{c\nu}^T \mathbf{f}_{ext}} f_1. \quad (4)$$

This suggests that a subharmonic resonance may simply be excited by initiating the structure to its primary resonance, and by subsequently performing a multiplication of the forcing frequency by ν and a change in amplitude according to Equation (4). The factor in this equation can readily be computed either numerically or experimentally, as it only requires to monitor the first and ν^{th} cosine Fourier coefficients of the response at the forcing location ($\mathbf{x}_{c1}^T \mathbf{f}_{ext}$ and $\mathbf{x}_{c\nu}^T \mathbf{f}_{ext}$).

Illustration with a Duffing oscillator

To illustrate the proposed approach, we consider a Duffing oscillator governed by the equation of motion

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) + k_{nl}x^3(t) = f(t), \quad (5)$$

with parameters $m = 1$ kg, $c = 0.01$ kg/s, $k = 1$ N/m and $k_{nl} = 1$ N/m³.

The structure is excited at its primary (phase) resonance with a harmonic forcing of amplitude 0.047 N at frequency $\omega = 2.14$ rad/s. A jump to the 1:3 subharmonic resonance is initiated by multiplying the forcing frequency by 3 and changing its amplitude to 0.49 N, this new amplitude being computed from Equation (4). The time simulation results (obtained with a Runge-Kutta time integration scheme) are depicted in Figure 1. In spite of the strong change in forcing featured in Figure 1a, nearly no transient is observed in the motion, and the forcing is effectively able to sustain a motion with threefold period. Figure 1b indicates that this regime is sustained after the transients died out, which confirms that this subharmonic motion is a stable attractor of the system.

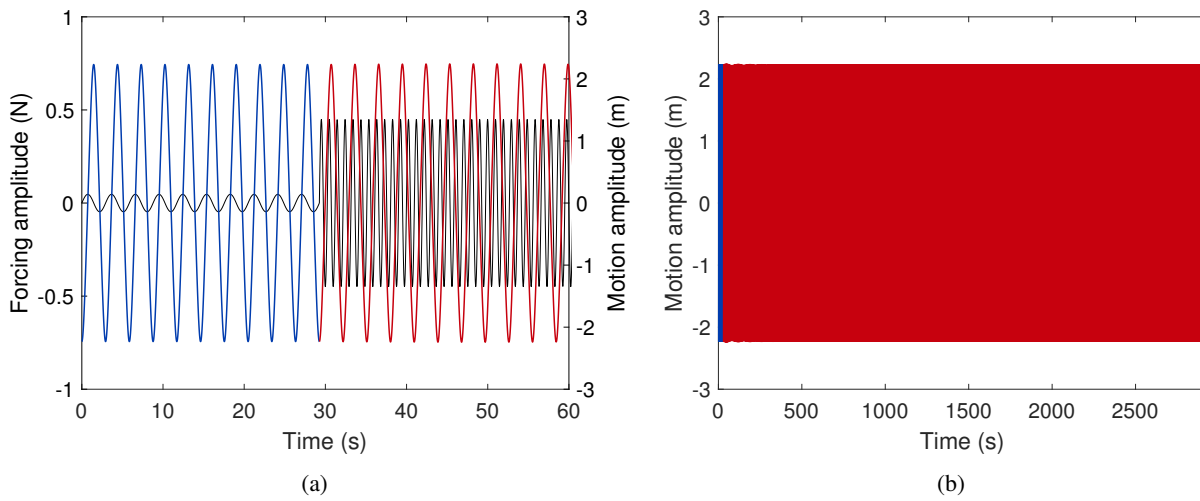

Figure 1: Time simulation of a Duffing oscillator undergoing a transition from a 1:1 to a 1:3 resonance: forcing $f(t)$ (—) and motion $x(t)$ before (—) and after (—) the change in forcing; close-up on the transition time (a) and full time simulation (b).

Conclusion

An approach to excite subharmonic resonances of nonlinear systems was proposed in this work. Based on the assumption that the resonant motions and the work provided by the external forcings are both identical for the primary and subharmonic resonances, an explicit relation was derived between the two forcing amplitudes. This allows for the transition from a primary to a subharmonic resonance through a suitable change in forcing amplitude and frequency. The proposed method was numerically demonstrated with a Duffing oscillator. This method is simple and holds great promises to find and predict subharmonic resonances of more complex nonlinear systems from the knowledge of their associated primary resonance, both numerically and experimentally.

Nonlinear Normal Modes in the pendulum system under magnetic excitation

Yuri V. Mikhlin*, Yuliia E. Surhanova*

*Dept. of Applied Mathematics, National Technical University “KhPI”, Kharkiv, Ukraine

Summary. Dynamics of two coupled pendulums under magnetic excitation is considered. Inertial components of the pendulums are essentially different, and a ratio of masses is chosen as a small parameter. Padé approximants is used to for the magnetic forces approximation. The small parameter method and the method of multiple scales are used to construct nonlinear normal modes (NNMs), one of them is localized one. Influence of the initial values and the system parameters, including the pendulum masses, change to the NNMs is studied.

Introduction. The basic model.

The system containing two pendulums under the electromagnetic motor influence is studied in few papers [1-3] where some corresponding mathematical models are constructed, and their validation is discussed after comparison of the numerical simulation and experimental results. Then some important aspects of the system dynamics are analyzed. Here we consider a similar system of two pendulums under magnetic force when inertial characteristics of these pendulums are essentially different. In this case, a localization of energy on the small mass pendulum is possible. To describe the system dynamics, the nonlinear normal modes (NNMs) theory is used. Different theoretical aspects of the NNMs theory and applications of the theory are presented in numerous publications, in particular, in reviews [4,5].

The Padé approximant and the nonlinear least squares method are used for analytical presentation of the magnetic force; such approximation demonstrates a good correspondence with experimental results presented in [2,3] as is shown in Fig.1.

Fig.1. Comparison of the magnetic force Padé approximation with experimental result [2,3].

Equations of motion of the system under consideration with respect to the pendulum angles are the following:

$$\begin{cases} \varepsilon I \ddot{\varphi}_1 = \varepsilon M_{mag1} - \varepsilon mgs \sin \varphi_1 - k_l(\varphi_1 - \varphi_2), \\ I \ddot{\varphi}_2 = \varepsilon M_{mag2} - mgs \sin \varphi_2 - k_l(\varphi_2 - \varphi_1), \end{cases} \quad (1)$$

Here I is the inertia moment of the big mass pendulum, rotating masses, $k_l(\varphi_1 - \varphi_2)$ is the moment of the torsional deformation, s is a distance between the pendulum centrum of masses and the axes of rotation. Later $\sin(\varphi) \cong \varphi - \frac{\varepsilon}{6}\varphi^3$. The small parameter ε characterizes the pendulum masses ratio. Then the small parameter method is used. In zero approximation, the relation $\varphi_{10} = \varphi_{20}$ is obtained for the coupled (in phase) vibration mode, and the relation $\varphi_{20} = 0$ is obtained for the localized vibration mode after the following time transformation: $t = \varepsilon \tau$. Without the magnetic influence in a wide range of changes in the system parameters, the error of the analytical solution is insignificant over sufficiently long time intervals and slowly increases with the growth of t up to the values of the pendulum initial angle deviations of the order 0.8727 rad (50°). Numerical simulations show a good exactness of the obtained analytical solution for relatively small values of the parameter ε . But with increasing of the parameter ε there is a gradual transition from the localized vibration mode to the out-of-phase one.

Influence of the initial deviations and the system parameters to the connected and localized nonlinear normal vibration modes under magnetic excitation

Considering numerical simulation of the connected and/or localized NNMs in the system under magnetic excitation we can conclude that at small angles, the influence of the magnetic force is greater, which means that the shape of the NNMs should not be preserved, although a localization of vibration is saved. At the same time, for large angles (for

high energies), the both stable NNMs take place. But, if the modulated magnetic effect itself is small, the in-phase mode will be observed even with small values of the initial deviations of the pendulums. The localized NNM for small and relatively large values of initial deviations is presented in Fig. 26 where the simulation is made for the following system parameters: $m = 0.5 \text{ kg}$, $k_l = 0.5 \frac{\text{Nm}}{\text{rad}}$, $s = 2.5 \text{ m}$.

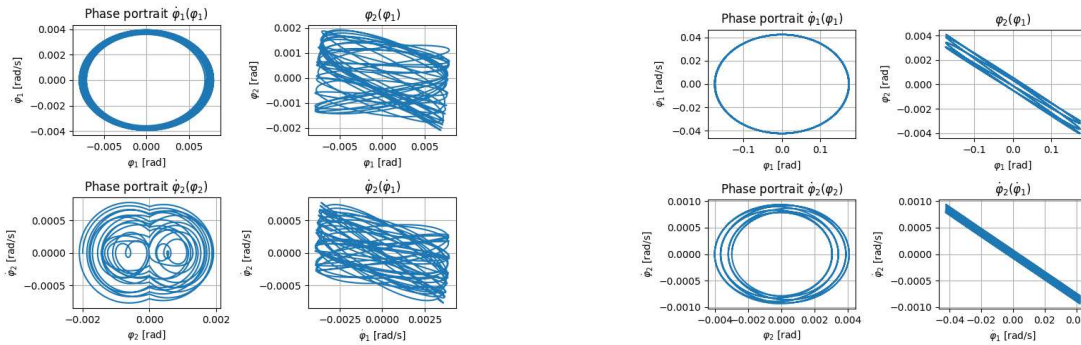

Fig. 2a: $\varphi_1(0) = 0.007 \text{ rad}$, $\varepsilon = 0.22$, $\varphi_2(0) = -0.002 \text{ rad}$ Fig. 2b: $\varphi_1(0) = 0.175 \text{ rad}$, $\varepsilon = 0.02$, $\varphi_2(0) = -0.003 \text{ rad}$
 Fig. 2. Localized NNM for small and relatively large values of the initial angles.

With the moderate increase of the parameter ε , the connected mode shape is observed with small deviations of the trajectories, but with further increase of ε , the deviations increase significantly for both pendulums, and some divergences from the connected mode shape is observed.

With increase of the coupling, the sharps of the in-phase and localized modes becomes more defined. It is true for a system with both a large magnetic effect and a small one.

Increase of the distance from the center of mass of the pendulum to the axis of rotation under both small and large initial conditions, as well as at small and large coupling coefficients, always leads to the clear manifestation of the connected (in-phase) mode. But if the initial angle of deflection of the pendulum is small, and the connection is small, both for a small magnetic effect and for a large magnetic one, then increasing the distance from the center of mass of the pendulum to the axis of rotation s does not contribute to the emergence of a stable localized shape.

A change in the distance from the center of mass to the axis of rotation with not too large values of the small parameter ($\varepsilon < 0.2$ and with a large value of the coupling coefficient), does not significantly affect the localized shape of the oscillations. With a small connection and a large distance from the center of mass of the pendulum to the axis of rotation, there are significant wanderings of trajectories around the localized mode

Conclusions

An analytical and numerical study of nonlinear vibration modes in a system consisting of two connected pendulums under the influence of electromagnetic forces is carried out, and here the masses of the pendulums differ significantly (*the masses ratio is characterized by the small parameter ε*), which leads to the appearance of a localized vibration mode. Both vibration modes are constructed by the small parameter method. Influence of the system parameters to the connected and localized NNMs is analyzed. In particular, we can conclude that both NNMs are clearly manifested for not small values of the initial angles. With a very small initial angle, the localized mode does not manifest itself.

Nonlinear Dynamics of a Body with Two Elastic Supports on an Inclined Rough Plane

Marat Dosaev, Vitaly Samsonov

Institute of Mechanics, Lomonosov Moscow State University, Moscow, Russia

Summary. The features of behavior of a dynamically asymmetric heavy body with two elastic supports on an inclined rough plane are studied. The classical Coulomb model of dry friction is used. The supports can move without friction along parallel guides fixed in the body and interact with the body by means of elastic springs. It is shown that the equilibrium position of the system is isolated. There is no stagnation zone by the tilt angle of the guides. Depending on the relationship between friction and the angle of inclination of the plane, the body can slide on one or both supports. The equations of motion represent a dynamic system of variable structure. The range of inclination angles of the supporting plane close to the critical one is considered. For inclination angle values smaller than the critical one, the body on rigid supports does not start sliding from rest along the given inclined plane; for angle values greater than the critical one, the body on rigid supports starts sliding from rest. For elastic supports, it is shown that if the initial position of the body is not equilibrium, then, starting from a state of rest, the center of mass of the system acquires a non-zero longitudinal velocity even if the angle of inclination of the supporting plane is less than the critical one.

Introduction

To ensure the stability of building structures when supported on a rough foundation, it is necessary to take into account various factors: deviations in the dimensions of finished structures from design ones, compliance of structures, deviation of the supporting surface from the horizontal, etc. In particular, it is of interest to model the behavior of structures for a case of various additional disturbances, such as an earthquake (see, for example, [1]). The difficulties of modeling mechanical systems with dry friction were actively considered at the end of the 19th century ([2]). At the beginning of the 20th century, the phenomenon of "friction impact" was substantiated ([3]).

Modeling the interaction of dry friction with elastic forces leads to the formation of dynamic systems of variable structure. Such systems, even after the linearization of the equations, have properties characteristic of nonlinear systems. Such equations have several singular points depending on the mode of motion. In [4], the sliding of a flat rigid body supported on a horizontal rough plane by two elastic telescopic supports was considered. The alternation of body sliding on one and two supports is described depending on the coefficient of friction.

In this paper, some effects of the behavior of a dynamically asymmetric heavy body on two elastic supports on an inclined rough plane are considered. The equations of plane-parallel motion of the system are obtained for the cases of sliding of one or two supports. The equilibrium position has been found. Conditions for falling one of the supports into a friction cone are obtained. A numerical calculation of motion from a state of rest in a position close to equilibrium has been carried out. It is shown that the center of mass of the system acquires a non-zero longitudinal velocity even when the angle of inclination of the reference plane is less than that required for the beginning of sliding of a solid (inelastic) body.

Problem statement

Consider a heavy body $ABCD$ with mass m (Fig. 1a) supported by supports AA_1 and BB_1 on an inclined rough plane. We assume that the angle α between the plane and horizontal H_1H_2 is small. For simplicity, we assume that the body is rectangular ($AB = 2a$, $AD = 2b$). The support rods can slide along parallel guides without friction. To simulate the compliance of the supports, we introduce identical springs of sufficiently high rigidity between the body and the rods. When the springs are not stressed, $AA_1 = BB_1 = l_0$, $l_0 < b < a$. The center of gravity G_1 of the rectangle is displaced from the center of the rectangle G along the straight line DC by a distance d . Consider $d > 0$, the right support is more loaded than the left one. Support springs act on the body by forces $F_{el1} = -k(l_1 - l_0)$, $F_{el2} = -k(l_2 - l_0)$, where k is the spring stiffness coefficient, l_1 is the length of the left support AA_1 , l_2 is the length of the right support BB_1 .

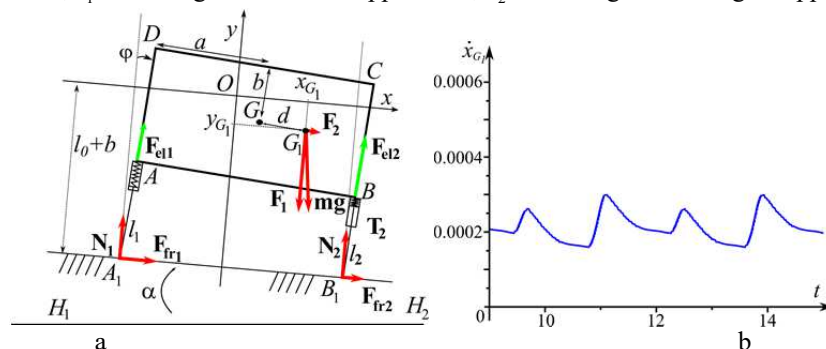

Figure 1: The body on a rough inclined plane. a) Mechanical system in consideration; b) Time dependence of the longitudinal velocity \dot{x}_{G_1} of the center of mass in the steady regime of motion for the angle of inclination $\alpha < \alpha_{crit}$.

The following external forces act on the system: gravity \mathbf{mg} , normal $\mathbf{N}_1, \mathbf{N}_2$ and tangential $\mathbf{F}_{fr1}, \mathbf{F}_{fr2}$ support reactions. The values of normal reactions at the support points are determined from the following relationships: $N_1 = F_{el1} \cos \varphi$, $N_2 = F_{el2} \cos \varphi$. In the case of sliding of the supporting legs, the reactions of the supports are interconnected according to the Coulomb law. In the case when the supporting leg is at rest, the value of the corresponding tangential reactions $F_{fr1} = F_{fr1stat}, F_{fr2} = F_{fr2stat}$ is determined from other motion characteristics.

Let us introduce a coordinate system Oxy . The axis Ox is parallel to the support plane and is at a distance $l_0 + b$ from it. The axis Oy is directed along the normal to the support plane. For convenience, we decompose the force of gravity into two components $\mathbf{mg} = \mathbf{F}_1 + \mathbf{F}_2$, where $\mathbf{F}_1, \mathbf{F}_2$ are the projections of the force of gravity on the Oxy axes.

As generalized coordinates, we choose the coordinates of the center of mass x_{G_1}, y_{G_1} and the angle φ between the vertical and the sides of the rectangle. We distinguish between longitudinal (along the inclined plane) \dot{x}_{G_1} and transverse \dot{y}_{G_1} velocities of the center of mass.

The equilibrium position $\{\varphi^*, y_{G_1}^*\}$ of the system does not depend on the presence of tangential reactions and can be obtained from the following equations:

$$\begin{cases} y_{G_1} = (F_2 \sin \varphi \cos \varphi - F_1 \cos^2 \varphi) / (2k) + (b + l_0)(\cos \varphi - 1) - d \sin \varphi \\ 2F_2 F_1 \cos^5 \varphi + ((F_1^2 - F_2^2) \sin \varphi - (2((b + l_0)F_2 + F_1 d))k) \cos^4 \varphi - \\ -(2k(-F_2 d + F_1(b + l_0)) \sin \varphi + F_2 F_1) \cos^3 \varphi - 2F_2 a k \cos \varphi \sin \varphi + 4a^2 k^2 \sin \varphi = 0 \end{cases}$$

In the region of small values φ^* , the dependences $\varphi^*(d), y_{G_1}^*(d)$ are single valued. The equilibrium position is isolated. There is no stagnation zone in the angle φ of inclination of the support guides.

Obviously, if friction is absent or sufficiently small, then both points of support slide during motion. If during some time period the point B_1 is motionless, then the number of degrees of freedom has decreased by one, the dynamical system must contain two equations of the second order. The immobility of the point is verified by the inequality: $\Delta = \mu N_2 - \text{abs}(F_{fr2stat})$. As the initial conditions we choose the position of rest, at which the guides of the supports are perpendicular to the supporting plane: $\varphi = 0, (x_{G_1}, y_{G_1}) = (d, -F_1 / 2k), \dot{\varphi} = 0, \dot{x}_{G_1} = 0, \dot{y}_{G_1} = 0$. Then the inequality takes

the following form: $\mu > \mu_2 = \frac{2|md(l_0 + b - 0.5F_1 / k) - ((a - d)^2 m + J)F_2 / (mg)|}{(J + m((a - d)^2 + (l_0 + b - 0.5F_1 / k)^2)}$, J is the central moment of inertia of

the body. If the inequality is satisfied, then the right support does not slide. For $\mu < \mu_2$ both supports start sliding. Similar reasoning can be carried out in the case of stopping the supporting point A_1 .

Let us single out the value of the angle of inclination $\alpha = \alpha_{crit}$ of the plane such that the force F_2 is equal in magnitude to the maximum value of the friction force of rest of the same body with rigid supports: $F_{2crit} = \mu F_1 = \mu$.

For smaller inclination angles, the body on rigid supports does not slip. It turned out that for the considered case of elastic supports, the body slides from a state of rest even if the angle of inclination of the plane is less than the critical one. Residual internal oscillations lead to a change in the normal pressure and, accordingly, to a change in the friction forces in the supports. In the final motion, the body has a variable non-zero longitudinal velocity. The time dependence of the longitudinal velocity \dot{x}_{G_1} of the center of mass in the steady regime of motion is shown in Fig. 1b for $F_2 = 0.00199, \mu = 0.002$. Such a regime, in particular, is possible due to the fact that the rear supporting point A_1 from time to time makes an instantaneous stop, and then slides in the opposite direction.

Conclusions

Plane motion of a heavy body supported by two elastic supports on a rough inclined plane is considered. The equations of motion are obtained, which are the dynamic system of variable structure. The isolated equilibrium position is found. It is numerically shown that from the state of rest, the center of mass of the system, can obtain a non-zero longitudinal velocity even if the angle of inclination of the supporting plane is less than the critical one required to start sliding of a rigid (inelastic) body.

The work is partially supported by Russian Science Foundation (project 22-21-00303).

The Role of Dynamics in Face sheet/Core Interface Debonding of Sandwich Panels

Vyacheslav N. Burlayenko*, Svetlana D. Dimitrova†

*Department of Applied Mathematics, National Technical University 'KhPI', Kharkiv, Ukraine

†Department of Higher Mathematics, National Technical University 'KhPI', Kharkiv, Ukraine

Summary. The current research addresses the study of debonding the face sheet from the core in a sandwich structure in dynamic regime by means of the use of a cohesive zone model accounting for contact and friction nonlinear effects. The finite element method within the ABAQUS environment is used for modeling and simulations of the dynamic debonding propagation problem. By numerical examples, the influence of different parameters, such as the adhesive properties in terms of the interface strength and toughness and the type of traction separation law and types and rates of the imposed loading, in relation to the double cantilever beam test are estimated. The obtained results demonstrate the relevance of both the adhesive properties and loading conditions, the changes of which may notably modify the stress state near the interface crack tip and the debonding evolution in the sandwich specimen in dynamics.

Introduction

The use of lightweight sandwich composites as primary structural components has been considered as one of the means for designing structures with increasing stiffness and strength at minimal increasing in their weight. However, sandwich structures are very susceptible to debonding of the face sheet from the core. Dynamic loading is relevant for many applications of sandwich structures. In dynamics, the debonding growth and eventual structural failure may happen even at a load level significantly lower than the predetermined critical one [1]. Therefore, sandwich composites to be safely exploited should be developed to withstand the debonding propagation at a certain level of dynamic loading.

In the present study, the cohesive element formulation is used to model the debonding behaviour along the face sheet/core interface of sandwich panels in dynamic regimes. First, the finite element formulation is outlined and the constitutive relationships for the cohesive element are introduced. Finally, the numerical calculations related to the finite element model of the double cantilever sandwich beam (DCB) test are carried out and the results are discussed in details.

Formulation and method of solution

A dynamic framework of the finite element method (FEM) combined with cohesive zone approach is considered. By assuming infinitesimal deformations, neglecting body forces, but accounting for cohesive and contact forces for a body occupying a space V and containing crack modeled by cohesive elements at the surface $\partial V_c = \partial V_c^+ \cup \partial V_c^-$, the principle of virtual work states as follows [2]:

$$\int_{V \setminus \partial V_c} (\boldsymbol{\sigma} : \nabla \delta \mathbf{u} + \rho \ddot{\mathbf{u}} \cdot \delta \mathbf{u}) dV + \int_{\partial V_c} \mathbf{T} \cdot \delta \Delta dA + \int_{\partial V_c} (t_N \delta g_N + \mathbf{t}_T \cdot \delta \mathbf{g}_T) dA - \int_{\partial V_t} \bar{\mathbf{t}} \cdot \delta \mathbf{u} dA = 0 \quad (1)$$

for all kinematically admissible displacement fields $\delta \mathbf{u}$ and given displacements $\bar{\mathbf{u}}$ at a boundary ∂V_u and a traction vector $\bar{\mathbf{t}}$ at ∂V_t . Herein, ρ is the density of material; $\boldsymbol{\sigma}$ is the Cauchy stress tensor associated with a displacement field \mathbf{u} , and $\ddot{\mathbf{u}}$ stands for an acceleration field; Δ is the displacement jump across and $\mathbf{T} = \boldsymbol{\sigma} \cdot \mathbf{n}_c$ are cohesive forces along ∂V_c oriented by the normal \mathbf{n}_c ; $t_N = t_N \mathbf{n}_c$ and \mathbf{t}_T are normal and tangential components of the contact traction which are interrelated with normal g_N and tangential \mathbf{g}_T gap functions [3]. It is assumed that a bilinear traction separation law (TSL) governs the fracture behaviour. The TSL has the following form for each fracture mode ($i = I, II, III$) [4]:

$$T = \begin{cases} k_i \Delta_i, & \Delta_i \leq \Delta_i^0 \\ (1 - D_i) k_i \Delta_i, & \Delta_i^0 \leq \Delta_i \leq \Delta_i^f \\ 0, & \Delta_i \geq \Delta_i^f \end{cases} \quad (2)$$

where $D_i = \left(\Delta_i^f (\Delta_i - \Delta_i^0) \right) / \left(\Delta_i (\Delta_i^f - \Delta_i^0) \right)$ is a damage variable. Herewith, damage initiates based on the quadratic stress criterion, whereas the damage evolves when the Benzeggagh-Kenane fracture criterion is met.

The impenetrability and friction constraints are stated in the form of Karush–Kuhn–Tucker conditions as follows:

$$t_N \leq 0, \quad g_N \geq 0, \quad t_N g_N = 0 \quad \text{and} \quad \|\mathbf{t}_T\| \leq \tau_{crit}, \quad \|\mathbf{g}_T\| \geq 0, \quad (\|\mathbf{t}_T\| - \tau_{crit}) \|\mathbf{g}_T\| = 0 \quad (3)$$

In the case of the Coulomb friction model, $\tau_{crit} = \mu t_N$, where μ is the coefficient of friction.

Following the FEM framework, the discrete system of dynamic equations of motion at time t takes the form:

$$[M] \{\ddot{U}\}_t + \{R_{int}\}_t + \{R_{coh}\}_t + \{R_{cont}\}_t = \{R_{ext}\}_t, \quad (4)$$

where $\{U\}$, $\{R_{int}\}$, $\{R_{ext}\}$, $\{R_{coh}\}$ and $\{R_{cont}\}$ are the vectors attributed to the nodal displacements, and the nodal internal, external, cohesive and contact forces, respectively; $[M]$ is the mass matrix. The system (4) is solved using either central difference explicit or Hilber-Hughes-Taylor implicit time-stepping schemes available in ABAQUS [5].

To estimate the stress state close to the crack tip appeared along the surface ∂V_c , the interaction integral method is used to calculate the components of stress intensity factors as follows:

$$K_i = \frac{H}{2K_i^{aux}} J_{int}^i, \quad \text{where} \quad H = (2 \cosh^2 \pi \epsilon) / (1/\bar{E}_1 + 1/\bar{E}_2), \quad (5)$$

where (aux) stands for auxiliary factors known from the asymptotic Williams type' solutions of the corresponding material system; $\bar{E}_k = E_k$ for in plane stress and $\bar{E}_k = E_k / (1 - \nu_k)$ for in plane strain, $k = 1, 2$; and ϵ is the bi-material oscillation index. Herewith, the interaction integral is defined as

$$J_{int}^i = \lim_{\Gamma \rightarrow 0} \int_{C+C_++\Gamma+C_-} \mathbf{m} \cdot \left\{ \boldsymbol{\sigma} : (\boldsymbol{\epsilon})_i^{aux} \mathbf{I} - \boldsymbol{\sigma} \cdot \left(\frac{\partial \mathbf{u}}{\partial x_1} \right)_i^{aux} - (\boldsymbol{\sigma})_i^{aux} \frac{\partial \mathbf{u}}{\partial x_1} \right\} \cdot \mathbf{q} d\Gamma, \quad (6)$$

where \mathbf{q} is a weighting function within the region enclosed by a contour $C \cup \Gamma \cup C_+ \cup C_-$; $\mathbf{q} = \mathbf{q}_1$ on Γ and $\mathbf{q} = 0$ on C ; \mathbf{m} is the outward normal. The line integral (6) is computed based on the domain integral formulation [6].

Results and conclusions

A 2-D finite element model of the DCB specimen is developed using eight-node reduced integration plane strain finite elements (CPE8R) available in ABAQUS. The mesh contained a refinement around the crack-tip.

The effect of impulsive loading on the transient dynamic SIFs of the DCB with stationary debonding is demonstrated in Figure 1. One can see that the DSIFs exceed their static counterparts for all the cases of loading. Also, the forms of impulse remarkably affect the time histories of the DSIFs. Herewith, unlike the stationary loading, the transient loads generate a high enough value of the mode II component.

Figure 1: Dynamic SIFs with a ramp time $t_0 = 1$ ms due to: (a) step loading; (b) rectangular pulse; (c) triangular pulse.

Four-node cohesive elements (COH2D4) satisfying the TSL (2) were inserted into the finite element mesh of the DCB model to simulate fracture of the specimens under dynamic loading. The debonding growth under impulse loads of different durations and the harmonic load at a certain driving frequency is shown in Figure 2.

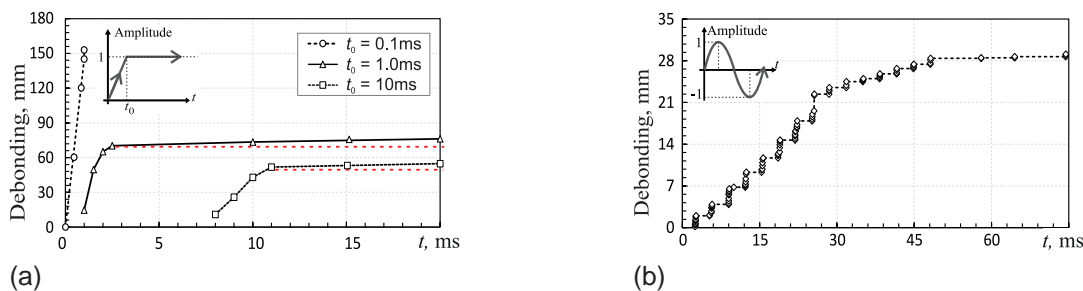

Figure 2: Debonding propagation versus time under: (a) impulsive step loading; (b) harmonic loading

The calculations revealed that there is a large dynamic effect in the DCB test, primarily due to stress waves from both the loading and crack face contact. Such waves interact with the crack tip and strongly affect the fracture parameters and the debonding behaviour of the DCB sandwich specimen.

Summary. In this paper a novel time-stepping approach for the linear stability analysis of elastic structures interacting with incompressible viscous flows is presented. The method is based on the coupling of an iterative Krylov-subspace algorithm for the solution of large eigenvalue problems within an Immersed-Boundary (IB) framework, to obtain a matrix-free global stability solver which extracts the necessary information directly from Direct Numerical Simulation (DNS).

In this work, the proposed approach is explained and validated with respect to test cases involving elastically-mounted rigid bodies immersed in open flows.

Introduction

The interactions of elastic structures with incompressible flows have been the subject of numerous works in recent years, due to their dynamically reach and complex behaviour. Despite the non-linear nature of these phenomena, the onset of the transition from a state of the system to another one can be predicted via a linear stability analysis. However, even with high-performing numerical tools, the global stability analysis of a fluid-structure system remains a prohibitive task due to considerable implementation difficulties; in particular, the linearisation of interface terms is often cumbersome.

This work presents an approach to perform the linear stability analysis of fluid-structure configurations which is incorporated into a validated FSI solver based on a Moving-Least-Squares Immersed boundary [1]. This technique has been largely used to explore the behaviour of fully coupled FSI applications involving large displacements, while linear stability analyses, on the other hand, are usually performed using mesh-deforming techniques. Although the latter methods are often chosen for two-dimensional cases, their implementation is often too expensive in three-dimensional applications. Furthermore, the extension to complex multi-body configurations is non trivial.

In this work, we adopt the approach followed by Mack and Schmid [2] for the global stability analysis of compressible flows and extend it to the coupled physics problem.

Methodology

We investigate the dynamics of elastically-mounted rigid bodies immersed in a Newtonian viscous fluid with homogeneous density. The flow is governed by the Navier-Stokes equations, here written in an Immersed-Boundary formulation,

$$\begin{cases} \frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} = -\nabla p + \frac{1}{Re} \Delta \mathbf{u} + \mathbf{f}, & \text{in } \Omega \\ \nabla \cdot \mathbf{u} = 0, & \text{in } \Omega \end{cases} \quad (1)$$

where \mathbf{u} and p denote the fluid velocity and pressure respectively, Ω is the physical region occupied by the fluid and \mathbf{f} is the volume force arising from the IB treatment. The immersed bodies are modeled as mass-spring-damper systems,

$$\mathbf{M} \ddot{\mathbf{x}} + \mathbf{C} \dot{\mathbf{x}} + \mathbf{K} \mathbf{x} + \mathbf{F}_{nl}(\mathbf{x}, \dot{\mathbf{x}}) = \mathbf{F}(t), \quad (2)$$

where \mathbf{x} is displacement vector, \mathbf{M} , \mathbf{C} and \mathbf{K} are the lumped mass, damping and stiffness matrix respectively, and \mathbf{F}_{nl} takes into account the non-linear contributions. The forcing vector $\mathbf{F}(t)$ provides the resultant force on the body which, in the absence of gravity and other volume force components, reduce to the hydrodynamic load on the immersed surfaces. Collecting fluid and solid variables into the state vector \mathbf{q} , the coupled problem can be reformulated as

$$\frac{\partial \mathbf{q}}{\partial t} = \mathbf{R}(\mathbf{q}), \quad (3)$$

where \mathbf{q} is the state vector, containing all the degrees of freedom of the problem, and \mathbf{R} is the nonlinear evolution operator. The stability of the system in the vicinity of a steady steady solution of (3), \mathbf{q}_b , is given by a generalized eigenvalue problem for the Jacobian operator \mathbf{J} , who is an unknown quantity in the general case. Therefore, following Eriksson and Rizzi [3], we linearise the system numerically, approximating the evolution in time of a small perturbation \mathbf{q}_p via the second-order accurate finite difference

$$\mathbf{q}_p(t_0 + n\Delta t) = \frac{\mathbf{q}_+ - \mathbf{q}_-}{2\epsilon}, \quad (4)$$

where \mathbf{q}_+ and \mathbf{q}_- are outcomes of two disjoint advancement carried out by the DNS-IB solver:

$$\mathbf{q}_+ = \mathbf{F}(\mathbf{q}_b + \epsilon \mathbf{q}_p(t_0), n\Delta t), \quad (5)$$

$$\mathbf{q}_- = \mathbf{F}(\mathbf{q}_b - \epsilon \mathbf{q}_p(t_0), n\Delta t). \quad (6)$$

Recalling that the evolution of a small perturbation \mathbf{q}' of the base state is given by

$$\mathbf{q}'(t_0 + T) = e^{JT} \mathbf{q}'(t_0), \quad (7)$$

we recognize that the finite difference (4) approximates the action of the exponential transformation of the Jacobian matrix on the perturbation vector. Thus, we can compute a set of the least stable eigenvalues of the system by means of an iterative algorithm such as those belonging to the general class of Krylov subspace methods.

In the present work, the approximation of the leading eigenvalues of the system is computed by using the *Implicitly Restarted Arnoldi Method* (IRAM) as implemented in the ARPACK open source package [4]. The steps of the algorithm are listed below:

1. The base flow is computed via the *BoostConv* [7] stabilization procedure;
2. Arnoldi iterations are performed until convergence is reached: ($k = 1, 2, \dots$)
 - (a) Vector \mathbf{q}_p^k is generated
 - (b) Reverse communication to the DNS-IB solver gives $\mathbf{q}_p^k(n\Delta t) = \frac{\mathbf{q}^+ - \mathbf{q}^-}{2\epsilon}$
 - (c) Convergence of the desired Ritz pairs is checked
3. A logarithmic transformation is performed to recover the eigenvalues of the Jacobian matrix.

Results and discussion

The presented methodology has been validated with respect to several literature cases involving rigid bluff bodies interacting with flows with low Reynolds numbers. As a proof of concept, figure 1 shows the growth rate and frequency of the first two eigenvalues for the case of an elastically-mounted circular cylinder, undergoing vortex-induced vibrations in a flow with $Re = 60$. The cylinder is allowed to move only in the direction orthogonal to the unperturbed flow.

Given its matrix-free and Immersed-Boundary formulation, the method is capable of coping with complex geometries,

Membrane flutter induced by radiation of surface gravity waves on a uniform flow

Joris Labarbe*, Oleg Kirillov*

*Northumbria University, NE1 8ST Newcastle upon Tyne, UK

Summary. We consider stability of an elastic membrane being on the bottom of a uniform horizontal flow of an inviscid and incompressible fluid of finite depth with free surface. The membrane is simply supported at the leading and the trailing edges which attach it to the two parts of the horizontal rigid floor. The membrane has an infinite span in the direction perpendicular to the direction of the flow and a finite width in the direction of the flow. For the membrane of infinite width we derive a full dispersion relation that is valid for arbitrary depth of the fluid layer and find conditions for the flutter of the membrane due to emission of surface gravity waves. We describe this radiation-induced instability by means of the perturbation theory of the roots of the dispersion relation and the concept of negative energy waves and study its relation to the anomalous Doppler effect.

Membrane flutter as a radiation-induced instability

Flutter of membranes is a classical subject for at least seven decades. Membranes submerged in a compressible gas flow and their flutter at supersonic speeds have been considered already in the works [1, 2]. Recent works on the membrane flutter are motivated by such diverse applications as stability of membrane roofs in civil engineering [3], flutter of traveling paper webs [4] and aerodynamics of sails and membrane wings of natural flyers [5, 6].

Surface gravity waves on a motionless fluid of finite depth is a classical subject as well, going back to the seminal studies of Russell and Kelvin [7]. Numerous generalizations are known taking into account, for instance, a uniform or a shear flow and surface tension [8], flexible bottom or a flexible plate resting on a free surface [9]. The latter setting has a straightforward motivation in dynamics of sea ice and a less obvious application in analogue gravity experiments [7].

Remarkably, another phenomenon that is being analysed from the analogue gravity perspective is super-radiance [7] and its particular form, discovered by Ginzburg and Frank [10], known as the anomalous Doppler effect (ADE) [11, 12]. In electrodynamics, the ADE manifests itself when an electrically neutral overall particle, endowed with an internal structure, becomes excited and emits a photon during its uniform but superluminal motion through a medium, even if it started the motion in its ground state; the energy source is the bulk motion of the particle [11].

Anomalous Doppler effect in hydrodynamics was demonstrated for a mechanical oscillator with one degree of freedom, moving parallel to the boundary between two incompressible fluids of different densities [13]. It was shown that the oscillator becomes excited due to radiation of internal gravity waves if it moves sufficiently fast. In [14] the ADE for such an oscillator was demonstrated due to radiation of surface gravity waves in a layer of an incompressible fluid.

Nemtsov [15] was the first who considered flutter of an elastic membrane being on the bottom of a uniform horizontal flow of an inviscid and incompressible fluid as an anomalous Doppler effect due to emission of long surface gravity waves. In the shallow water approximation, he investigated both the case of a membrane that spreads infinitely far in both horizontal directions and the case when the width of the membrane in the direction of the flow is finite whereas the span in the perpendicular direction is infinite. Nevertheless, the case of the flow of arbitrary depth has not been studied in [15] as well as no numerical computation supporting the asymptotical results has been performed. Another issue that has not been addressed in [15] is the relation of stability domains for the membrane of the finite width to that for the membrane of the infinite width.

Vedenev studied flutter of an elastic plate of finite and infinite widths on the bottom of a uniform horizontal flow of a compressible gas occupying the upper semi-space. He performed analysis of the relation of stability conditions for the finite plate with that for the infinite plate using the method of global stability analysis by Kulikovskii [16, 17]. However, no connection has been made to the ADE and the concept of negative energy waves.

In the present work we reconsider the setting of Nemtsov in order to address the finite height of the fluid layer, find flutter domains in the parameter space, analyze them using perturbation of multiple roots of the dispersion relation, find the domains of absolute and convective instability and investigate dependence of the flutter onset on the width of the membrane including the limit of infinite width. We will explain the instabilities via the interaction of positive and negative energy waves by finding an appropriate G-Hamiltonian formulation and relate them to the anomalous Doppler effect.

Passive Fluidic Control of Flow around Circular Cylinder

James Ramsay*, Mathieu Sellier* and Wei Hua Ho†

**Department of Mechanical Engineering, University of Canterbury, Christchurch, New Zealand*

† *School of Mechanical, Industrial & Aeronautical Engineering, University of Witwatersrand, Johannesburg, South Africa*

Summary. Suction of the boundary layer is an effective means of delaying separation and reducing drag on external flows. However, if a pumping system is required to generate the suction, the weight and power consumption of the system can undo that benefit. ‘Autogenous’ (self-generating) suction control is a type of flow control that utilises the energy already within a flow (notably the pressure gradients) to drive the suction, thereby requiring no further energy to the system. This paper describes numerical studies that were performed on the flow around the circular cylinder in the 2D laminar range: $Re = 40$ (steady) and $Re = 120$ (unsteady). Suction and blowing control were implemented by imposed velocity boundary conditions. These controls were then modified using optimisation methods to generate arrangements of suction and blowing that can be passively generated by their pressure differential (i.e. $P_s \geq P_b$). Steady and unsteady simulations were performed. It was found that at both $Re = 40$ and $Re = 120$ drag-reducing arrangements could be produced. At $Re = 120$ a reduction in drag of 4.3% was found while maintaining a positive pressure differential from the suction to blowing loci. This approach for developing passive suction control can be applied to other bluff body flows and higher Reynolds numbers to design efficient optimised flow control.

Introduction

Boundary layer suction has a long history as an effective means of flow control. The first recorded use of suction to control a fluid flow was by Ludwig Prandtl to test his boundary layer theory (1). It has been shown by many experimental (2; 3; 4) and numerical (5; 6; 7; 8) studies that suction control is extremely effective at reducing drag, subduing vortex shedding, or improving lift in external flows. Additionally, optimised non-uniform suction can be much more efficient and effective than uniform suction or slot suction (9). In some applications, suction control is effective not by its influence on the boundary layer, but by its body force imposed on the flow, for example when suction is applied on the already separated wake behind an object (10).

On the other hand, to generate the suction flow, an appropriate pressure gradient is required. This pressure gradient must be sufficient to overcome porous and viscous losses through any suction ducting, and depending on the strength of suction desired, must also overpower the momentum of fluid outside the boundary layer. This is the case whether the suction is applied through slots or with a porous surface. In practice, this is typically achieved using a pump or compressor (11; 3). The energy required to power this pump may exceed the savings in energy from drag reduction. Additionally, the weight of the pump and suction system will increase the mass needed to accelerate for transportation applications. Due to this and other considerations, while suction control may be extremely effective, it may be inefficient (12).

One alternative to a pump system is to use the pressure gradients already within a flow to drive a suction/blowing through the bounding surface. This was coined ‘autogenous suction control’ by Atik and van Dommelen, meaning ‘self-generating’ (13). By connecting a region of high pressure to a region of low pressure, a secondary flow can naturally develop. Autogenous suction was first explored behind shocks (14; 15; 16), but Atik and van Dommelen were the first to explore its potential in subsonic and laminar flows.

In their numerical study, it was shown that autogenous suction control was possible for a thin airfoil and could delay separation over a range of angles of attack (13)). The autogenous suction control was achieved by applying suction over a distributed area downstream of the location of minimum pressure (and separation point) while exhausting the fluid removed by suction upstream. The numerical approach by Atik and van Dommelen was limited in that it solved the boundary layer equations rather than the full Navier-Stokes equations, which was appropriate for their idealised airfoil but is unlikely to be so for other flow cases. Additionally, their study was intentionally idealised, and many considerations of a physical implementation were ignored or set to arbitrary values (e.g. viscous and porous losses, the effect of tangential pressure gradients). However, a type of autogenous suction control device was patented by inventor Pradip Parikh and assigned to Boeing, to delay separation over an aircraft wing (17).

The paper by Atik and van Dommelen demonstrated the potential for autogenous suction to beneficially control the flow around an aerodynamic shape (delayed separation), while the patent held by Boeing demonstrates how it might be used for a real-world application (13; 17). However, it has not been shown whether autogenous suction control can reduce drag on a body, and whether other arrangements – such as suction upstream of the minimum pressure location – would be beneficial. Therefore, in this study, autogenous suction control was developed on a canonical flow with the objective to minimise drag and develop a methodology for designing autogenous suction control using the Navier-Stokes equations. A bluff body was chosen as the geometry in order to supplement the work of Atik and van Dommelen on a streamlined shape, hence, the flow around the circular cylinder in the 2D laminar range ($Re \leq 188.5$) was modelled numerically. Parameterised boundary conditions were used to impose the suction and blowing flows, which were then optimised with constraints so as to be autogenous.

Methodology

Computational Domain & Governing Equations

The flow around the circular cylinder was modelled numerically for $Re = 40$ and $Re = 120$ using COMSOL Multiphysics, a commercial Finite Element software package. The governing equations are the incompressible isothermal Navier-Stokes equations:

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{u} - \nu \nabla^2 \mathbf{u} + \frac{1}{\rho} \nabla p = \mathbf{f}, \quad (1)$$

$$\nabla \cdot \mathbf{u} = 0, \quad (2)$$

where \mathbf{u} and p are the velocity vector and scalar pressure fields respectively (the dependent variables), $\nu = \mu/\rho$ is the kinematic viscosity, ρ is the fluid density, and \mathbf{f} is the vector for all external forcing terms (in this case, zero). Both steady-state and unsteady simulations were employed in this study, and in the former case the time-derivatives vanish (first term of Equation (1)).

The computational domain is shown in Figure 1. This is the same as in (9), where the model was extensively validated against experimental data for drag and separation angle from the literature (18; 19; 20; 21). The flow around the circular cylinder is commonly studied, and its characteristics are well known (22). The flow is characterised by its Reynolds number, $Re = \frac{\rho U D}{\mu}$, where the characteristic length is the cylinder diameter, D . For $Re \leq 188.5$ the flow is 2D and wholly laminar, but for $Re \geq 47$ the flow is unsteady.

With 31,640 elements and a time-step of $dt = \frac{1}{30}T = \frac{1}{30} \frac{D}{U St}$, where T is the vortex shedding period and St is the Strouhal number, the model is sufficiently mesh and time independent for $Re \leq 180$ (see (9)). Here, the control was ramped up over $1T$ on a fully-developed solution of the uncontrolled flow. The simulation was run until the flow was fully-developed again (usually $10T$). The unsteady studies always commenced using a fully-developed uncontrolled flow as the initial condition.

Figure 1: Computational domain for simulations (a); Schematic illustrating the key parameters for the dual-loci control. The subscript 'b' denotes a blowing control parameter, while no subscript indicates suction (b).

Boundary Conditions

The numerical boundary conditions consist of a uniform inlet on the left, lower and upper boundaries, $u = U = \frac{Re\nu}{D}$, $v = 0$. A zero relative pressure outlet is defined on the right boundary. The boundary on the cylinder was defined with a prescribed velocity Dirichlet condition. Suction and blowing profiles were implemented through this boundary condition as a function of angle from the trailing edge, θ . Theoretically infinite suction/blowing profiles could be implemented, however it was found in (9) that optimal suction in this range typically consisted of a single locus of suction. A bell-shaped (cubic) profile was effective. Hence, in this work varieties of this 'single locus' profile for the suction and blowing profiles were considered, and with suction/blowing in the normal direction only ($\mathbf{u} = (u_n, u_t) = (u_n, 0)$ at the cylinder wall).

The suction/blowing profiles on the cylinder were defined to have one area (locus) of suction and one locus of blowing. This is called the 'dual-loci' approach in this paper. Each control locus utilises the 'single locus' profile from (9) which defines a smooth cubic profile with zero derivatives at its centre and edge. Three parameters are needed to define the profile: the location of the locus centre as measured from the trailing edge (TE), θ_q , the spread of the locus measured as an angle, γ_q , and the maximum strength (which is applied at the centre, c_{qmax}). These are illustrated in Figure 1. By superimposing two single locus profiles – one for blowing, one for suction – the dual-loci control is achieved. The control applied is mirrored across the streamwise axis of the cylinder.

Outline of Studies

The results of two studies on autogenous suction control are presented here:

1. Q-balanced control: flow-rates of the suction and blowing loci must be equal ($Q_s = Q_b$), but no pressure requirement is imposed.
2. P-Q-balanced control: Flow-rates must be equal and the pressure gradient negative from suction to blowing ($Q_s = Q_b, P_s - P_b \geq 0$).

The first represents a case where a pump or other device must be used in order to produce the suction/blowing, whereas the second is the autogenous case.

Optimisation Approach

Control Parameters

In each model there were five independent control parameters and one dependent control parameter as summarised in Table 1. As Q_s must equal Q_b to maintain continuity, the sixth control parameter ($c_{q_{max_b}}$) is dependent on the rest.

Table 1: Control Parameters

Parameter Name	Suction Parameter	Blowing Parameter
Control angle ($^\circ$)	$0 \leq \theta_q \leq 180$	$0 \leq \theta_{qb} \leq 180$
Control spread ($^\circ$)	$0 \leq \gamma_q \leq 90$	$0 \leq \gamma_{qb} \leq 90$
Control peak strength	$0 \leq c_{q_{max}} \leq 1$	$c_{q_{max_b}} = \frac{\gamma_{qs}}{\gamma_{qb}} c_{q_{max}}$

Objectives and Constraints

The major control objective in each study was to minimise the total drag on the cylinder as evaluated by integrating the stream-wise normal and shear forces:

$$J_{dt} = C_{dt} = C_{dp} + C_{df} = \frac{1}{\frac{1}{2}\rho U^2 D} \oint \left(-p(\theta) + \mu \frac{-\partial u_t(\theta)}{\partial r} \right) \cos(\theta) R d\theta, \quad (3)$$

where R the radius of the cylinder, and θ the angle measured anti-clockwise from the trailing edge.

For the autogenous control studies (Model III), an additional objective that the averaged suction pressure must be greater than the averaged blowing pressure was included:

$$J_{auto} = \Delta P = P_s - P_b \geq 0. \quad (4)$$

The suction and blowing parameters were optimised with a nested approach, as shown in Figure 2. I.e. the suction control parameters are selected by the control algorithm, then a secondary optimisation occurs to arrange the blowing locus such that the drag is minimised and pressure drop maximised for that particular suction arrangement. The major optimisation then evaluates how well this combined suction/blowing control achieves the total objectives. The inner (minor) optimisations had a maximum of 50 model evaluations each time it was called.

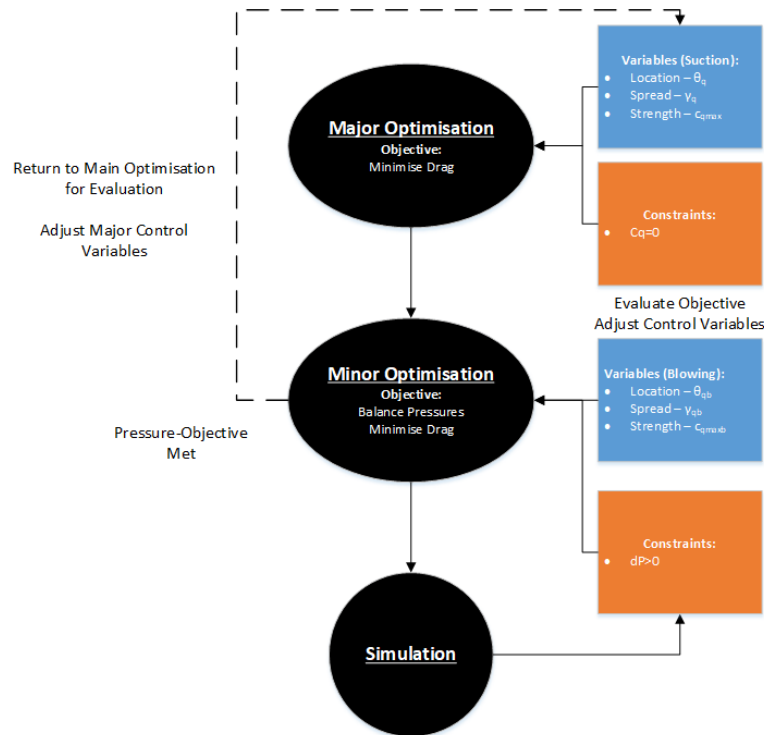

Figure 2: Flow-chart of P-Q-Balanced Dual-Loci optimisation (autogenous suction control).

An additional constraint was also implemented, preventing the suction and blowing loci from overlapping in order to generate realisable controls.

Results & Discussion

Optimisation of Non-Autogenous Dual-Loci Control

Optimisation of the Q-balanced dual-loci control resulted in suction/blowing control which reduced drag by up to 13% at $Re = 40$ and 22% at $Re = 120$. The control parameters and key results for the optimised control summarised in Table 2 and Table 3 while the velocity and pressure contours are shown in Figure 3. The improvement in drag is strong at both Re , but more potent at the higher Reynolds number of $Re = 120$. However, when the pressure differential between the suction and blowing loci are considered ($-dP = -1.5387\& - 1.4143$), it can be seen that this control would require substantial power to run due to the strong APG between the suction and blowing loci.

The optimised control profiles feature suction upstream and blowing near the trailing edge of the cylinder. The suction removes the low momentum fluid and entrains higher momentum which delays the separation. Consequently the pressure drag is greatly reduced, while there is a smaller increase in skin friction drag due to the now higher velocity gradient at the wall. At both Reynolds numbers there is a narrow spread for the suction and a wider spread for blowing. This reflects the previous findings shown in (9) where the drag is very sensitive to the location of suction - with clearly advantageous locations. Therefore, the most efficient control targets these locations. Similarly, it appears that the trailing edge is the best location for blowing control. This helps to increase the base pressure.

Table 2: Key control parameters for drag-optimised Q-balanced dual-loci control compared to its unbalanced variety.

Time-Dependent Simulation Verification

Time-Dependent Simulation Verification

The key results for best non-autogenous control from the optimisation study at $Re = 120$ are shown in Table 4. This optimised control is strong enough to fully stabilise the flow, therefore the results from the steady-state simulations match perfectly with the time-dependent simulations. However, since this control should be compared against the drag for the time-dependent case, the improvement is now seen to be 38.7%. The data in Table 6 clearly indicates that this massive improvement comes from the large reduction in pressure drag, while the skin friction drag has almost doubled. The control arrangement is still highly unfavourable for autogenous control, and its actual efficiency would be low given the large adverse pressure gradient (APG) that the control flow has to overcome. However, it is encouraging to see that the dual-loci control can be extremely effective on unsteady flows. The pressure and velocity contours are not shown for this simulation as they match in practically every aspect, those in Figure 3.

Table 4: Key results for optimised Q-balanced dual-loci control verified on time-dependent simulations at $Re = 120$.

Parameter	No Control (SS)	No Control (TD)	Q-Opti (SS)	Change from No Control SS (%)	Q-Opti TD	Change from No Control TD (%)

Optimisation of Autogenous Dual-Loci Control Steady-State Optimisation

Using the two-optimisation process, the dual-loci control was successfully optimised to minimise drag while enforcing the constraint on pressure drop between the suction and blowing loci. The optimised control parameters and key results are shown in Tables 6 to 8.

The improvement in drag is much weaker when the autogenous constraint is imposed compared to the Q-balanced approach above. Nevertheless, the drag on the cylinder was reduced while maintaining a positive pressure gradient from the suction to blowing loci. In other words, autogenous suction control was effective for this flow. It was found that the optimised control was quite sensitive to the initial control parameter values for this flow, so two sets of initial values were used at both Re - IV1 and IV2 as described in Table 5. For IV1, at $Re = 40$ the drag was reduced by 5.45% while at $Re = 120$ a more modest 3.68% improvement was achieved while the improvements from the IV2 case were even lower.

Table 5: Initial values of control parameters for P-Q-balanced dual-loci optimisation.

Control parameter	Initial Values (IV1)	Alternative Initial Values (IV2)
θ_q	150°	120°
γ_q	20°	40°
$c_{q_{max}}$	0.1	0.1
θ_{q_b}	90°	80°
γ_{q_b}	10°	10°
$c_{q_{max_b}}$	-0.2	-0.4

In both cases, the drag improvement was through a combination of the pressure drag and skin friction drag. This is unlike for the case of suction only or Q-balanced control, where the pressure drag is substantially improved but the skin friction worsened to produce a net benefit. At both Reynolds numbers, a quite different control flow was utilised to achieve the drag objective. This was to produce a suction and blowing very close to each other on the front half. This is effective at manipulating the C_f and C_p profiles over the front half, reducing the pressure and skin friction, rather than delaying separation or improving the base pressure.

This dramatically different control arrangement appears to be a factor of the initial values provided for the control. When alternative initial values – IV2 – were used, the resulting control was quite different. The final optimised controls were very similar to their initial conditions which suggests that there are other local optima that may be found also.

Table 6: Optimised control values for different dual-loci settings.

The pressure contour and velocity surfaces are shown for the best optimised P-Q-Balanced dual-loci control (IV1 case) below at $Re = 40$ & 120 in Figure 4. The control is concentrated on the front-half and improves both the skin friction and pressure drag modestly. This control arrangement is highly dependent on the initial values used for the optimisation study.

Figure 4: Velocity surface (a,c) and pressure contours (b,d) for optimised P-Q-balanced dual-loci controlled flow round cylinder at $Re = 40$ (a,b) and $Re = 120$ (c,d).

Overall, the major research question of “can autogenous suction control theoretically be used to reduce drag for bluff body flows?” has been found to be true. Certainly for $Re = 40$, whereas the flow at $Re = 120$ should be resolved with

an unsteady simulation to confirm.

Time-Dependent Verification

As for the non-autogenous Q-balanced control, to verify whether these results are feasible for the true unsteady flow at $Re = 120$, time-dependent simulations were carried out with the optimised control parameter. These simulations were successful and found that the optimised controls still satisfied the pressure-drop requirements in both time-dependent cases. Unlike for the Q-balanced control, the optimised autogenous control does not stabilise the flow at $Re = 120$ and therefore the steady-state simulations are flawed. The time-averaged values (over one vortex-shedding period), and their fluctuation are given for the key parameters of the first P-Q-balanced design compared to the steady-state values in Table 9. The key parameters for both P-Q-balanced designs are provided in Table 10.

As expected, the drag coefficient values are quite different from the steady-state values, but the reaction to the control is consistent in the TD simulations. For the first optimised arrangement (with the suction and blowing situated at the front of the cylinder), the improvement in drag is dulled. An average 2.5% improvement was produced compared to the 3.7% predicted by the steady-state study. Importantly, the positive pressure gradient between the suction and blowing loci remains, and in fact is greater for the TD case (0.5764 vs. 0.4928). This makes sense as the pressure profile is steeper and has a larger fluctuation for the unsteady case, even for the uncontrolled flow, which is beneficial for the autogenous constraint.

The most interesting result is the dramatic change in performance for the second P-Q-balanced design (produced using the second set of initial values in the optimisation). Where the steady-state result suggested a reduction in drag of only 0.83%, the actual result when applied to the unsteady cylinder flow was actually 4.3%. This is not just better than the SS estimate, but it is a greater improvement than the first P-Q-balanced design. While the first design reduces both skin friction and pressure drag modestly, the second design uses the same mechanisms as suction-only control to minimise total drag by greatly reducing the pressure drag at the cost of slightly increasing the skin friction drag. The design of this control fits better with previous findings that suction near the 90° mark with blowing situated near the rear produces the best drag-reduction but is difficult to achieve with autogenous pressure gradients (5).

dP	-	-	0.5764	0	0.0747	0.0027

This second arrangement of the autogenous suction control is particularly promising for a variety of reasons. Firstly, the control flow rates are much lower. While the relationship between the control flow rate and the necessary pressure to drive it has mostly been ignored in the present study, it is likely that large control flows will require larger pressure drops. The peak suction strength is only $c_{q_{max}} = 0.053$ which is more like the level of suction seen for early boundary layer studies (23, p. 383). Secondly, the flow-path for the control is better. While the optimisation procedure accounts for the effects of blowing control on the boundary layer and the second-order impact on the pressure profile, it seems logical to have the flow exhausted out the rear of the cylinder. This prevents the boundary layer from being blown away, and does not have to produce a dramatic change in the momentum direction of the control flow. Finally, the second control arrangement appears to dampen the dynamics of the flow. The fluctuations of the drag coefficients are all reduced from the uncontrolled case. The time-averaged flow fields are shown for the two controlled and uncontrolled cases in Figure 5.

The changes to the flow are subtle so there is little to remark on except the small morphing of the reversed flow region in the wake from the blowing in the second case.

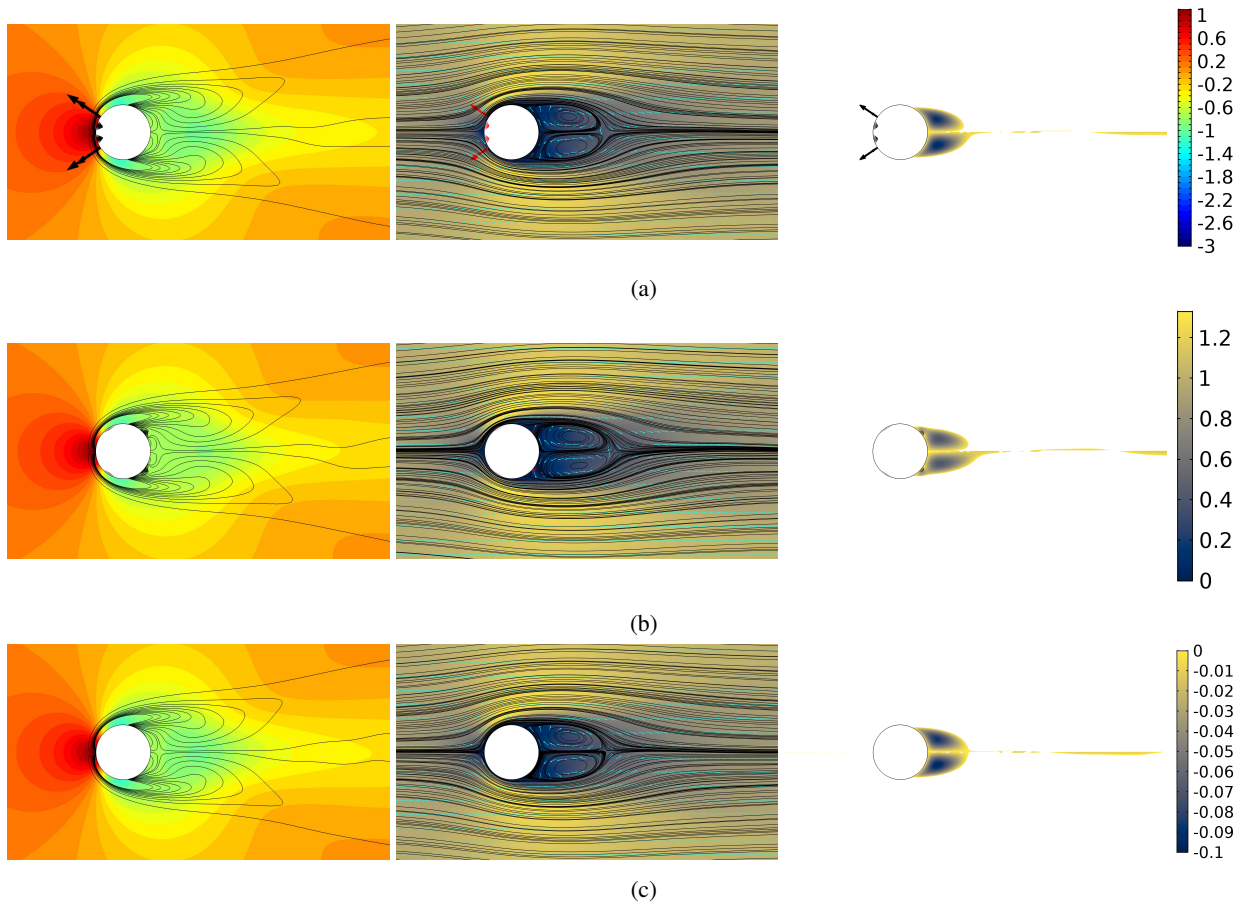

Figure 5: Pressure contours with vorticity streamlines (left), velocity surface with streamlines (middle) and reversed flow surfaces for the time-averaged flow round the cylinder for the IV1 optimised control (a), IV2 optimised control (b) and no control (c). Flow field is averaged over 1 vortex shedding period of the uncontrolled flow. The colour bars for the pressure, velocity and reversed flow surfaces are shown in the final column (in descending order).

Conclusions

Numerical studies were carried out on laminar flow around a circular cylinder to develop autogenous suction control. Dual-loci control - consisting of a locus of suction and one of blowing - was imposed using velocity outlet condition on the cylinder. The parameters of this control were optimised to minimise total drag at $Re = 40$ and $Re = 120$. To impose autogenous control, a constraint that the average pressure of the suction locus is greater than or equal to that of the blowing locus. Steady-state and unsteady simulations were performed.

The optimised autogenous control was able to successfully reduce drag while maintaining the pressure gradient needed to be self-generating at both Reynolds numbers. The optimal control arrangements featured suction on the front half and blowing on the leeward half. This arrangement results in the pressure being reduced on the front half and a modest increase on the rear, resulting in a reduced pressure drag. This comes at the cost of slightly higher skin friction drag, however. Total drag was reduced by up to 4.3% at $Re = 120$ using dual-loci control with a positive pressure gradient from the suction to blowing locations, and 5.45% for $Re = 40$.

Overall the results are encouraging for the development and use of autogenous suction control in real flows. The numerical results showed improvement over the uncontrolled case, and this increased with Reynolds number. On the other hand, more work is needed. The pressure constraint is idealised - not accounting for any losses in internal ducting. The investigation successfully extended the findings of Atik and van Dommelen to show that autogenous suction control is viable for bluff body flows also.

Summary. Micro-nano-robotic swimmers have a promising potential for future biomedical tasks such as targeted drug delivery and minimally-invasive diagnosis. An efficient method for controlled actuation of such nano-swimmers is applying a time-varying external magnetic field. While rigid helical nano-structures that move in corkscrew motion under a rotating magnetic field are hard to fabricate, we recently found that two nano-rods (magnetized nickel and a rhodium tail) connected by a soft polysaccharide hinge may also exhibit helical motion under a rotating magnetic field. We also discovered interesting mode transitions depending on the actuation frequency. In low frequency regime, the nano-swimmer tumbles in plane, while larger frequencies lead to out-of-plane helical motion, optimum of peak speed, followed by step-out loss of synchronization. In this work, we analyzed these effects by formulating the spatial dynamics of 3D rotating nano-swimmer compose of two links connected by a passive rotary joint with a torsion spring representing the flexible hinge. Assuming quasi-steady Stokes drag acting on the links, numerical simulations and analysis of the nano-swimmer's nonlinear dynamics reveal the stability transitions of possible synchronized solution, as well as bifurcations with respect to actuation frequency. The results highlight the importance of simple low-dimensional models of nonlinear dynamics and their utility in predicting and optimizing motion of magnetically-actuated nano-swimmers.

Introduction

Inspired by the motion of bacteria and other microorganisms, researchers have developed artificial helix-shaped micro- and nano-structures that can perform corkscrew motion and helical-path swimming upon a suitable stimulation with external energy sources. These small-scale helical devices attract much interest because of their great potential for disease diagnosis, minimally invasive surgery, telemetry, targeted therapies, or plasmonic-based nanorheology. The most common strategy consists of actuating magnetically responsive structures comprising helical components that revolve around their long axis when they are actuated using rotating magnetic fields resulting in corkscrew locomotion.

In this work (recent paper [1]), we show that incorporating a complex helical body shape in swimmers' architectures is not necessary to enable helical swimming. This is an advantageous feature of the presented hinged swimmers, especially in terms of fabrication, adjusting the length of hinges and rods becomes easier. In this contribution, we show for the first time that a highly integrated multifunctional nonhelical nano-swimmer is capable of helical klinotactic swimming when stimulated by purely rotating magnetic fields.

Modeling

Figure 1: (A) Simplified Theoretical model; (B) A SEM image of the finalized structure of nano-swimmer

The nano-swimmer consists of two cylindrical rigid metallic links (nickel and rhodium) joined by a soft polymeric hinge (Figure 1B). The ferromagnetic nickel link serves as the magnetically responsive motile head component. The non-ferromagnetic rhodium segment acts as a tail, while the polymeric hinge functions as a flexible joint to promote the swimmer's motion by deformation. In the experiments [1], we observed different motion phases, as shown in previous helical nanobots' papers [2,3], at low frequency tumbling, low-speed movements, at a higher frequency, moving forward in a helical path, in further frequency increase we obtain asynchronous swimming.

In order to systematically understand the theoretical mechanism of the spatial dynamic motion of the swimmers, a theoretical model was developed. The theoretical model of the two-link nano-swimmer comprises two rigid slender cylinders connected by a point-size revolute joint, with a relative angle δ of rotation about a body-fixed axis perpendicular to the link's longitudinal direction (Figure 1 A). The flexibility of the revolute joint represented by a linear torsion spring with stiffness k , the torque at the joint is given by $\tau_k = -k\delta$. The head link made of ferromagnetic material, its magnetization vector \mathbf{m} directed along the link's longitudinal axis $\hat{\mathbf{t}}_1$. While being actuated by a rotating magnetic field. The external magnetic field $\mathbf{B}(t)$ is rotating in the Y-Z plane by $\mathbf{B}(t) = [0 \quad \sin(\omega t) \quad \cos(\omega t)]b$, where b is the magnetic field's intensity and ω is its rotational frequency.

Assuming a spatially uniform magnetic field, it induces a pure torque $\boldsymbol{\tau}^m$ on the magnetized head link, which depends on its orientation and the time-varying field $\mathbf{B}(t)$ as $\boldsymbol{\tau}^m = \mathbf{m} \times \mathbf{B}$. The nano-swimmer submerged in a viscous fluid. The Stokes drag forces and torques acting on each of the two links $\mathbf{f}_i, \boldsymbol{\tau}_i$ depend linearly on their angular velocity vectors $\mathbf{v}_i, \boldsymbol{\Omega}_i$. Neglecting hydrodynamic interactions between the links implies linear drag resistance relations.

The vector of generalized coordinates describing the swimmer's spatial pose is $\mathbf{q}=(x, y, z, \phi, \theta, \psi, \delta)^T$, where (x, y, z) denote the position of the head link's center, (ϕ, θ, ψ) are Euler angles describing its spatial orientation (ZXZ convention), and δ is the joint angle. Formulating the links' linear and angular velocities $\mathbf{v}_i, \boldsymbol{\Omega}_i$ in terms of orientation and generalized velocities, \mathbf{q} and $\dot{\mathbf{q}}$. Static equilibrium balance of forces and torques on the two links, including viscous drag terms

$\begin{pmatrix} \mathbf{f}_i \\ \boldsymbol{\tau}_i \end{pmatrix} = -\begin{pmatrix} \boldsymbol{\xi}_i & \mathbf{B}_i \\ \mathbf{B}_i^T & \boldsymbol{\kappa}_i \end{pmatrix} \begin{pmatrix} \mathbf{v}_i \\ \boldsymbol{\Omega}_i \end{pmatrix}$, where $\boldsymbol{\xi}_i, \mathbf{B}_i, \boldsymbol{\kappa}_i$ are the translational, rotational and coupling viscous resistance tensor as notated in [2], magnetic torque $\boldsymbol{\tau}^m$ and elastic joint torque $\boldsymbol{\tau}_k$, leads to a system of first-order nonlinearly coupled ordinary differential equations of the form $\dot{\mathbf{q}}=\mathbf{g}(\mathbf{q}, t)$.

Results

This system is integrated numerically using MATLAB's ODE15s function, under initial conditions $\mathbf{q}(0) = \mathbf{0}$ of straightened links aligned with X-axis. The swimmer's motion is extracted from solutions of $\mathbf{q}(t)$ after convergence to steady-state synchronized periodic motion, whenever it exists. Beyond the step-out frequency, such synchronized motion no longer exists, and we observe quasi-periodic oscillations.

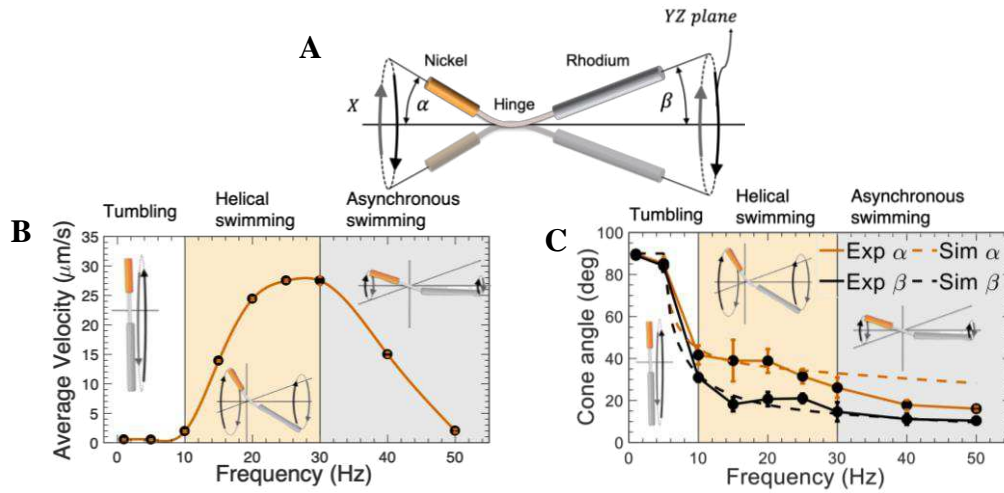

Figure 2: (A) schematic diagram of nano-swimmer illustrating precession angles and XYZ coordinate. (B) Simulation's values of the average speed of a flexible hinged nano-swimmer as a function of rotating magnetic frequency. (C) Mean precession cone angles α and β as a function of the external rotating magnetic field frequency in the experiment.

In order to study the locomotion behavior of nano-swimmers, we define the following parameters shown in Figure 2A. YZ plane corresponds to the plane of the magnetic field rotation. α is the maximum angle between the magnetic head and the X-axis, and β is the maximum angle between the tail link and the X-axis. For the analysis of nano-swimmers' locomotion characteristics, magnetic fields of 15 mT and rotational frequencies of up to 50 Hz with steps of 5 Hz investigated. At low frequency below 10 Hz, the nano-swimmer's movement speed was relatively low at around 0.5 $\mu\text{m/s}$. The nano-swimmer was bent a little and rotated in YZ plane. From 10 Hz to 30 Hz, it started to move forward in a helical path. The speed increased almost linearly up to 27.49 $\mu\text{m/s}$ in the frequency region of 10 – 25 Hz. At the frequency range of 25 – 30 Hz, the speed curve shows an inflection point corresponding to a maximum speed of around 28 $\mu\text{m/s}$. A further increase in the frequency results in a decrease in the speed towards zero.

We classify the precession behavior into three different motion phases: tumbling, helical and asynchronous swimming, based on the speed and precession angles of the swimmer, as shown in Figures 2B and 2C. The transformation of the nano-swimmer's locomotion from tumbling to helical motion is supported by the fact that the precession angle α and β dramatically decrease as the rotational magnetic frequency increases. The simulation results in [1] were in good agreement with the experimental results.

The different dynamic behavior by in-plane tumbling or spatial helical klinotactic swimming can be switched by changing the magnetic field frequency and strength. The effects of the magnetic field strength, the Ni head length, and the hinge length on locomotion behavior were investigated by numerical simulation and experiments in [1], were in good fit. We will also present new analytical results of the system's periodic solutions, their existence and stability conditions, for specific limit cases.

Stochastic resonance in a parametrically perturbed aeroelastic system

Varun H. S.^{*}, M. S. Aswathy^{*} and Sunetra Sarkar^{*}

^{*}Department of Aerospace Engineering, Indian Institute of Technology Madras, Chennai, India

Summary. In this work, we investigate the effect of parametric noise on a classical two degree-of-freedom pitch-plunge aeroelastic system and study the manifestation of stochastic resonance in the same. The non-dimensional form of the governing equations are studied, considering nonlinear soft-springs. The reduced velocity of the flow is modelled as a stochastically varying parameter by the Ornstein-Uhlenbeck (OU) process. This parametric noise significantly changes the qualitative dynamics of the system. One such new qualitative dynamics that we observe is noise induced intermittency, where the system hops between two attractors— $\bar{0}$ fixed point and a stable limit cycle oscillation (LCO). Next, we fix the mean reduced velocity near the onset of bifurcation and examine effect of noise intensity. We see that the signal to noise ratio (SNR) of the system responses reaches a maxima for an optimum value of the noise intensity. This characteristic feature in the aeroelastic system perturbed by parametric noise indicates the phenomenon of stochastic resonance.

Introduction

The response of an elastic structure in a fluid flow is a very important research area as the applications range from aeroelastic system design to design of tall buildings, bridges [1]. The design of these structures requires careful consideration as there is interplay between three kinds of forces — inertial, elastic and aerodynamic forces. The interaction between the three forces can cause the structure to exhibit LCOs, which is undesirable as it can cause fatigue failure in the structure [2]. These self-excited LCOs of the structure is termed as the flutter phenomena. Recently, a lot of importance is being given to the role played by parametric noise in such engineering systems [3, 4]. Noise is known to bring drastic qualitative changes in the dynamical behaviour of such systems. One important feature in physical and biological systems subjected to noise is the phenomenon of stochastic resonance [9, 10], which manifests due to a change in noise intensity. It is known that such systems attain a maximum SNR at an optimum noise intensity. Inspired from these works, we make an attempt to study the effect of parametric noise and the role played by the noise intensity on a classical pitch-plunge aeroelastic system.

Methodology

The aeroelastic system is modelled as an airfoil undergoing motion in the pitch and plunge degrees-of-freedom under a steady, uniform incoming flow and is based on the model by Lee *et al* [6, 7]. The non-dimensional governing equations of motion are given in Equation 1.

$$\begin{aligned} \epsilon'' + x_\alpha \alpha'' + 2\zeta_\epsilon \left(\frac{\bar{\omega}}{U}\right) \epsilon' + \left(\frac{\bar{\omega}}{U}\right)^2 (\epsilon + \beta_\epsilon \epsilon^3) &= -\left(\frac{1}{\pi\mu}\right) C_L(\tau) \\ \left(\frac{x_\alpha}{r_\alpha^2}\right) \epsilon'' + \alpha'' + 2\left(\frac{\zeta_\alpha}{U}\right) \alpha' + \left(\frac{1}{U^2}\right)^2 (\alpha + \beta_\alpha \alpha^3) &= \left(\frac{2}{\pi\mu r_\alpha^2}\right) C_M(\tau) \end{aligned} \quad (1)$$

where $x_\alpha b$ is the distance between the elastic axis and the centre of mass of the airfoil, $r_\alpha b$ is the radius of gyration of the airfoil, b is the semi-chord length of the airfoil. ' denotes differentiation with respect to non-dimensional time, ϵ is the non-dimensional plunge of the elastic axis, α is the pitch of the elastic axis, U is the reduced velocity, $\bar{\omega}$ is the ratio of uncoupled natural frequencies in the plunge to the pitch mode, μ is the mass ratio, β_α and β_ϵ denote the coefficients of the cubic term of stiffness in the pitch and plunge modes respectively, ζ_α and ζ_ϵ are the damping ratios in the pitch and plunge modes respectively. C_L and C_M are the lift and moment coefficients respectively, which are derived based on the Wagner function formulation [5]. The springs are assumed to be soft springs (β_α is $-ve$).

Noise model

The reduced velocity U in Equation 1 is stochastically modelled as an OU process, which is generated by the Stochastic Differential Equation (SDE) given in Equation 2

$$dU = \lambda(U_m - U) dt + \sigma dW \quad (2)$$

where U_m is the mean reduced velocity, λ is the inverse of the correlation time, σ is the noise intensity — parameters of the OU process, W represents the standard brownian motion. The generated process has a correlation $R_{UU}(\Delta\tau) = \exp(-\lambda\Delta\tau)$ with variance $\sigma^2/(2\lambda)$. The entire system when cast in state space form looks like Equation 3

$$\begin{aligned} d\vec{X} &= \mathbf{f}(\vec{X}, U, \tau) d\tau \\ dU &= \lambda(U_m - U) d\tau + \sigma dW \end{aligned} \quad (3)$$

where \vec{X} consists of the system and auxillary variables (see [6, 7]). The Equations in 3 are interpreted as an Itô SDE and are integrated by using the Euler-Maruyama method [8, 9].

Results and Discussions

Firstly, the bifurcation behaviour of the deterministic system is studied by varying reduced velocity (U). The system undergoes a sub-critical Hopf bifurcation (flutter point, $U = 6.29$) beyond which it gets attracted to a stable LCO. The unstable LCO takes a turn and becomes the stable LCO branch (turning point, $U = 5.93$). Now we investigate how these responses get altered in the presence of parametric noise. Figure 1 (a) and (b) show time histories of $U(\tau)$, $\alpha(\tau)$ respectively for $\sigma = 0.37$ and Figure 1 (c) and (d) shows the same for $\sigma = 0.27$. For $U_m = 6.25$ the system starts to display hopping dynamics (Figure 1 (b) and (d)), wherein it intermittently switches between the $\bar{0}$ fixed point and the LCO. This effect is solely due to the presence of parametric noise in the system and is dubbed as noise induced intermittency in the literature [3, 11]. Next, we fix $U_m = 6.25$ and vary the noise intensity σ . As σ is increased, the SNR value of

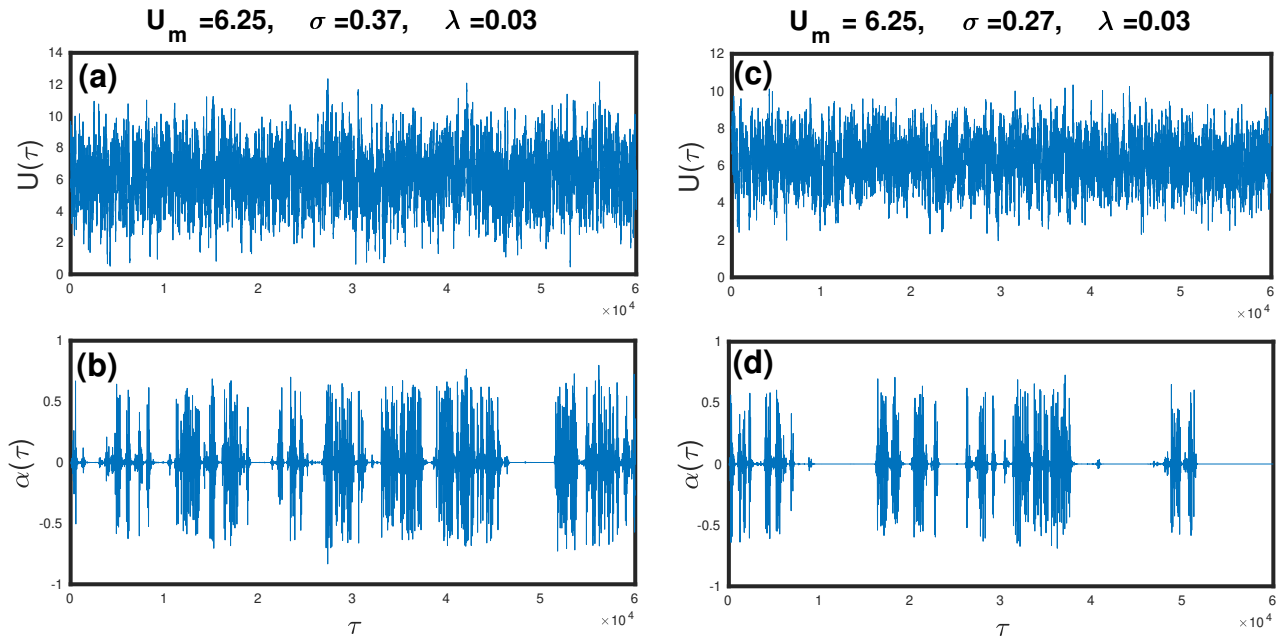

Figure 1: Time histories for $\alpha(\tau)$ and $U(\tau)$. (a) and (b): $\sigma = 0.37$, (c) and (d): $\sigma = 0.27$

the response increases as the system starts spending greater amounts of time in the LCO attractor. Further increase in σ leads to a decrease in the value of SNR due to frequent switching between the attractors and the dynamics gets dictated by the noise. This is further confirmed by plotting the power spectra and mean residence times of the responses. This phenomenon where the SNR reaches a maxima for an optimum value of intensity of the noise is termed as stochastic resonance [9, 10] and is being reported in the aeroelastic system for the first time.

Conclusions

We have investigated the effects of parametric noise on the considered aeroelastic system. The introduction of parametric noise in U , modelled as an OU process brings about drastic changes in the system dynamics. The system starts hopping between the two attractors and displays a new state of intermittent oscillations. The phenomenon of stochastic resonance is observed when the noise intensity σ is varied. These changes in the system dynamics and the manifestation of stochastic resonance brought on due to the parametric noise presents new challenges during design and use of aeroelastic systems.

Influence of friction damping on frequency lock-in in cyclic structure

Miroslav Byrtus* and Štěpán Dyk *

*Department of Mechanics, University of West Bohemia, Pilsen, Czech Republic

Summary. The paper deals with modelling and investigation of lock-in phenomena in bladed cyclic structure which is further influenced by friction damping couplings. The investigation is focused on how the friction can affect the unstable behaviour during frequency lock-in regimes.

Introduction

The fluid-structure interaction (FSI) phenomenon arises when an elastic structure interacts with the embracing fluid flow. A particular case of FSI in which an alternate shedding of vortices forms the vibration of the structure is Vortex-Induced Vibration (VIV). The natural vortex shedding frequency is dependent on the velocity of the flow. The vortex shedding exerts a periodic unsteady force on the body. As the vortex shedding frequency approaches the natural frequency of the body, the two frequencies lock-in for a small range of the velocity flow [2]. Experimental characterization of lock-in is performed in [1].

The FSI plays significant role in modern aerofoils and turbine blades which are designed for higher efficiencies and higher power under higher operational temperatures and flow rates. Higher operational safety and economical demands force the designers to be more precise during phase of design with respect to operational condition laying out of the area with loss of stability [3, 4, 5]. The fluid-induced forces create an aero-elastic couplings between the aerofoils and the fluid flow. Moreover, in the case of periodical structures (gas or steam turbine blades in bladed disks) the aero-elastic coupling influences not only the single blade but the adjacent blades as well. There are many experimental works investigating experimentally the conditions of instability origin, e.g. [7, 8]. The paper deals with the modelling and dynamical analysis of a periodic blade system influenced by VIV and friction-damping in inter-blade couplings.

Cyclic structure of blade profiles influenced by VIV

Further, it is assumed the cyclic structure formed by a bladed disk has N_B blades which are created by identical airfoil profiles. Each blade is modelled by the approach presented in the previous section, i.e. it comprises two degrees of freedom (bending and torsion) and moreover these two motion are mutually coupled by so called bending-torsion coupling, see [6]. Usually, in steam turbine applications, the bladed disks are equipped with different kinds of shrouding, which causes that the system of blades mounted on a rotating disk become more stiff, especially with respect to axial flow direction.

The time-varying vortex force due to the alternating shedding of vortices in the wake causing the VIV is modeled by the van der Pol equation. The van der Pol model has two significant properties: i) self-sustained stable limit cycle oscillation and ii) the lock-in with the frequency of external forcing [2].

In Fig. 1, the blade cascade of a bladed disk is depicted in a plane view. The axis of rotational symmetry designates the axis of rotor symmetry which is the bladed disk attached to. Further, it is assumed that the flow direction is parallel with the blade chords. The shrouding is supposed to be mounted at tips of the blades and it is modelled by means of two lumped springs representing bending k_{shb} and torsional k_{sht} stiffness of each shrouding section between two adjacent blades.

Figure 1: Bladed cascade section with contact-friction shrouding coupling modelling.

The derivation of the linearized mathematical model of a bladed disk with the influence VIV is based on the methodology presented in [2]. Here, it is extended for a cyclic structure and completed by the influence of interblade damping-friction forces which are incorporated in shrouding coupling. It can be advantageously written in matrix form

$$\mathbf{M}_{BD}\ddot{\mathbf{q}}_{BD} + \mathbf{C}_{BD}\dot{\mathbf{q}}_{BD} + \mathbf{K}_{BD}\mathbf{q}_{BD} = \mathbf{f}_{BD}^E + \mathbf{f}_{BD}^{FC}, \quad (1)$$

where \mathbf{M}_{BD} , \mathbf{C}_{BD} and \mathbf{K}_{BD} are rectangular of order $3N_B$ mass, damping and stiffness matrices of a complex bladed disk model. Right hand side of (1) contains force vectors of friction coupling \mathbf{f}_{BD}^{FC} . Vector of generalized coordinates is of following form $\mathbf{q}_{BD} = [\dots, x_i, \varphi_i, q_i, \dots]^T \in \mathbb{R}^{3N_B}$, where index $i = 1, \dots, N_B$ designates the particular blade. The coordinate q_i is governed by van der Pol equation which is used for the wake dynamics.

Lock-in in the cyclic structure

The figures below show multiple frequency lock-in regarding different mode shapes of the structure (left). Real parts of the eigen values witness of the stability. It is clear that when the frequency lock-in happens, the system exhibit can unstable vibration.

Figure 2: Frequency lock-in areas and stability charts for cyclic structure created of identical air-foil profile connected by shrouding.

Conclusions

The paper presents phenomenological model of vortex-induced vibration in a cyclic structure which is formed by blade profiles. The attention is paid on the investigation of lock-in phenomenon using linearized model, which will further completed by nonlinear friction terms based on LuGre friction model. There is obvious in the presented results, that the system losses its stability during the lock-in phases. The future aim is to propose suitable damping mechanism which is based on friction dampers and complete the analyses with experimental data.

Computation of Damped Nonlinear Normal Modes Using Force Appropriation Technique and Efficient Path Following Method

Meisam Jelveh*, Seyyed Mojtaba Musavi* and Mohammad Homayoune Sadr**

*Ph.D candidate, Faculty of Aerospace Engineering, Amirkabir University of Technology, Tehran, Iran

**Associated professor, Faculty of Aerospace Engineering, Amirkabir University of Technology, Tehran, Iran

Summary. In this paper a new method is presented for computation of nonlinear normal modes (NNMs) of damped nonlinear systems. Pseudo arc length continuation of periodic solution method is well accepted as a strong tool for computation of NNMs and in many literature is used as reference solution. However, this method is limited to conservative systems and its application to damped nonlinear systems is still an open field of problem and very few attempts were made to solve that. In this article a new algorithm based on combination of force appropriation technique and a modified version of pseudo arc length continuation method called efficient path following method (EPFM) is presented to compute NNMs of damped nonlinear system. In order to investigate the capability of the algorithm, NNMs of a two D.o.Fs damped mass-spring system was calculated. It was observed that the results were in very good agreement to those obtained in other references.

Introduction

In recent decade, NNMs have attracted many researchers and comprehensive article reviews are published on the concept, theory and application of them. Nowadays, there are two common definitions for NNMs: a) periodic motion of nonlinear autonomous system b) two dimensional invariant manifold in phase space. As Renson et al. mentioned, The role played by damping in the dynamics of nonlinear structures is not yet completely uncovered and its effect on the modal interactions and invariant manifolds are largely unanswered [5].

Pseudo arc length continuation is used to compute NNMs based on periodic motion definition of them. However in general autonomous motions of damped systems are not periodic. This makes it difficult to use pseudo arc length continuation for computation of damped NNM. Kuether and Allen used combination of Force appropriation technique, complex Fourier expansion and numerical continuation to compute NNMs of damped systems [3]. They compute NNMs up to moderate levels of energy, but they couldn't capture internal resonances. Krack added an artificial damping proportional to mass matrix to the equation of motion of the system with suitable sign to cancel the effect of system's damping[2]. By adding this artificial damping, he made the solution of the system periodic and used pseudo arc length continuation for computation of NNMs. This method was limited to low damped systems and he didn't capture any modal interactions.

In this paper a novel method is presented based on force appropriation technique and EPFM. EPFM is a modified version of pseudo arc length continuation method which Sadr et al. showed that, it is up to 70% faster than similar algorithms [4]. This new method is capable to compute damped NNMs and their interactions with no limitation on energy level. In order to use this algorithm

Theory and application

One of the most important properties of NNMs is that force resonances occur near them. The governing equation of motion under harmonic force in state space is written as equation (1) in which z is vector of state variables defined as $Z^T = [\dot{x}^T \ x^T]$ where \dot{x} is velocity vector and x is vector of displacements. F_0 is the amplitude of external force, V_F is the shape of external force and ω is frequency of external force which could be defined as $\omega = \frac{2\pi}{T}$ where T is the period of the external force.

$$\dot{Z} = g(Z) + F_0 V_F \sin(\omega t) \quad (1)$$

The shooting function would be defined as follow:

$$H(Z_0, T, F_0) = Z(T) - Z_0 \quad (2)$$

So the Tylor expansion of H and correction vector of initial guess maybe found by formula of equation (4). The matrix $\frac{\partial H}{\partial Z_0}$ and $\frac{\partial H}{\partial T}$ are computed according to [4] and $\frac{\partial H}{\partial F_0}$ is computed by means of finite difference method.

$$H(Z_0, T, F_0) + \frac{\partial H}{\partial Z_0} \Delta Z_0 + \frac{\partial H}{\partial T} \Delta T + \frac{\partial H}{\partial F_0} \Delta F_0 + HOT = 0 \quad (3)$$

$$\frac{\partial H}{\partial Z_0} \Delta Z_0^k + \frac{\partial H}{\partial T} \Delta T^k + \frac{\partial H}{\partial F_0} \Delta F_0^k = -H^k \quad (4)$$

$$Z_0^{k+1} = Z_0^k + \Delta Z_0^k; T^{k+1} = T^k + \Delta T^k; F_0^{k+1} = F_0^k + \Delta F_0^k \quad (5)$$

Among all possible periodic solution of forced vibration, solutions satisfying phase quadrature lag criterion are NNMs of the nonlinear systems. It means that each harmonic in the excitation must be 90 degrees out of phase with each harmonic in the response. From energy point of view, phase quadrature lag criterion is defined as equation (6)[1].

$$\int_0^T \dot{x}^T C \dot{x} dt = \int_0^T \dot{x}^T F(t) dt \quad (6)$$

Because the periodic solution of the system is invariant wrt linear shift of time origin, a phase condition equation may be used. In pseudo arc length continuation method, to make the convergence faster, the correction vector is forced to be perpendicular to the prediction vector. So the correction vector is calculated from following set of equations in which j is the continuation index and k is the iteration index in each step of continuation. Prediction vector of each continuation step is defined as $P = [P_{Z_0j} \ P_{Tj} \ P_{Fj}]$.

$$\begin{bmatrix} \frac{\partial H}{\partial Z_0} & \frac{\partial H}{\partial T} & \frac{\partial H}{\partial F} \\ h(Z_0) & 0 & 0 \\ P_{Z_0j} & P_{Tj} & P_{Fj} \end{bmatrix} \begin{Bmatrix} \Delta Z_0^k \\ \Delta T^k \\ \Delta F^k \end{Bmatrix} = \begin{Bmatrix} -H \\ 0 \\ 0 \end{Bmatrix} \quad (7)$$

In order to implement the algorithm, forced response of the system at two near constant force amplitude are calculated using method developed by Sadr et al. and solutions satisfying energy condition defined by equation (8) are selected. ε is the acceptable tolerance. Then prediction vector is constructed using these two point. Then continuation procedure is applied as stated before.

$$E_{err} = \left| \frac{\int_0^T \dot{x}^T C \dot{x} dt - \int_0^T \dot{x}^T F(t) dt}{\text{Mechanical energy}} \right| < \varepsilon \quad (8)$$

Results

The method is applied to a two D.o.Fs Damped cubic nonlinear mass spring system and its first NNM is investigated. As stated in many references, NNMs of very lightly damped systems are similar to that of corresponding conservative systems. As seen in the results, when the damping is very low, the NNM is very close to conservative NNM. As the damping increases the modal interaction tong gets shorter and wider. It is observed that, the obtained solutions completely satisfy energy condition of equation 4.

Figure 1: (a) damped cubic nonlinear mass spring system (b) forced response of the system at constant amplitude of force (c) energy condition of the forced response

Figure 1: (a) FEP of First NNM for different values of damping (b) Detail view of first NNM (c) energy condition for obtained results

conclusion

in this paper a new method based on force appropriation technique and pseudo arc length continuation is presented for computation of damped NNMs of nonlinear system. The method applied to a two D.o.Fs system. As observed the accuracy of results was very good. The method can capture the modal interactions without any difficulties. It was seen from the results as the damping of the system increases, the FEP tongs becomes shorter and wider.

Bifurcations and stability transitions in nonlinear dynamics of a planar undulating magnetic microswimmer

Jithu Paul*, Yizhar Or* and Oleg Gendelman*

**Faculty of Mechanical Engineering, Technion–Israel Institute of Technology, Haifa, Israel*

Summary. A microswimmer, motivated from biological microorganisms or cells motion, which has two links representing a tail and a magnetized head is studied. The links are connected by a passive elastic joint and the microswimmer is actuated by an external time – periodic magnetic field. This simple system is very rich in dynamics and we identified that there exists co-existing periodic solutions – symmetric as well as asymmetric, and stability transitions with pitchfork bifurcations. There is optimum observations for the displacement and velocity of the swimmer with respect to the system parameters, may enable significantly improving the design aspects of the robotic microswimmer.

The micro swimmers are motivated by biology [1], and their dynamics is always interesting . Among the simplest and most efficient techniques for actuation of robotic microswimmers , is by applying time-varying external magnetic fields [2]. One of the important milestones in the field of magnetically actuated microswimmer is given in by Dreyfus et. al [3]. Inspired from the classical work of Purcell [4], a very simple model of two-link swimmer has been presented by Gutman et. al [5], with an external magnetic actuation on the head as shown in Fig. 1. The external magnetic field, $B(t) = [\gamma, \beta \sin(\omega t)]^T$ has an oscillating component in y direction and a constant x component, γ . The same model with paramagnetic excitation is studied in [6] with interesting observations on bistability and analogy of tilted Kapitza pendulum. We revisit the model in [5] and explore co-existence of periodic solutions as well as their bifurcations, stability transitions, and symmetry-breaking.

The system in Fig. 1 has four coordinates: body position (x,y) and two angles θ and ϕ , which represent body orientation angle and relative angle between the links, respectively. Invariance with respect to x and y enables reduction of the system into two dimensional state equations in two variables, θ and ϕ only. The stiffness of the torsional spring at the passive elastic joint is given by k. Coming to the major assumptions, the swimmer is submerged in a Newtonian fluid and it remains neutrally buoyant (no effect due to gravity). The micron size of the swimmer allows assuming low Reynolds number hydrodynamics where viscous forces dominate while inertial effects are negligible. The resistive force theory for slender bodies governs the net forces and torques acting at the links' centers due to viscous drag. In the work of Gutman et. al [5], fixed, $\gamma = 1$ and small $\beta \ll \gamma$ are assumed, and focused only on symmetric periodic solutions with mean $(\theta, \phi) = (0, 0)$.

Here, as an extension to [5], as shown in Fig. 2, we extracted other co-existing solutions, symmetric around mean $(\theta, \phi) = (\pi, 0)$, as well as asymmetric, and their stability transitions (Fig. 2(a)) and bifurcation (Fig. 2(b)). Upon varying the actuation parameters (β, γ, ω), the results are obtained by numerical analysis using the MATLAB tools ODE45 and fsolve. There are also optimum plots (for stable region) for X , net displacement in x versus β , amplitudes of excitation (Fig. 2(c)) and V , mean velocity versus ω , frequency (Fig. 2(d)), where all the parameters are in experimentally relevant region. It can be analytically studied since there exists small amplitudes for θ, ϕ for $\gamma \ll 1$. These stable optimum regions and indications towards stability transitions can improve designing a simple efficient two link robotic microswimmer, which can be used for a wide range of applications.

Fig. 1. Model system, (a) shows two link microswimmer which are connected by torsional spring and its head receives magnetic actuation. (b) shows the details of magnetic actuation

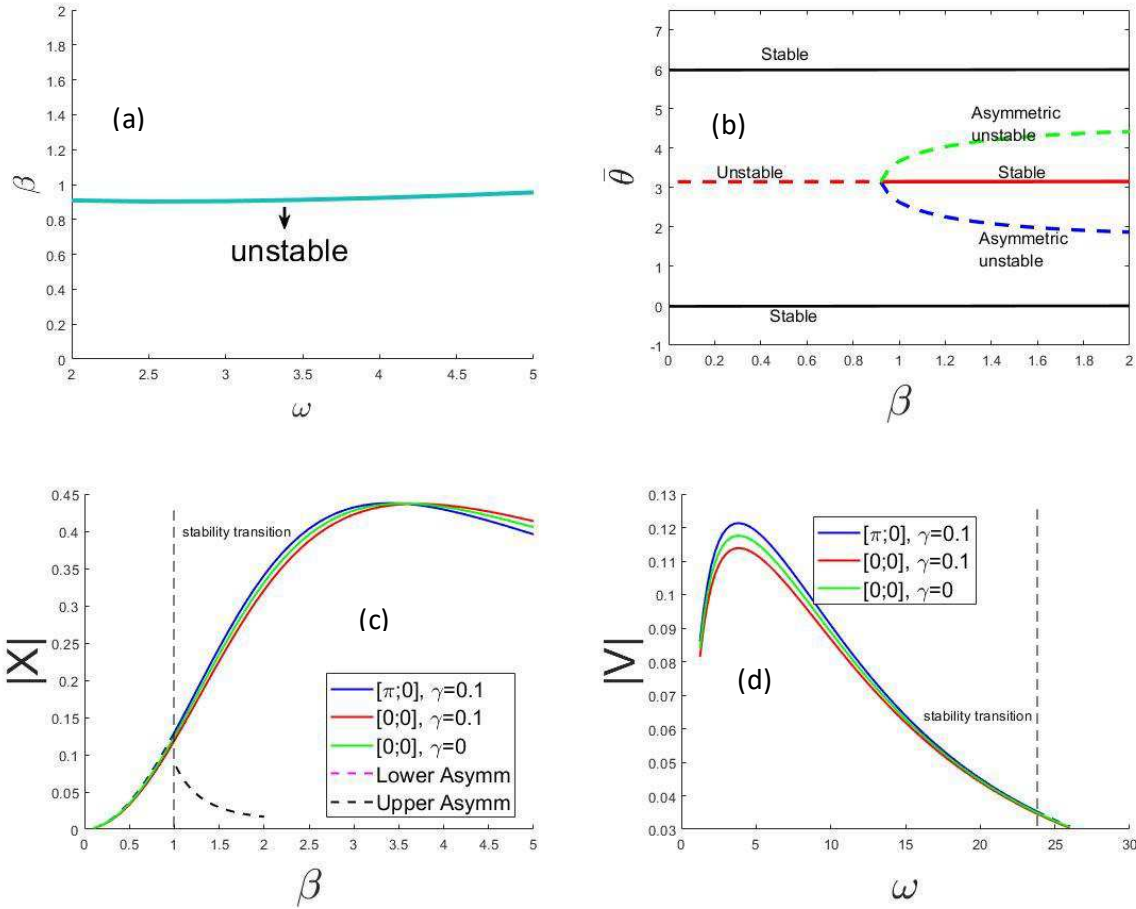

Fig. 2. (a) shows Stability transition in $\beta - \omega$ plane at $\gamma = 0.1$, (b) shows possibility of a subcritical pitchfork bifurcation at the stability transition where $\omega = 2$, $\gamma = 0.1$, (c) shows optimum displacement plot with respect to amplitude of actuation oscillations β and (d) shows the optimum velocity plot versus frequency ω .

Stability of Nonlinear Normal Modes under Stochastic Excitation

Yuri V. Mikhlin* and Gayane V. Rudnyeva*

*National Technical University “Kharkiv Polytechnic Institute”, Kharkiv, Ukraine

Summary. Two-DOF nonlinear system under white noise excitation is considered. It is assumed that the system allows from two up to four nonlinear normal modes (NNMs) with rectilinear trajectories in the system configuration space. Influence of the random excitation to the NNMs stability is analyzed by using the analytical-numerical test, which is an implication of the well-known Lyapunov stability criterion. Boundary of the stability/ instability regions is obtained in place of two parameters, namely, a connection between partial oscillators, and the excitation intensity. Stability of the NNMs under deterministic chaos excitation is also considered.

Introduction

Investigation of nonlinear normal modes (NNMs) is an important part of general analysis of dynamical systems. Different theoretical aspects of the NNMs theory and applications of the theory are presented in numerous publications, in particular, in review [1]. NNMs having rectilinear trajectories in configuration space (so-called similar nonlinear normal modes) were first found in some essential nonlinear systems by Rosenberg [2].

Numerous publications are dedicated to investigation of behavior of dynamical systems under stochastic excitation. In this regard, different theoretical and numerical procedures are developed. We cite here only few publications on the subject, namely, books [3-5]. In [6] the dynamics of aerospace vehicles and/or other structures subject to random excitation is investigated using a reduced order model in terms of its nonlinear normal modes. Evolution of NNMs is studied by the continuation algorithm and presented in the plot “energy-frequency”.

Here some numerical-analytical test [7] which is a consequence of the well-know Lyapunov criterion of stability is used to analyze a stability of NNMs in two-DOF nonlinear system under white noise excitation. We assume that the system allows from nonlinear normal modes with rectilinear trajectories in the system configuration space. We analyze also a stability of the NNMs under deterministic chaos excitation.

Principal model under consideration

The following two-DOF nonlinear system under stochastic excitation is considered:

$$\begin{cases} \ddot{x}_1 + x_1^3 + \gamma(x_1 - x_2)^3 = \varepsilon \xi_1(t), \\ \ddot{x}_2 + x_2^3 + \gamma(x_2 - x_1)^3 = \varepsilon \xi_2(t), \end{cases} \quad (1)$$

where ε is the small parameter, and the functions $\xi_1(t)$, $\xi_2(t)$ represent stochastic excitation. When $\varepsilon=0$ the system allows so-called similar NNMs in the form $x_2 = cx_1$, where c is the modal constant. We can note that the equations (1) always allow two similar NNMs, where $c_{1,2} = \pm 1$. The solution $c_1 = +1$ corresponds to the in-phase nonlinear normal mode, and the solution $c_2 = -1$ corresponds to the out-of-phase (anti-phase) one. We consider the external excitations which save the in-phase and out-of-phase NNMs but can change their stability and point of bifurcation.

Test of stability as implication of the Lyapunov stability criterion

Consider the well-known Lyapunov definition of stability which can be presented in the simplest variant as the following: the solution $y = 0$ is stable if for any positive ε there a positive δ exists such that for all $y_0 \in N_\delta(0)$ and $t \geq 0$ we have the following: $y(t) \in N_\varepsilon(t)$ where stated neighborhoods can be determined using norms in some functional space. Here the variable y has meaning of variation with respect to the solution studied for stability. Later a modulus of the function is used as the norm. One introduces a relation between the quantity ε and the initial value of the variable y ; it corresponds to a sense of the definition by Lyapunov when the initial variations must not tend to zero. Let

$$\varepsilon = \rho |y_0| \leq \rho \delta \quad (\rho = \text{const}) \quad (2)$$

We can note that a value of δ is not arbitrarily small; it corresponds to essence of the Lyapunov definition because in this definition the initial values of variations cannot tend to zero. One has from the Lyapunov stability definition that $|y(t)| \leq \rho |y(0)|$ for a case of stability.

We introduce the following test for the system under consideration [6]: Instability of the solution $y = 0$ is fixed if

$$|y(t)| \geq \rho |y(0)| \quad (0 \leq t \leq T). \quad (3)$$

In contrast to the Lyapunov definition a time of numerical calculations T is limited in the test (3). It is necessary to discuss a choice of values of ρ and T . There is some arbitrariness in a choice of the value ρ . In fact, in the instability region the variations leave the solution ε -neighborhood under increase of t for any choice of the parameter ρ . We can choose, for example, $\rho = 10$. One discusses now a choice of the constant T . Note that all concrete calculations are realized by using the standard Runge-Kutta procedure. These calculations are made at points on some chosen mesh of

the system parameter space. Calculations are conducted as long as boundaries of stability/instability regions in a chosen scale on the system parameter space are variable. This is a principal criterion for the choice of the calculation time T [7]. Taking into account a specific character of the stability problem under stochastic excitation, we are introduced some important modification to the proposed test (3). Namely, we can observe that in the last case some variations can leave the ε -neighborhood and then return back to one. Thus, we will allow that some small part of variations (not more than 10 percent) is out of the neighborhood during each fixed interval of time.

Stability of the similar NNMs: results of simulation

To investigate the stability/instability of the in-phase and out-of-phase nonlinear normal modes, we pass to the systems in variations by means of change of variables in (1), namely:

for the out-of-phase NNM $x_1 = (u - v) / \sqrt{2}, x_2 = (u + v) / \sqrt{2}, u = 0 + \Delta u, v = v_0 + \Delta v, \xi_2 = -\xi_1;$

for the in-phase NNM $x_1 = (u - v) / \sqrt{2}, x_2 = (u + v) / \sqrt{2}, u = u_0 + \Delta u, v = 0 + \Delta v, \xi_2 = \xi_1.$

Some results of numerical simulation for the presented NNM stability problem by using the stability criterion (3) are presented. Figs. 1 and 2 demonstrate boundaries of stability/instability of the out-of-phase nonlinear normal mode for different values of parameters. Figs. 3 and 4 show a behavior in time of the out-of-phase NNM simulated for different values of the connection parameter: $\gamma=0.24$ and $\gamma=0.26$, correspondingly. Fig.5 shows boundaries of the stability/instability regions in the place (γ, ε) . Note that such results are obtained for four different kinds of stochastic excitation.

Figure 1

Figure 3

Figure 4

Figure 5

Stability of NNMs under excitation in the form of determined chaos

Determined chaotic excitation can be obtained, in particular, by solution of the non-autonomous Duffing equation for some values of the equation parameters. Numerical simulation shows that excitation in the form of the determined chaos does not influence to stability of the NNMs in the system under consideration.

Conclusions

It is shown that the analytical-numerical test, which is an implication of the Lyapunov stability criterion, can be successfully used in analysis of stability of NNMs in two-DOF system under white noise excitation. Boundary of the stability/instability regions is obtained in place of the system parameters, including parameter of the excitation intensity. It is shown also that the deterministic chaos excitation does not affect to the NNMs stability.

SIR model for rumor propagation

Cristiane M. Batistela*, Manuel A. M. Cabrera*, Antonio C. B. Godoi* and José R. C. Piqueira*

* *Control Engineering Department, São Paulo University, São Paulo, Brazil*

Summary. Similarities exist between rumor propagation and disease spreading. In analogy with the SIR (Susceptible-Infected-Removed) epidemiological model, the ISS (Ignorant-Spreader-Stifler) rumor model has been developed. Here, the SIR model was modified with the new compartment, originating the ISSV (Ignorant-Spreader-Stifler-Verifier) rumor model. In this work, the model is presented and how its parameters are related to network characteristics is explained. This paper presents a system of differential equations that describes the spreading of a rumor in a new model, with a novel compartment, the verifier. By using concepts from Dynamical Systems Theory, equilibrium point is calculated, the stability and bifurcation conditions are derived. According parameters and initial conditions, the model is validated with numerical experiments. The relations among the model parameters in the several bifurcation conditions allow a rumor propagation design minimizing risks.

Introduction

With the rapid development of the Internet, the way to acquire information changed. There are a lot of platforms for this, as a typical example, social networks and they have been widely recognized. The media commonly releases their latest information through social networks, consequently can bring efficiency to daily life and information exchange, but it also results in gradual prevalence of online rumor.

Rumor, as a part of everyone is daily life, has often been defined as a type of social phenomenon with which some unconfirmed elaboration or annotation of the public interested events or issues spread on a large scale within a relatively short period of time through various channels, whether it is true or false [3].

People disseminate rumors as a mean of increasing awareness, orienting society, slandering others and so on. The spread of rumors can shape the public opinion and impact financial markets and change population behavior [10].

The research on rumor propagation models started with development the stochastic rumor propagation proposed by Daley-Kendall, which divided people into classes: ignorant, spreaders and stiflers, based on the infectious disease research method [1]. Maki-Thompson believed that rumors were disseminated through the two-way contact between the disseminators and other people in the crowd based on Markov chain [11]. Zanette first studied the dynamic behavior of rumor propagation in small world networks, and similarly to disease models he obtained the spreading threshold [17].

Based on the fact that social behavior and biological diseases are a result of interaction between individuals, many researchers have studied the dynamics of social systems by applying epidemiological models.

The epidemiological model proposed by Kermack and McKendrick, the SIR (Susceptible-Infected-Removed) compartmental model [7, 8, 9], has been used in several areas and modifications of this work allowed Daley and Kendall (DK) to propose a rumor spread model [1], the ISS (Ignorant-Spreader-Stifler) model which shares common characteristics with epidemic model [2], being an important mark in rumor propagation.

The equations that model are similar with the ignorant and spreading populations from ISS model being analogous to susceptible and infected populations of the SIR model, respectively. The main difference between the models, is that, in ISS, the stifler population plays a different role from the removed population because they do not propagate the rumor and remains in a constant state. In the other way, in SIR models, the removed individuals can be transformed into susceptible ones.

Based on the DK model, in which the participants were divided into three groups: one group of people who never heard the rumor (ignorant), one knowing and spreading the rumor (spreader), and one knowing the rumor but never spreading it (stifler). Afterwards, the rumor spreading model was refined with consideration of the forgetting mechanism [14] and by incorporating the effects of remembering mechanism in complex networks [18].

Various mathematical models for the propagation of a rumour within a population have been developed: the rumor spreading process with denial and skepticism [5], rumor spreading model with skepticism mechanism in social networks, epidemiological approach to model viral meme propagation [16], deterministic models for rumor transmission with constant and variable rumor in an age-independent population, models considering limited information exchange, which two types of rumors spread simultaneously among the crowd, stochastic rumor propagation model [6]. Recently, based on the classical SIR rumor propagation model, a new Susceptible-Infected-Hibernator-Removed model by adding a direct link from ignorants to stiflers and a new group hibernator [18].

Here, assuming an ISS model as a generalization of DK model and with analogies with the SIR model, the rumor spreading is studied, considering a new compartment, the verifier, ISSV (Ignorant-Spreader-Stifler-Verifier). The different dynamical propagation behaviors are possible, depending on how the nodes are connected. Furthermore, the model is studied under the assumption of homogeneous distribution of social network that gives plausible qualitative results.

First, the differential equations representing the ISSV model are presented, followed by the stability analysis of the equilibrium points and the possibility of the bifurcation. Numerical experiments are performed to validate the analytical results. Finally, we present our conclusions and discuss some implications of the results.

ISSV Model: hypothesis and equations

The model proposed here is based on the original SIR model with analogies in epidemiologic models. A quantitative version of this model associated with compartmental model was analysed by Moreno et al. [13].

By using concepts from Dynamics Systems Theory and assuming the ISS (Ignorant-Spreader-Stifler) models as generalization of DK model, the rumor spreading representation was studied, the several asymptotic behaviors are discussed and the possible bifurcations are shown by Piqueira [15] with the total population (T), divided into three groups: ignorants (I), spreaders (S) and stiflers (R).

Here, the proposed models have a new compartment and each of the elements of the network can be one of the four different states: the first class are ignorants, and represents those individuals that never heard the rumor and are susceptible to be informed (I); the second group contains the individuals that are spreading the rumor, the spreaders (S); the third compartment, the verifier (V), can verify the rumor and finally, stiflers are those who know the rumor but that are no longer spreading it (R). This model is shown in Figure 1.

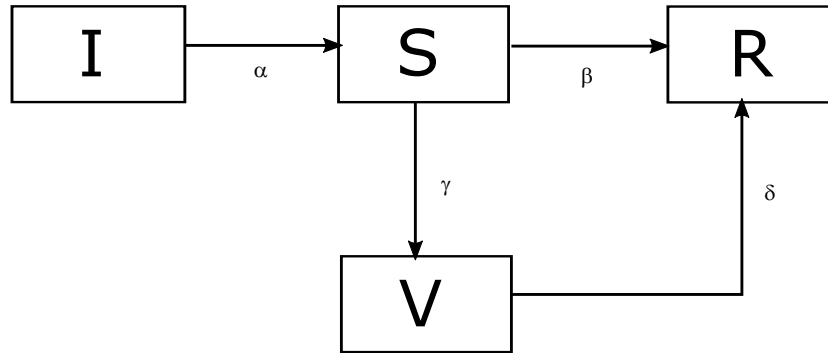

Figure 1: ISSV model.

The dynamical behavior of the spreading process depends on the way the individuals encounter each other. When a spreader meets an ignorant, the latter becomes a new spreader with probability α . Similar to the SIR model, the decay of the spreading process could be either when a spreader meets a stifler and contacts are supposed to have a probability equal to β or became verifier with the rate coefficient γ ; in addition, verifier transform into stiflers with the rate coefficient δ . The dynamic equation for the populations I , S , V and R are:

$$\begin{cases} \dot{I} &= -\alpha IS; \\ \dot{S} &= \alpha IS - \gamma S - \beta S; \\ \dot{V} &= \gamma S - \delta V; \\ \dot{R} &= \beta S + \delta V. \end{cases} \quad (1)$$

The initial conditions are assumed to be $S(0) \geq 0$, $I(0) \geq 0$, $V(0) \geq 0$ and $R(0) \geq 0$. It is noticed that, for the model represented by (1), the total population $T = I + S + V + R$ remains constant and one of the equations can be expressed by a linear combination of the other three.

Bifurcation of the equilibrium states

In order to explore the influence of the verifiers during the rumor propagation, the dynamic system can be studied considering the equilibrium point of the model represented by (1).

The local stability of these points is analysed using Hartman-Grobman Theorem and the Jacobian derivative is calculated for each equilibrium points and the eigenvalues is calculated.

Examining the dynamical equation for the model, it is possible to determine that there is no spreader equilibrium point, i.e., equilibrium with spreaders nodes. This equilibrium states, spreader-free, corresponding to the absence the spreaders ($S = 0$) and the models in study presented one equilibrium condition, $P = (I, S, V, R) = (I^*, 0, 0, R^*)$.

To analyze the stability of this point, the general Jacobian (J), for the model (1), is constructed as:

$$J = \begin{bmatrix} -\alpha S & -\alpha I & 0 & 0 \\ \alpha S & \alpha I - \gamma - \beta & 0 & 0 \\ 0 & \gamma & -\delta & 0 \\ 0 & \beta & \delta & 0 \end{bmatrix}.$$

The Jacobian calculated in the equilibrium point P is reduced to:

$$J_P = \begin{bmatrix} 0 & -\alpha I & 0 & 0 \\ 0 & \alpha I - \gamma - \beta & 0 & 0 \\ 0 & \gamma & -\delta & 0 \\ 0 & \beta & \delta & 0 \end{bmatrix}.$$

Using MATLAB R2013a [12], the eigenvalues can be calculated: $\lambda_1 = 0$, $\lambda_2 = \alpha I - \gamma - \beta$, $\lambda_3 = -\delta$ and $\lambda_4 = 0$.

Considering the eigenvalues in J_P , for $\lambda_1 = 0$ and $\lambda_4 = 0$, one zero eigenvalue corresponds to the fact that the order of the dynamical system is three and other represent the central manifold [4] represented by the degenerated equilibrium. The eigenvalue $\lambda_2 = \alpha I - \gamma - \beta$, suggesting the detailed analyses because of the bifurcation possibility.

Examining the eigenvalue $\lambda_2 = \alpha I - \gamma - \beta$ and considering $T = I + R$ for the equilibrium point, the λ_2 can be rewritten as $\lambda_2 = \alpha T - \gamma - \beta$.

Analysing the signal of the second eigenvalue, the equilibrium point is asymptotically stable if $T < (\gamma + \beta)/\alpha$ and if $T > (\gamma + \beta)/\alpha$, the equilibrium point is unstable.

Numerical Experiments

To quantitative analyze the influence of verification nodes on the rumor network, numerical simulations of the model are performed considering the unitary total population ($T = I + S + V + R = 1$). Thus, the instantaneous values of the populations I , S , V , and R are expressed in percentage.

By using the Simulink tool from MATLAB R2013a [12], model simulations were performed to confirm the analytical results, showing the possible behaviors of the dynamical system when verifier compartments are present. The chosen parameters must be corrected to reproduce the results for different population sizes.

In order to simulate the stability of equilibrium point, the parameters must respect the condition $T < (\gamma + \beta)/\alpha$. Then, for $\alpha = 0.5$, β is chosen equal 0.3, $\gamma = 0.25$ and $\delta = 0.5$.

Starting with a condition with at least one percent spreader, the asymptotically stable equilibrium, P , is reachable and the rumor is not propagated. Figure 2 shows the time evolution of the model starting with $I_0 = 0.99$ and $S_0 = 0.01$. The spreaders become stiflers as well as a small percentage of ignorant. The resulting time evolution obtained and ending at the spreader-free equilibrium P .

Figure 2: Simulating near stable equilibrium ($\alpha = 0.5$; $\beta = 0.3$; $\gamma = 0.25$; $\delta = 0.5$).

Remaining with the same parameter values and changing the initial conditions, the Figure 3 shows the spreader-free equilibrium P being reached for the initial conditions $I_0 = 0.89$, $S_0 = 0.10$ and $V_0 = 0.01$. In this situation, the spreaders and verifiers become stiflers and some ignorants came to know the rumors.

Satisfying the condition $T < (\gamma + \beta)/\alpha$, the rumor is contained and decreasing the parameter α or increasing the parameter γ or β , rumor propagation dynamics are not changed.

In order to study the dynamics of the rumor propagation by varying the parameters, the initial condition is considered $I_0 = 0.99$ and $S_0 = 0.01$ and the β value was changed to 0.03. Then, for $\alpha = 0.5$, γ is chosen equal 0.25 and $\delta = 0.5$. Even decreasing the transformation rate of spreaders into stifflers, the rumor propagation occurred by the increase of the stifflers. Figure 4 shows part of the ignorants become stifflers and in this situation $T > (\gamma + \beta)/\alpha$.

Figure 3: Simulating near stable equilibrium changing the initial percentage of spreader.

 Figure 4: Changing β ($\alpha = 0.5$; $\beta = 0.03$; $\gamma = 0.25$; $\delta = 0.5$).

Changing the parameter α and considering the initial condition $I_0 = 0.98$, $S_0 = 0.01$ and $V_0 = 0.01$, Figure 5 shows the unstability of the equilibrium point P . The parameters are: $\alpha = 5$; $\beta = 0.03$; $\gamma = 0.25$; $\delta = 0.5$ and in this situation all the population become stiflers.

Considering $\delta = 0.05$ and the initial condition $I = 0.98$, $S = 0.01$ and $V = 0.01$, Figure 6 shows the influence of this parameter in the dynamics of the rumor propagation. The others parameters are: $\alpha = 5$; $\beta = 0.03$; $\gamma = 0.25$; $\delta = 0.05$ and in this situation all the population become stiflers. With the decreasing of this rate, the time evolution is changed but the qualitative behavior is the same.

Conclusions

The analysis of the ISSV model shows that, for a given total population, T , the main control parameters are probabilities α , β and γ measuring the efficient communication ignorant-spreader (α), spreader-stifler (β) and spreader-verifier (γ), respectively.

Perturbing near the equilibrium point with at least one spreader, for any combination the parameters, satisfying the condition $T > (\gamma + \beta)/\alpha$, the steady state is composed of a few ignorants, a lot of stiflers, and no spreaders, meaning that almost all the population heard the rumor.

Under the same initial conditions but satisfying the condition $T < (\gamma + \beta)/\alpha$, the equilibrium point is not changed meaning that the rumor is not propagated.

Figure 5: Changing α ($\alpha = 5$; $\beta = 0.03$; $\gamma = 0.25$; $\delta = 0.5$).

Figure 6: Changing α ($\alpha = 5$; $\beta = 0.03$; $\gamma = 0.25$; $\delta = 0.05$).

Changing the δ parameter, which transform verifier into stifler, does not change the qualitative behavior associated with the spread of rumors.

Dynamics and minimalistic control of a flexible structure containing bi-stable elements

Yamit Geron*, Sefi Givli*, Yizhar Or *

*Faculty of Mechanical Engineering, Technion - Israel Institute of Technology, Haifa, Israel.

Summary. This study aims to design and analyze a system of mechanically-coupled bistable elements such that transitions between states (different equilibrium branches) take place in a desirable order by controlling a single degree of freedom. Such systems may be useful in a range of applications, e.g. soft robots or foldable structures, where a complex sequence of movements or configurations needs be achieved by minimal control. The theoretical part involves analytical and numerical investigation of the non-linear dynamic response of an array of bistable elements connected in series. The model accounts for the non-linear behavior of the bistable elements assuming linear damping and negligible inertia where the only control input is the displacement at the end of the chain (u_0). The quasi-static and dynamic response of a chain of two elements is studied. Focus is put on the multiplicity of equilibrium states, stability, and conditions for transition between stable states. Special attention is given to identifying critical rates that separate between different transition sequences, and how they are influenced by the properties of the bistable elements and the variability between them. We show, and demonstrate experimentally, that by clever design of the bistable elements, one can robustly control the order of transitions between states by merely varying the rate (speed) of the applied overall extension.

Introduction

A bi-stable mechanical element has two stable equilibrium states for the same external load and allows transition between states. The behavior of a chain of bistable elements has been studied extensively in various contexts. For example, in [1] the quasi-static behavior and stability of equilibrium configurations of a chain of identical bistable elements was investigated. Recently, robotic systems with bistable elements have been proposed for achieving controlled transitions using minimalistic control [2]. In another recent work [3], such concept was demonstrated on a system of identical hyper-elastic thin-walled balloons connected in series, where a desirable state is attained by a sequence of quasi-static inflations and deflations using a single flow control input.

Figure 1: (a). A 3D-printed bistable element made of ABS material. (b). The measured force–elongation relation of the 3D-printed bistable element.

Results

The dynamic equations of a system comprising two bistable elements connected in series were formulated by assuming linear damping and negligible inertial forces. A thorough investigation revealed that the sequence of transitions between stable equilibrium branches can be dictated by merely controlling the input (elongation) speed.

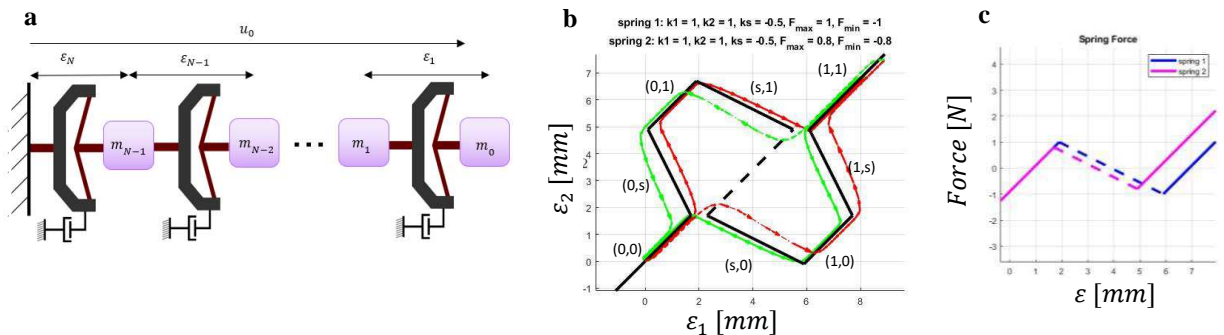

Figure 2: (a). Dynamic model; u_0 is the input control and ϵ_i is the elongation of element i . (b). Equilibrium curves (dashed – unstable) and dynamic trajectories on the map of the elongation of the elements. (c). The force – elongation relation of the elements in the system.

For example, during stretching, the condition for generating a sequence of transition events that differs from that of the quasi-static (or slow) loading is that the first element reaches the negative-stiffness branch (right of the red vertical line in Fig. 3b) before the second element does (above the horizontal gray line in Fig. 3b).

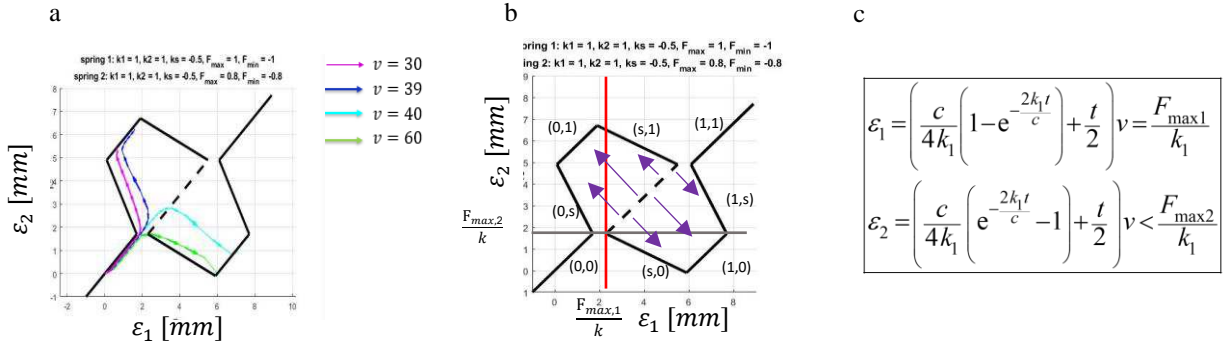

Figure 3: **(a)**. It can be seen in the graph that there is a critical speed which changes the trajectory of the movement from the trivial trajectory to the non-trivial trajectory. **(b)**. Shows the requirements for the transition to the non-trivial route on a force – elongation profile. **(c)**. Algebraic transition conditions according to the conditions in graph b.

Let us define the following non-dimensional parameters: $\tau = \frac{k_1}{c} t, \bar{u} = \frac{cv}{2(F_{max1} + F_{max2})}, \beta = \frac{(F_{max1} - F_{max2})}{(F_{max1} + F_{max2})}$. The condition for changing transition sequence is $\beta + \bar{u} \left(e^{-\frac{1}{\bar{u}}} - 1 \right) > 0$. We find that for relatively small values of β , even up to $\beta=0.18$, the critical speed may be well approximated by $v > \frac{2(F_{max1} - F_{max2})}{c}$.

To test the theoretical predictions, we designed and built an experimental setup. The bistable elements were manufactured by 3D-printing, and the details of their bistable behavior (including the desired difference between the two) were tailored by careful design of the geometry of the parallel bending beams. Damping was introduced by strong magnets attached to each element and hovering over a copper plate (see Fig. 4).

Figure 4: **(a)**. Experimental system. **(b)**. Two bistable elements are printed on a 3D printer made of ABS material.

The dynamic response was recorded using a digital camera and then analyzed by means of standard image processing tools. The experimental results, in terms of elongation of each of the two bistable elements, are shown in Fig. 5, and display a very good agreement with the theoretical predictions.

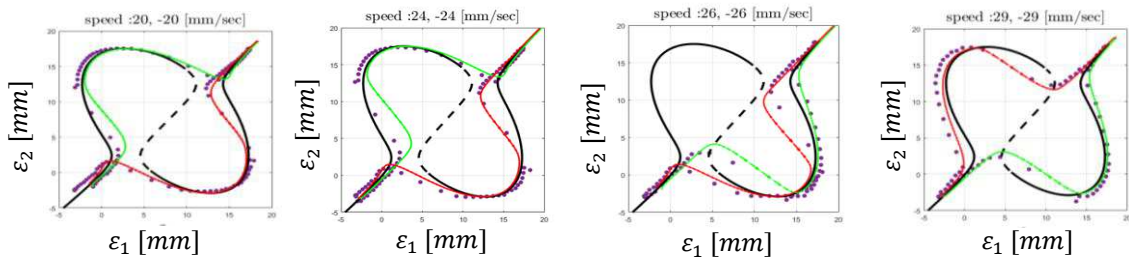

Figure 5: Comparison of the results of the experiment measured in image processing to the results of the simulation. Purple dots (experiment results), red line (stretching simulation) green line (compression simulation), dashed line black (unstable equilibrium), black line (stable equilibrium).

Optomechanical cavities: from synchronization to mode locking

Eyal Buks*

**Andrew and Erna Viterbi Department of Electrical Engineering, Technion, Haifa 32000 Israel*

Summary. We experimentally study a fiber-based optical ring cavity integrated with a mechanical resonator mirror and an optical amplifier. The device exhibits a variety of intriguing nonlinear effects including synchronization and self-excited oscillation. Passively generated optical pulses are observed when the frequency of the optical ring cavity is tuned very close to the mechanical frequency of the suspended mirror. The optical power at the threshold of this process of mechanical mode locking is found to be related to quantum noise of the optical amplifier.

Analytical study of interfacial three dimensional gravity waves in presence of current

Soraya Salmi^{*,**}, Nabil Allalou^{***}

Summary. Analytical study of short crested interfacial gravity waves propagating between two infinite fluids layers has been carried out. These waves are the simplest form of three dimensional waves and are obtained through a reflection of a 2D wave train into a vertical wall. The fluids have different densities and the upper is moving relative to the lower with horizontal and uniform velocity U . The fluids are taken to be incompressible and inviscid and the motion assumed to be irrotational. Using a perturbation method, the forth order solutions was obtained. Using this method attention was focused for the determination of the harmonic resonance of short-crested interfacial waves.

Introduction

For several years efforts have been devoted to the study of the two dimensional interfacial gravity waves in the presence of current. The most interesting approach to this issue has been proposed by Saffman [1], where he identified the critical current which limiting the existence of steady solutions. However, modeling some aspects of three dimensional interfacial gravity waves in the presence of current is essential for more realistic descriptions. Applying this modeling to appropriate cases of practical interest is the main goal of the present work. Most of the work published for three dimensional waves often deals with short crested waves which represent the simplest form, that is why, in our study we focused in this wave form. Using perturbation method an analytical approach has been presented up to the fourth order for the case of interfacial waves between two infinite fluid layers with different densities.

System of equations.

Considering Cartesian coordinate composed of the horizontal plane (x - y) of propagation's interfacial three dimensional wave between two infinite fluid layers (fig.1.a). Herein, short crested-wave field generated from the nonlinear interaction of two wave trains propagating to each other's having the same amplitude and wavelength. L is the wavelength of the incident wave, θ is the angle between the direction of incidence and the normal to the wall. U is the uniform current paralleling to the direction of propagation on the upper layer as shown in (fig.1.b).

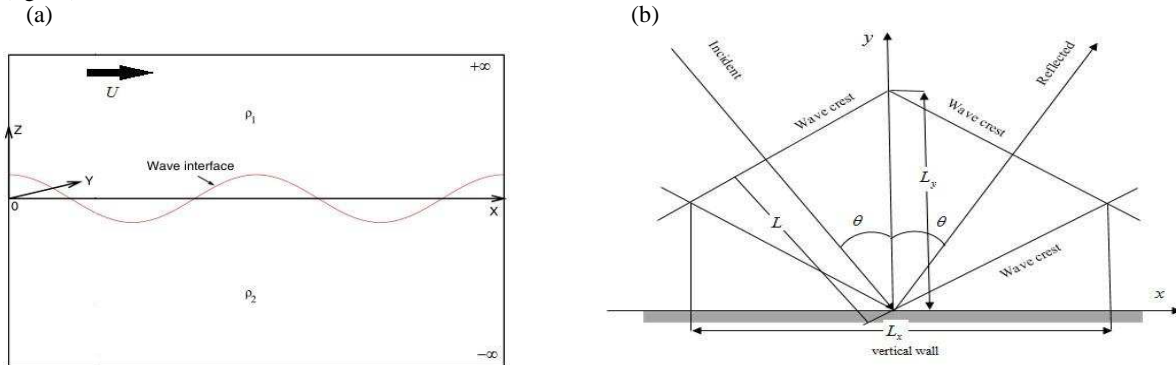

Figure.1: schematic presentation of a short crested wave in presence of current.

The two fluids with densities ρ_1 and ρ_2 are assumed to be inviscid, incompressible and the motion is irrotational. However, with this assumptions the fluid motion can be described by the velocity potential $\phi_1(X, Y, Z)$ and $\phi_2(X, Y, Z)$, which satisfy the dimensionless Laplace's equation in the two fluid layers domain.

$$\Delta \phi_1 = 0 \quad \text{for} \quad 0 < Z < +\infty, \quad (1)$$

$$\Delta \phi_2 = 0 \quad \text{for} \quad +\infty < Z < 0. \quad (2)$$

And due to the presence of a current on the upper layer, herein, the total velocity potential can be expressed by:

$$\phi_T(X, Y, Z) = pUX + \phi_1(X, Y, Z). \quad (3)$$

Solutions of equations (1) and (2) are obtained using some boundary conditions for each layer of fluid, they are summarized in dimensionless form as below:

$$\text{Kinematic boundary conditions at the interface: } (pU - \omega)\eta_X + p^2\eta_X\phi_{1X} + q^2\eta_Y\phi_{1Y} - \phi_{1Z} = 0, \quad (4)$$

$$-\omega\eta_X + p^2\eta_X\phi_{2X} + q^2\eta_Y\phi_{2Y} - \phi_{2Z} = 0, \quad (5)$$

Dynamic boundary condition resulting from the Bernoulli's theorem where C is the Bernoulli's constant:

$$\mu \left\{ (pU - \omega) \phi_{1X} + \eta + \frac{1}{2} (p^2 \phi_{1X}^2 + q^2 \phi_{1Y}^2 + \phi_{1Z}^2) \right\} + \omega \phi_{2X} - \eta - \frac{1}{2} (p^2 \phi_{2X}^2 + q^2 \phi_{2Y}^2 + \phi_{2Z}^2) + C = 0, \quad (6)$$

$$\text{Bottom boundary conditions: } \phi_{1Z} = 0 \quad \text{at} \quad Z \rightarrow +\infty, \quad (7)$$

$$\phi_{2Z} = 0 \quad \text{at} \quad Z \rightarrow -\infty. \quad (8)$$

Perturbation method

The problem is solved by the perturbation method. Such an analysis assumes that the non linearities present a small corrections to linear wave theory. The parameters of the problem are developed in power series based on a small parameter h :

$$\phi = \sum_{r=1}^{\infty} h^r \phi_i^r(X, Y, Z), \quad \eta = \sum_{r=1}^{\infty} h^r \eta_i^r(X, Y), \quad \omega = \sum_{r=1}^{\infty} h^r \omega_r, \quad (9)$$

Where the wave steepness defined by $h = \frac{1}{2} (\eta(0, 0) - \eta(0, \pi))$.

In the first order, we retain only the linear terms. Thus, the linear solution is:

$$\begin{cases} \phi_1^{(1)} = (pU - \omega_0) \sin X \cos Y e^{-Z}, \\ \phi_2^{(1)} = \omega_0 \sin X \cos Y e^Z, \\ \eta^{(1)} = \cos X \cos Y, \\ \omega_0 = \mu p U + \sqrt{-\mu^2 - \mu p^2 U^2 + 1} / \mu + 1, \end{cases} \quad (10)$$

$$\text{The dispersion relation for the linear interfacial wave can be expressed by: } \mu(pU - \omega_0)^2 + \omega_0^2 = 1 - \mu, \quad (11)$$

$$\text{From this relation the value of the critical current is given by: } U_{cl} = \sqrt{-\mu(\mu^2 - 1)} / \mu p. \quad (12)$$

As $U > U_{cl}$ the three-dimensional waves cannot be observed in regular form, in other words steady solutions no longer exist and the wave profile becomes unphysical.

In the higher order, the linearization of kinematic and dynamic equations is carried out by performing a Taylor series expansion of the potential velocities in the neighbourhood of $\eta = 0$. After solving the system of equations, the following solutions are obtained in each order:

$$a_{mn}^{(r)} = - \frac{m(\mu p U f_{1,mn}^{(r)} - \mu \omega_0 f_{1,mn}^{(r)} - \omega_0 f_{2,mn}^{(r)}) - \alpha_{mn} F_{mn}^{(r)}}{m^2(\mu p^2 U^2 - 2\mu \omega_0 p U + \mu \omega_0^2 + \omega_0^2) + \alpha_{mn}(\mu - 1)}, \quad (13)$$

$$b_{mn}^{(r)} = \frac{(pU - \omega_0)m^2 \omega_0 f_{2,mn}^{(r)} + (pU - \omega_0)m F_{mn}^{(r)} \alpha_{mn} + (m \omega_0 + \mu \alpha_{mn} - \alpha_{mn}) f_{1,mn}^{(r)}}{\alpha_{mn} [m^2(\mu p^2 U^2 - 2\mu \omega_0 p U + \mu \omega_0^2 + \omega_0^2) + \alpha_{mn}(\mu - 1)]}, \quad (14)$$

$$c_{mn}^{(r)} = - \frac{(\mu p U - \omega_0)m^2 \omega_0 f_{1,mn}^{(r)} - \omega_0 m F_{mn}^{(r)} \alpha_{mn} + (p^2 U^2 + 2pU \omega_0 + \omega_0^2) \mu m^2 f_{2,mn}^{(r)} + (\mu - 1) \alpha_{mn} f_{2,mn}^{(r)}}{\alpha_{mn} [m^2(\mu p^2 U^2 - 2\mu \omega_0 p U + \mu \omega_0^2 + \omega_0^2) + \alpha_{mn}(\mu - 1)]}, \quad (15)$$

A secular term appears when the denominator of the coefficients becomes zero. This condition is called harmonic resonance. The appearance of secular terms is characteristic of nonlinear short crested waves. Roberts [2] was the first to discover the phenomenon of harmonic resonance of short crested surface waves, and then extended by Allalou, Debiane and Kharif [3] for 3D interface waves in finite depth. When the resonance occurs, we have:

$$m^2(\mu p^2 U^2 - 2\mu \omega_0 p U + \mu \omega_0^2 + \omega_0^2) + \alpha_{mn}(\mu - 1) = 0. \quad (16)$$

Relationship (16) is considered an extension of Allalou's, study in the presence of a uniform current.

Conclusions

In this work, we presented the internal three-dimensional gravity waves in the presence of a parallel current. The latter gave an original aspect to this study. Based on previous work mainly that carried out by N. Allalou & al. [3] it was found that our results were in good agreement. We presented all the physical aspects of the internal three-dimensional wave and we were able to extend our analytical results to the fourth order. We deduced the values of the critical velocity that did not exceeded throughout the study. Moreover, we were able to determine the neighbourhood of the harmonic resonance, and the observation of the wave profile was made by varying several parameters.

Control-Oriented Modeling of a Planar Cable-Driven Parallel Robot with Non-Straight Cables

Rima Saadaoui^{*†}, Olivier Piccin^{*‡}, Hassan Omran^{*†}, Iuliana Bara^{*†}, and Edouard Laroche^{*†}

^{*}*ICube, engineering science, computer science and imaging laboratory, Strasbourg, France*

[†]*University of Strasbourg, France*

[‡]*INSA of Strasbourg, France*

Summary. This communication deals with the control-oriented modeling of cable-driven parallel manipulators when the cables are not considered as straight but show transverse deflections due to fast movements of the platform. The model has been derived from Euler-Lagrange equations with multipliers in order to deal with the kinematic constraints (DAE model). The number of generalized coordinates have been reduced by performing a transformation of the DAE model to an ODE model. The ODE model has been linearized and an \mathcal{H}_∞ controller has been synthesized to control the cable tension and enable the platform to track a reference trajectory.

Introduction

Cable-driven parallel robots (CDPR) are composed of a platform attached to fixed points by cables. The movement of the platform is obtained by winding the cables. One usually distinguishes fully-constrained robots where the number of cables exceeds the number of degrees of freedom and suspended robots. Notwithstanding the commercially available CableCam system¹, CDPR are considered in a number of research projects for applications such as aircraft and ship construction, building facade cleaning and rescue in open air [1].

We are interested here in the modeling of cable robots taking into account cables deflections. More precisely, we take into account the cables inertial effects on the transverse displacements. A planar robot model with three cables made it possible to assess the effects of transverse displacements and the limits of a conventional control strategy [2]. The model was developed from the Lagrangian calculation by approximating the transverse displacements of the cables by parabolic functions.

Albeit this model allows to evaluate the system in simulation, it cannot be readily used to determine the stability properties and properly assess the system performance during a path-following task due to a lack of controllability. This communication discusses three possible methods to obtain such a control-oriented model from a model derived from the laws of physics, taking the example of the planar CDPR.

CDPR description and model

A planar robot with three cables holding a point mass is considered. The dynamic model has been obtained with the Lagrange method with multipliers that suit for dynamic systems with kinematic constraints. Each of the three cables is considered without elongation as depending on three variables: its length l_k (for the cable $\#k$), its transverse displacement (only one mode is considered, corresponding to a parabolic transverse displacement equal to $\frac{w_k}{l_k} x^2$ for cable $\#k$ and $x \in [0; l_k]$) and its orientation at the attachment point. The x and y coordinates of the platform are also included, thus yielding a geometric representation based on 11 variables stacked in the generalized coordinates vector q . The three loop-closure equations of the parallel robot provide six kinematic constraint equations $A(q) \dot{q} = 0$. This model, described in details in [2], is given as

$$\begin{bmatrix} M(q) & -A^T(q) \\ A(q) & 0 \end{bmatrix} \begin{bmatrix} \ddot{q} \\ \dot{\lambda} \end{bmatrix} = \begin{bmatrix} F(q, \dot{q}, \Gamma) \\ -\dot{A} \dot{q} \end{bmatrix} \quad (1)$$

where λ is the multiplier vector, Γ is the vector of the winder torques, M is the kinetic energy matrix and F is the generalized force vector.

From the laws of physics to a control model

Whether based on the Hamiltonian or the Lagrangian [9], the methods of analytical mechanics render possible to determine models of poly-articulated systems with continuous displacements [3]. In addition to the dynamic equations, the model often includes algebraic equations, resulting in a system of differential-algebraic equations (DAE). This is generally the case for parallel robots (including CDPR) when we consider the geometric and kinematic constraints linking the displacements of cables and those of the platform [2, 4].

The control methods allow to study the stability and performance of systems governed by dynamic equations, with the advantage of providing results that are independent from a considered trajectory, thus allowing to reduce the number of simulations to be made in a validation step. Powerful methods allow to evaluate the stability and the performance of ODE

b. Modal coordinates for the displacements of the cables

Figure 1: Simulation results

systems with uncertainties on parameters. However, a basic prerequisite is that the model is both controllable and observable [5]. Properties can be established globally, for example using methods based on Lyapunov functions which mimic energy functions [6], or more simply locally in which case a linear model, approaching the behavior in a neighborhood of an equilibrium point, is enough [7].

Starting from the nonlinear DAE model, several ways can be followed in order to get a model suitable for control:

- A1. The left-hand side matrix in the model (1) can be inverted in order to reveal a second order ODE model $\ddot{q} = f(q, \dot{q}, \Gamma)$ depending on 11 state variables. But it was not possible to conclude on the controllability of the resulting model: the tests on its linearized version failed due to ill-conditioned matrices of the state-space representation. Moreover, standard tools were not able to provide a controllable and observable reduced-order model.
- A2. Rather than making the linearization after inversion of the left-hand side matrix as described in A1, model (1) can be directly linearized so as to obtain a linear descriptor model for which analysis and controller synthesis methods are available [8]. However, the linearized descriptor system was also found uncontrollable and unobservable.
- A3. When possible, algebraic equations $A(q)\dot{q} = 0$ could be solved in order to obtain a description based on a reduced generalized position vector \tilde{q} . This leads to a fewer number of equations of higher complexity (transformation of the DEA model to an ODE model).

Controller synthesis

Approach A3 has been implemented and has lead to a model depending on only 5 generalized coordinates. This ODE linear model was found controllable and observable and an \mathcal{H}_∞ control synthesis has been performed in order to control the cables mean tension and the end-effector position (x, y) (refer to [10] for details on the control strategy). Considering a 1 kg platform and a linear density of cables is 0.17 kg/m, the performance of the \mathcal{H}_∞ closed-loop non linear ODE model for a square reference trajectory at a speed of about 1 m/s has been depicted in Fig. 1. The results show a good trajectory tracking and disturbance rejection.

Experimental verification of the crossover between the time-fractional and standard diffusion in a hierarchical porous material

Alexey Zhokh* and Peter Strizhak*

*L.V. Pisarzhevskii Institute of Physical Chemistry of the National Academy of Sciences of Ukraine, Kiev, Ukraine

Summary. A transport process may cross over from the standard to anomalous diffusion. Herein, we experimentally verify the relevant changes of the diffusion regimes via an analysis of the diffusion concentration profiles in a hierarchically porous material. It is shown that at relatively short times the transport process experiences anomalous diffusion, whereas the standard Fickian diffusion is obeyed at relatively long times. The anomalous diffusion is described by the time-fractional diffusion equation with the superdiffusive anomalous diffusion exponent. The observed transitions seem to be associated with the transport in different components of a porous material.

Objectives

The transitions between the diffusion regimes in a porous medium are fairly typical. In a geometrically restricted environment, e. g. microchannels, an increase in the width of a channel governs the change of the diffusion regime from the single-file to the standard Fickian. This phenomenon has been experimentally verified for the transport process in single-wall carbon nanotubes [1]. Moreover, the analytic approaches for evaluation of the transition time have been established [2]. The effect of the pore size may not be the only reason for the diffusion regime transitions. The crossover between different diffusion regimes may also depend on the evolving time. The experimental investigation on the diffusion of silicon atoms in bulk germanium demonstrated the change in the diffusion kinetics from the anomalous superdiffusion to the standard Fickian versus observation time [3]. To this end, investigating the transport peculiarities through a porous material at various time scales is important for better understanding the fundamentals of the anomalous transport.

Linearized solutions of the standard and time-fractional diffusion equations

The experimental configuration is subjected to the following initial and boundary conditions: $C(x, 0) = C_0 = \text{const}$, $\partial C(0, t)/\partial x = 0$, $-D \cdot \partial C(L, t)/\partial x = \gamma \cdot C(L, t)$. The relevant linearized solutions of the standard and time-fractional diffusion equations, which are suitable for medium and long times, may be expressed as follows [4]:

$$\ln \left[\ln a - \ln \left[\frac{C(L, t)}{C_0} \right] \right] = \ln \left[\frac{D \cdot \pi^2}{4 \cdot L^2} \right] + \ln t \quad (1)$$

$$\ln \left[\frac{C(L, t)}{C_0} \right] = \ln \left[\frac{4 \cdot L^2 \cdot a}{\pi^2 \cdot K \cdot \Gamma[m - \alpha]} \right] - \alpha \cdot \ln t \quad (2)$$

Herein, L is the thickness of a solid porous particle, γ is the penetration coefficient, D and K are the standard and time-fractional diffusion coefficients, respectively, a is a coefficient defined by the initial and boundary conditions, α is a fractional order, m is 1 for $0 < \alpha < 1$, and m is 2 for $1 < \alpha < 2$, $\Gamma(z)$ is the Euler gamma function. For the standard diffusion, the corresponding solution (eq. (1)) is linearized in the bi-logarithmic coordinates with slope that equals unity. In contrast, the solution of the time-fractional diffusion equation (eq. (2)) admits linearization in the logarithmic coordinates possessing the slope directly proportional to the time-fractional order. To this end, if the slope of the experimental data under the relevant bi-logarithmic transformations deviates from unity, the standard diffusion equation fails to describe the experimental transport kinetics.

Experimental procedure

To identify different transport regimes, a combined porous material with hierarchical porous structure was used. The used porous solid consisted of ZSM-5 zeolite and alumina with zeolite/alumina ratio equal to 1/1 by mass. The porous material was prepared using extrusion technique. The as-prepared porous material was characterized by the low-temperature nitrogen adsorption-desorption isotherm. The textural properties estimated from the isotherm data are as follows: BET surface area is 272 m²/g; pore volume is 0.22 cm³/g; BJH pore diameter is 3.9 nm; external surface area is 21 m²/g; micropore volume is 0.04 cm³/g; mesopores surface area is 177 m²/g. The X-ray diffraction revealed the presence of the crystalline phase relevant to ZSM-5 zeolite and γ -alumina. The latter demonstrated rather low amount of crystalline phase.

Methyl alcohol was utilized as a diffusing agent. The methanol transport through the porous solid material was studied using commercial LHM-72 gas chromatograph with the flame ionization detector equipped by the diffusion cell instead of the chromatograph column. The detailed description of the diffusion cell design, as well as the experimental procedure, may be found in our previous report [5]. The mass transfer was investigated under the following experimental conditions. The purge flow rate (argon) was 30 cm³/min; the temperature inside the diffusion cell was kept 120 °C. The methanol amount injected into the diffusion cell using the syringe for gas chromatography was 0.4 μ l. The thickness of the porous zeolite/alumina particle was 2 mm.

Results

Fig. 1a demonstrates the relative methanol concentration decaying in time obtained in the experiment. At relatively small times, i.e. $C(L, t)/C_0 < 0.30$, the standard diffusion equation fails to describe the experimental data because the experimental slope in the bi-logarithmic coordinates significantly deviate from unity (Fig. 1b). At these times, the time-fractional diffusion equation may be successively utilized (Fig. 1c). The decrease of the relative concentration at the starting point of the calculation from 0.30 to 0.15 results in the change of the diffusion regime from the time-fractional to the standard Fickian (Fig. 1d). Therefore, the transport process studied in the current paper exhibits the anomalous time-fractional diffusion at shorter time crossing over to the standard diffusion at a long time. This phenomenon may be associated with the fact that the standard diffusion equation admits the infinite propagation velocity, which is physically unreliable. To eliminate this issue, the Cattaneo-type diffusion equation has been proposed. The Cattaneo diffusion equation implies finite propagation velocity, which is recovered by introducing a relaxation time τ . The time-fractional Cattaneo diffusion equation is given by:

$$\tau^\alpha \cdot \frac{\partial^{\alpha+1} C}{\partial t^{\alpha+1}} + \frac{\partial C}{\partial t} = D \cdot \frac{\partial^2 C}{\partial x^2} \quad (3)$$

The relaxation time is individual for each diffusing substance and porous material. The higher is the crystallinity of a material, the lower is the relaxation time. The solid porous particle used in the present study consists of the two phases, particularly, the crystal phase of ZSM-5 zeolite and the partially amorphous phase of the alumina. To this end, the relaxation times may be different in different parts of the porous material, e.g. in the micropores of zeolite crystallites and the mesopores of the amorphous alumina matrix. In this respect, the diffusion in zeolite micropores seems to be characterized by smaller relaxation time compared to the diffusion in the alumina mesopores. The pores may be also formed by the cavities between the amorphous alumina globes and zeolite crystallites. In these pores, the relaxation time may be different from the relaxation times in either zeolite micropores or alumina mesopores.

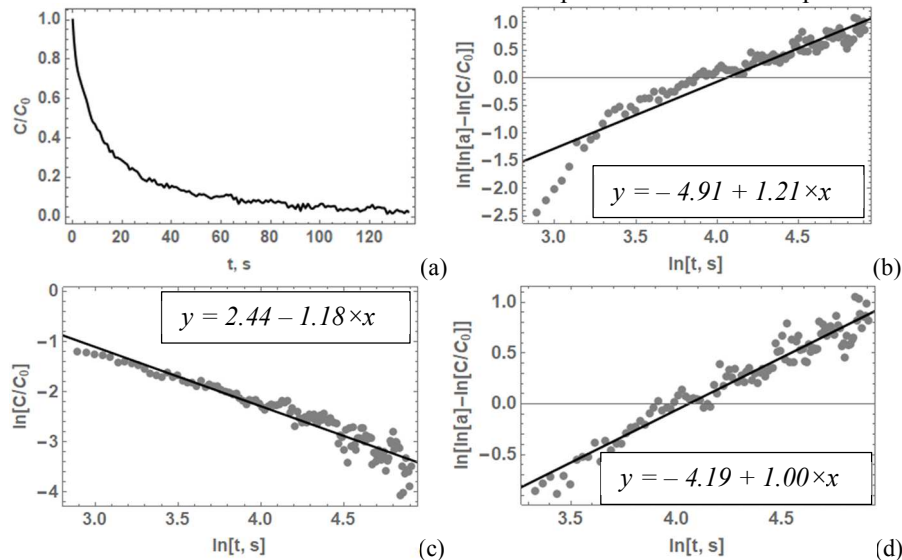

Figure 1: Concentration evolution versus time (a), short time, i.e. $C/C_0 < 0.30$ (b) and (c), and long time, i.e. $C/C_0 < 0.15$ (d) analysis

Conclusions

Investigation of the mass transfer in a hierarchically porous material consisting of crystalline and amorphous parts provides experimental evidence of the crossover between the anomalous diffusion at relatively short times and the standard diffusion at long times. The time-fractional diffusion equation is successively applied to describe the mass transfer kinetics at relatively short times. Unequal relaxation times in crystalline and amorphous parts of a combined porous material allows obeying either time-fractional or the normal diffusion behavior.

Investigation of vibro-impact dynamics in PILine[®] ultrasonic motors

Simon Kapelke*, Felix Hartenbach* and Wolfgang Seemann**

*Physik Instrumente (PI) GmbH & Co. KG, Karlsruhe, Germany

**Institute of Engineering Mechanics, Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany

Summary. PILine[®] ultrasonic motors belong to the group of standing wave ultrasonic motors and, as common for this kind of drives, use certain eigenmodes of a piezoelectric actuator to generate motion. The motion of the actuator is transmitted to a moving slider by means of friction using a coupling element, which performs a high-frequency oblique or elliptical motion. Within this contribution, the possible onset of impact oscillations in standing wave ultrasonic motors is investigated. After introducing a basic motor structure, corresponding experimental results are presented accounting for low-frequency dynamics. Subsequently, a simple mechanical model for normal oscillations of the piezoelectric actuator is evaluated by means of numerical integration. The derived results are compared qualitatively to experimental observations and provide good insight into the relevant dynamics.

Introduction

Piezoelectric motors are commonly used in several commercial, industrial or research related applications. Depending on the specific driving principle, piezoelectric motors can be divided into different categories, such as ultrasonic, stepping or inertia type drives. Ultrasonic motors, and in particular standing wave ultrasonic motors, are known for their high dynamics and accuracy in motion and positioning while providing long travel ranges and self-locking capabilities at rest. These basic properties are achieved by exciting certain eigenmodes of one or more piezoelectric actuators, such that a coupling element attached to the piezoelectric actuator performs a high-frequency oblique or elliptical motion, which is transmitted to a linear or rotational slider by means of friction [1].

The underlying dynamic processes are highly non-linear and, among others, include electro-mechanical coupling, vibro-impact dynamics and friction. Nevertheless, some effort has been spent in the past in order to establish mathematical descriptions of the corresponding dynamics [2, 3]. While most publications assume quasi-static behaviour of the piezoelectric actuator, the exceptional role of actuator inertia properties and, accordingly, the possible onset of impact oscillations has been pointed out recently [4].

Within this contribution, both experimental and model-based investigations related to vibro-impact dynamics of standing wave ultrasonic motors are carried out. Based on the schematic structure of PILine[®] ultrasonic motors and corresponding experimental observations, a simple mathematical model is presented accounting for vibro-impact dynamics. The model can be investigated either by separating slow and fast system dynamics or in terms of direct numerical integration and, together with the experimental observations, gives good insight into relevant dynamic processes.

Basic motor structure and experimental observations

The basic structure of PILine[®] ultrasonic motors is depicted in Fig. 1 and contains a rectangular piezoelectric actuator (1) and the attached coupling element (2). Due to electrical excitation of the piezoelectric actuator, the coupling element performs an elliptical motion, which is transmitted to the slider (3) with horizontal guiding by means of dry friction. The actuator has a pre-stressed elastic foundation, while transverse motion is suppressed by a corresponding suspension (4).

Under certain driving conditions, many ultrasonic motors show undesired vibrations in the audible range, although typical driving frequencies can easily exceed 100 kHz. Among undesired noise phenomena, this behaviour can even cause a loss of performance and is mostly handled by using advanced driving or control techniques [5]. However, in terms of system modelling and for improved control design, deeper understanding of the corresponding dynamics is required.

A recent publication has pointed out the possible onset of impact oscillations resulting from the high-frequency motion of the piezoelectric actuator in combination with the non-linear contact mechanics between coupling element and slider [4].

Figure 1: Schematic PILine[®] motor structure (1–4) and vibrometer measurement beam (5)

Figure 2: Experimental results for linearly increasing (first half) and decreasing (second half) excitation amplitude

Figure 3: Average normal contact force for different excitation amplitudes

Figure 4: Exemplary solutions for different excitation amplitudes: floating type (left) and period- n solution (right)

Corresponding experimental results, where the normal motion of the piezoelectric actuator has been investigated using a *Polytec VibroFlex Xtra* laser vibrometer (5), are shown in Fig. 2. Herein, the frequency content of the normal actuator motion has been recorded, while increasing and decreasing the excitation amplitude at fixed driving frequency. Apart from the basic driving frequency f_e , the results contain several lower frequencies and other non-linear characteristics, which can be used to validate model-based approaches. Important observations are related to bifurcations, co-existing stable solutions, amplitude-dependent frequencies and the non-linear amplitude evolution.

Modelling approach and first numerical results

In order to simplify the mathematical description and focus on normal oscillations of the actuator, normal and tangential components are investigated separately. This approach appears suitable, since the friction type coupling of normal and tangential motion is mainly unilateral. According to the basic structure of the ultrasonic motor introduced before, the equation for normal actuator motion can be stated as

$$m\ddot{y}_A + d\dot{y}_A + c_A y_A + N = 0 \quad \text{with} \quad N = \begin{cases} c_P(y_A + y_C - h), & \text{contact} \\ 0, & \text{separation} \end{cases} \quad (1)$$

Herein, y_A is the normal displacement of the actuator, m is the corresponding mass and d , c_A are damping and stiffness coefficients of the foundation. N is the normal contact force with local contact stiffness c_P , $y_C = a \sin \omega t$ is the high-frequency motion of the coupling element and h corresponds to the location of the slider.

The system can be investigated by using separate descriptions for slow and fast system dynamics. This approach results in a compact formulation for the slow dynamics and allows for further (semi-)analytical investigations, e. g. smoothing of the normal contact force as depicted in Fig. 3 or evaluation of the corresponding amplitude-dependent natural frequency. However, for a first qualitative comparison between model-based results and experimental observations, simple numerical evaluation appears more suitable. Fig. 4 shows two exemplary solutions of the system depending on the chosen parameters and initial conditions: The first one is a typical floating type solution without low-frequency motion and one contact phase per period of the excitation. This kind of solution is commonly regarded as the desired mode of operation of standing wave ultrasonic motors. The second solution is obtained for the same model parameters and initial conditions, but with increased excitation amplitude. The resulting motion can be referred to as a period- n solution of the system showing large low-frequency oscillations together with the high-frequency excitation. Herein, long separation phases can be observed and the interval between two contact phases is mainly determined by the low-frequency actuator motion.

Conclusions and outlook

The given results can be regarded as a first local analysis of the presented model showing possible mechanisms for the non-linear system behaviour observed experimentally. However, further investigations require a global analysis of the modelling approach and improved experimental validation. First results as well as practical experience indicate the importance of considering further compliant properties of the slider. Otherwise, many of the previously observed phenomena are limited to transient behaviour or minor basins of attraction. Nevertheless, the presented results give good insight into relevant dynamic processes and their impact on the basic driving principle of standing wave ultrasonic motors.

Summary. We propose a new model order reduction (MOR) approach to obtain effective reduction in the context of transport-dominated problems or hyperbolic partial differential equations. The main ingredient is a novel decomposition of the solution into (i) a function that tracks the evolving discontinuity and (ii) the residual part that is devoid of shock features. This decomposition strategy is then combined with Proper Orthogonal Decomposition which is applied to the residual part only to develop an efficient reduced-order model representation for problems with multiple moving and possibly merging discontinuous features. Numerical case-studies show the potential of the approach in terms of computational accuracy compared with standard MOR techniques.

Problem Description

Hyperbolic partial differential equations (PDEs) are ubiquitous in science and engineering. Applications encompassing the fields of chemical industry, nuclear industry, drilling industry, etc., fall within this class. Moving discontinuities (such as shock-fronts) are representative features of this class of problems and pose a major hindrance to obtain effective reduced-order model representations [1]. As a result, standard Model Order Reduction techniques [2] do not fit the requirements for real-time estimation and control or multi-query simulations for such problems. This motivates us to investigate and propose efficient, advanced and automated approaches to obtain reduced models, while still guaranteeing the accurate approximation of wave propagation (and wave interaction) phenomena.

The main contribution of the work is to propose a new decomposition ansatz that decomposes the solution into (i) a basis function that tracks the evolving discontinuity (wave front) and (ii) the residual part that is expected to be devoid of shock features. This decomposition renders the residual part to be amenable for efficient basis generation. We, then, use these generated bases to apply Proper Orthogonal Decomposition (POD) on the residual part and later reconstruct the solution by lifting it to the high-dimensional problem space. We finally assess the combined performance of decomposition, reduction and reconstruction approach (as opposed to conventional reduction and reconstruction approach) in the scope of transport-dominated problems with moving and interacting discontinuities.

Mathematical Formulation

We discuss the proposed decomposition ansatz and outline the whole procedure in order to obtain a reduced-order model.

Decomposition step

We consider a scalar 1D conservation equation of the form:

$$\partial_t u(x, t) + \partial_x f(u(x, t)) = 0, \quad u(x, 0) = u_0(x). \quad (1)$$

We assume that $u(x, 0) = u_0(x)$ already has S number of shocks at locations $x_1(0), \dots, x_S(0)$ with values $u^-(x_s(0), 0)$, $s = 1, \dots, S$ from the left and values $u^+(x_s(0), 0)$, $s = 1, \dots, S$ from the right. We associate a single basis function $\sigma_s(x - x_s(t))$ to each discontinuity at their respective locations. This basis function has a jump of height 1, i.e., $\sigma_s^+(0) - \sigma_s^-(0) = 1$, at the location of the discontinuity. We now decompose the solution, u , in the following way:

$$u(x, t) = \sum_{s=1}^S j_s(t) \sigma_s(x - x_s(t)) + u_r(x, t), \quad (2)$$

$$j_s(t) = u^-(x_s(t), t) - u^+(x_s(t), t).$$

When $x_s(t)$ exactly matches the location of the shocks and (2) is exactly fulfilled, then $u_r(x, t)$ represents a function without any shocks (discontinuities) and hence is amenable to a low-rank approximation.

The time-stepping scheme can be defined in the following manner. In each time step, we first compute updated shock locations $x_s(t^{n+1})$, jumps $j_s(t^{n+1})$ and then compute the residual part $u_r(x, t^{n+1})$ from

$$u_r(x, t^{n+1}) - u_r(x, t^n) = \sum_{s=1}^S j_s(t^n) \sigma_s(x - x_s(t^n)) - \Delta t \partial_x f(u(x, t^n)) - \sum_{s=1}^S j_s(t^{n+1}) \sigma_s(x - x_s(t^{n+1})). \quad (3)$$

Reduced Order Model

The standard way to construct a reduced-order model (ROM) is to reduce (1) by applying Galerkin projection on u . Instead, we apply POD on the residual part, i.e., we reduce (3) via Galerkin projection onto $V_N \subseteq V_h$ (where V_N is a

reduced space and V_h is a high-fidelity space). Upon considering the projection operator $P_N : V_h \rightarrow V_N$, the reduced scheme on the residual part is:

$$u_{r,N}^{k+1} = u_{r,N}^k + P_N \left(\sum_{s=1}^S j_{s,N}(t^k) \sigma_s(x - x_{s,N}(t^k)) - \Delta t \partial_x f(P_N' u_N^k) - \sum_{s=1}^S j_{s,N}(t^{k+1}) \sigma_s(x - x_{s,N}(t^{k+1})) \right), \quad (4)$$

where k indicates the time-instant, $u_{r,N}^k \in V_N$, $u_{r,N}^0 = P_N(u_r^0)$ with u_N^k defined as:

$$P_N' u_N^k = \sum_{s=1}^S j_{s,N}(t^k) \sigma_s(x - x_{s,N}(t^k)) + P_N' u_{r,N}^k. \quad (5)$$

Numerical Experiments

We reduce the Burgers equation given by: $\partial_t u + \partial_x(\frac{u^2}{2}) = 0, x \in [0, L]$, for illustrating the potential of the proposed approach. The case studies under consideration assume that the shock is already present in the initial data, which for single and multiple wavefront scenarios, is respectively given by:

$$u(x, 0) = u_0(x) = \begin{cases} x, & 0 \leq x \leq 1, \\ 0, & \text{otherwise} \end{cases} \quad \text{and} \quad u(x, 0) = u_0(x) = \begin{cases} x - 2, & 2 \leq x \leq 4, \\ (x - 5)/2, & 5 \leq x \leq 7, \\ 0, & \text{otherwise.} \end{cases}$$

We consider the spatial domain to be of length $L = 10$ and use an upwind finite volume scheme for the spatial discretization and a first-order Forward Euler for the time-stepping. We take 8000 steps in time for the scenarios under consideration i.e., $t \in [0, 4]$ with a timestep of 0.0005. We consider three different spatial mesh resolutions (spatial step size of 0.005, 0.002 and 0.001) to assess the performance of the standard (POD without decomposition) and the proposed approach.

Figure 1: ROM error for the single wavefront scenario (left) and multiple wavefront scenario (right) under different mesh sizes.

We consider that $j_{s,N} = j_s$ and $x_{s,N} = x_s$ and use these jumps and shock locations during the ROM time-stepping. We, further, use the computed residual part to generate the bases and build a ROM. Figure 1 demonstrates the decay of the ' L^2 in space and L^2 in time' (absolute) error (between the full-order model governed by (1) and the reconstruction given by (5)) for the scenarios of interest. Firstly, the initial error incurred via the proposed approach is lower than that of the standard approach. This is attributed to the fact that our decomposition approach associates a basis function corresponding to the travelling discontinuity. Secondly, the rate of decay of the error is better for the proposed approach compared to the standard approach. Moreover, the ROM error for the proposed approach stagnates later for finer mesh-sizes. It is also observable that the mesh refinement reduces the ROM error obtained via proposed approach in contrast to the ROM error obtained via standard approach. The difference in the order of magnitude of the ROM error (at a certain number of basis function) computed via standard and proposed approach is even more pronounced for fine mesh-sizes.

Conclusions

We have proposed a decomposition ansatz for problems with moving discontinuities and combined it with POD applied to the residual part only. We have show-cased the performance of the proposed approach on the Burgers equation. The proposed approach is able to resolve the discontinuities and also offers reduction in ROM error by using much less number of basis functions. We will perform numerical experiments on many other mathematical models (falling within the class of transport-dominated problems) in the near future.

Numerical investigation on storage tank buckling near the liquid level under seismic loading

Christophe Collignon

Mechanical Engineer, structural analysis, Framatome, Lyon (France) -
christophe.collignon@framatome.com

ABSTRACT

In Nuclear Power Plants, storage tanks are used to contain a large volume of borated water which can be injected into the reactor pool and the spent fuel pool cooling system. Considering they are subjected to the hydrostatic pressure only in normal service conditions, these components are usually designed as thin-wall large shell, which presents the characteristic of being more sensitive to dynamic excitation loads, such as the ones arising from earthquakes.

The most common damages caused to steel tanks of industrial facilities in recent earthquakes are the “elephant foot” buckling and the “diamond shape” buckling, both phenomena are located at the lower part of the cylindrical shell, close to the anchorage. These two kinds of buckling are well-known and usually analyzed within the engineering practice. Nevertheless, the current design standards do not cover another type of instability which is sometimes observed after an earthquake: the shell buckling at the upper part of the cylindrical wall, near the liquid free level, due to the sloshing motion.

The present paper describes the numerical investigations performed on a typical storage tank of the nuclear industry to assess whether the upper shell buckling can lead to a severe damage or not (collapse, cracks). The EUROPLEXUS software is used for the modelling and computation considering its very efficient fluid-structure interaction algorithms and liquid-gas flow models. As a first step, the EUROPLEXUS explicit time integration scheme capability of simulating sloshing motion for a long duration (typically up to 30 s) is validated reproducing the Hinatsu’s experimental tests. As a second step, several simulation tests are run on a full 3D model of the tank to analyze the structure post-buckling states during and after the seismic event.

The numerical results show that the vibration amplitudes on the shell buckling modes are small enough to keep the structure globally in the elastic range, even for strong earthquake with a Peak Ground Acceleration of 0.5g. Only low plastic strains confined near the liquid free level are calculated. It is noted that the deformed shapes at the end of the computation are consistent with the post-seismic observations on actual tanks.

Nonlinear Dynamics of a Ring-Type MEMS Gyroscope

Ibrahim F. Gebrel*, Ligang Wang** and Samuel F. Asokanathan*

* Dept. of Mech. and Matls. Engineering, The University of Western Ontario, London, ON N6A5B9, Canada

** Dept. of Mathematica, Harbin University, Harbin, Heilongjiang 150001, China

Summary. This paper investigates the nonlinear dynamic behavior of a rotating ring that forms an essential element in MEMS ring-based vibratory gyroscopes that utilize oscillatory nonlinear electrostatic forces. Mathematical model that incorporates geometric nonlinearities for the MEMS ring structure as well as a model that represents nonlinear electrostatic forces that act on the ring structure are formulated. Galerkin's procedure is employed to reduce the equations of motion to a set of ordinary differential equations. Understanding the effects of nonlinear actuator dynamics is considered important for characterizing the dynamic behavior of such devices. For investigating the dynamic response behavior of a ring-type vibratory angular rate, the equations of motion are simplified by ignoring the extensional vibrations, since the second resonant flexural mode is excited in this class of applications. Dynamic responses in the driving and the sensing directions are examined via time responses, phase diagram, and Poincaré map plots when the input angular motion and the nonlinear electrostatic force are considered simultaneously. The analysis is envisaged to aid fabrication of this class of devices as well as for providing design improvements in MEMS-based Ring-type Gyroscopes.

Concept and Modeling

In the present paper, nonlinear dynamic behavior of rotating thin circular rings for use in vibratory angular rate sensors have been investigated via numerical simulations. A homogenous, isotropic ring is chosen for the angular rate sensor. Cho [1] developed mathematical models for rotating ring based angular rate sensors for the purpose of investigating linear as well as nonlinear dynamic behavior and dynamic stability of angular rate sensors which are subjected to external excitation. In the past, Huang and Soedel [2] and Natasiavas [3], among others, have also studied the nonlinear dynamic behaviour of rotating thin circular rings. Dynamic response behavior of rotating thin circular rings for use in vibratory angular rate sensors was investigated by Gebrel et al [4] via numerical simulations by employing the linearized model considering the second mode. In this study, a suitable theoretical model is developed for the purposes of representing the nonlinear electromagnetic actuation forces that are used for exciting the ring from two positions to obtain improved device sensitivity. Figure 1(a) illustrates the geometry and parameters used in the present study while Figure 1(b) illustrates the two degenerate modal configurations associated with the second flexural mode, and are separated by 45 degrees. The schematic of the rotating ring geometry used in present study have been described in detail in [1, 4].

Figure 1: (a) schematic of the rotating ring geometry, and (b) Visualization of second flexural modes of ring

In the present paper, the nonlinear equations of motion in terms of the generalized coordinates associated with the flexural coordinates A_n and B_n [1, 5] are developed for the purposes of illustrating the dynamic behavior. The discretized equations of motion that govern the dynamics with suitable nonlinear harmonic electrostatic forces are derived:

$$\left[\rho h \pi + 2 \rho h \pi \left(\frac{ny}{2r} \right)^2 A_n^2 \right] \ddot{A}_n + 2 \rho h \pi \left(\frac{ny}{2r} \right)^2 A_n B_n \ddot{B}_n + 2 \zeta \omega_0 \dot{A}_n + \left[\frac{EI}{br^4} (n^2 - 1) n^2 + \rho h \Omega^2 (n^2 - 2) + k_r \right] \pi A_n + \left[\frac{EA}{br^2} + k_r \right] \left(\frac{ny}{2r} \right)^2 [A_n^2 + B_n^2] \pi A_n + 2 \rho h \pi \left(\frac{ny}{2r} \right)^2 [\dot{A}_n^2 + \dot{B}_n^2] A_n - \rho h \pi \Omega \frac{1}{n} B_n - 2 \rho h \pi \Omega \frac{1}{n} \dot{B}_n = f_{Nes}(A_n, B_n, \theta_i) \cos(\omega t) \quad (1)$$

$$\left[\rho h \pi + 2 \rho h \pi \left(\frac{ny}{2r} \right)^2 B_n^2 \right] \ddot{B}_n + 2 \rho h \pi \left(\frac{ny}{2r} \right)^2 A_n B_n \ddot{A}_n + 2 \zeta \omega_0 \dot{B}_n + \left[\frac{EI}{br^4} (n^2 - 1) n^2 + \rho h \Omega^2 (n^2 - 2) + k_r \right] \pi B_n + \left[\frac{EA}{br^2} + k_r \right] \left(\frac{ny}{2r} \right)^2 [A_n^2 + B_n^2] \pi B_n + 2 \rho h \pi \left(\frac{ny}{2r} \right)^2 [\dot{A}_n^2 + \dot{B}_n^2] B_n + \rho h \pi \Omega \frac{1}{n} A_n + 2 \rho h \pi \Omega \frac{1}{n} \dot{A}_n = 0 \quad (2)$$

where ρ is mass density, EI represents flexural rigidity, A is the cross sectional area of ring, b denotes axial thickness of ring, h is radial thickness, r is the mean radius of the ring, and k_r support spring stiffness in the radial direction. The

quantification of the nonlinear terms are governed by the parameter γ . Oscillatory external nonlinear electrostatic actuator force that acts along the A_n direction is considered to have a magnitude f_{Nes} and frequency ω , while input angular velocity and acceleration, respectively, are denoted by Ω and $\dot{\Omega}$. The area moment of inertia of the ring cross section about its neutral axis is expressed as $I = bh^3/12$. The parameter ζ represents the mechanical damping ratio, and n denotes the number of modes which is taken to be 2 in the present study. The angular positions of electrostatic forces that excite the ring in the primary direction is denoted by θ_i , $i = 1, 2, 3, 4$. In order to represent the oscillatory electrostatic force, a suitable theoretical formulation is employed:

$$f_{Nes} = \sum_{i=1}^4 (\cos(n\theta_i) - \left(\frac{n\gamma}{2r}\right) A_n) * \left[\frac{\epsilon_0 V^2 a}{2 \left\{ d - A_n \cos(n\theta_i) - B_n \sin(n\theta_i) + \frac{n\gamma}{4R} [A_n^2 + B_n^2] \right\}^2} \right], \quad (3)$$

where the parameter ϵ_0 represents the permittivity of air, V represents the applied voltage between the electrode and the ring, a represent the electrode width which represents the space between electrode and the surface of the ring, d is the distance between electrode and ring

Results and Discussion

For the purposes of predicting the nonlinear response characteristic of MEMS ring-type gyroscope, equations (1) and (2) have been solved numerically. Parameters associated with a typical MEMS ring-type gyroscope are considered. The following ring design parameters: radius of $500 \mu m$, thickness of $12.5 \mu m$, and a height of $30 \mu m$ with Young's modulus of $210 Gpa$ and the density of $8800 Kg/m^3$ have been chosen. At a nominal input angular rate of $2\pi rad/sec$ and a typical device high quality factor of 1×10^5 , the resulting frequencies have been evaluated as $\omega_1 = 2.1422 \times 10^5 (rad/sec)$, and $\omega_2 = 2.1428 \times 10^5 (rad/sec)$. The generalized coordinates $q_1 = A_n/h$, $q_2 = B_n/h$ have been used for the non-dimensional equations. For an input angular velocity $\Omega = 2\pi (rad/sec)$, under nonlinear oscillatory electrostatic excitation, the time response of the ring in the sensing direction in the presence of geometric nonlinear terms is depicted in Figure 2(a). Figure 2(b) depict the phase portrait based on the steady-state response in the sensing direction. The effects of nonlinearities due to the nonlinearities of the system as well as nonlinear electrostatic force are evident from the plots. Furthermore, nonlinearity can be seen in the Poincare' map results as shown in Figure 2(c), where the Poincare' maps appear as a cloud of unorganized points in the phase plane in Figure 2(b) due to the influence of nonlinear terms in the model as well as nonlinear actuator. Internal resonance behavior is not analyzed in this study since the natural frequencies are close to each other and cannot be equal in the typical device operating range.

Figure 2: (a) Time Response, (b) Phase diagram, and (c) Poincare' map.

Conclusions

Nonlinear dynamic behavior of a MEMS-scale ring-type vibratory gyroscope has been examined via numerical simulations. The device exhibits nonlinearity in the presence of geometric nonlinear term in the model which may be attributed to high vibration amplitudes. In addition, nonlinearities due to electrostatic actuation have also been incorporated. Results on the dynamic response obtained via time-response, Phase portraits and Poincare' maps indicate significant influence of geometric nonlinearities on the resulting steady state behavior. The analysis is envisaged to aid fabrication of this class of devices as well as for providing design improvements in MEMS Ring-based Gyroscopes.

Summary. In this abstract, we focus on the study of a single degree-of-freedom Mathieu-type differential equation, which can be found in engineering examples such as in the modelling of geared systems. We consider that the variable part of the stiffness is composed of several harmonic components and that the forcing terms contain a constant component along with an harmonic component. The phenomenon of parametric amplification is described in the case of a single harmonic force, as well as in the case of a purely constant force. The combination of both forces is also considered in the study

Introduction

This abstract presents a study of a Mathieu type equation arising, for example, when modelling the meshing of two gears mounted on rigid shafts [1] or when studying a pendulum attached to a moving point [2]. The equation represents the motion of a (damped and forced) single degree-of-freedom attached to the ground through a periodically time varying stiffness and is given by the following:

$$\ddot{x} + \mu\dot{x} + [\omega_0^2 + g(t)]x = h(t), \quad (1)$$

where $x(t)$ represents the variable under interest, μ is the damping coefficient, ω_0 is the natural angular frequency, $g(t)$ is the periodic time varying stiffness (with zero mean) and $h(t)$ is the external force.

In the following, we will assume that the stiffness $g(t)$ is periodic with fundamental pulsation Ω , such that it can be represented by its Fourier series: $g(t) = \sum_{p \neq 0} \hat{\chi}_p e^{ip\Omega t}$, where $\hat{\chi}_p \in \mathbb{C}$ is the complex amplitude of the p -th harmonic of the stiffness. The external force $h(t)$ will be considered to be the sum of a constant part h_0 and an harmonic part $h_n(t)$ at a given order $n \in \mathbb{N}$: $h(t) = h_0 + (\hat{h}_n e^{in\Omega t} + c.c.)$, where $\hat{h}_n \in \mathbb{C}$ is the complex amplitude of the n -th harmonic of the external force, and *c.c.* stands for complex conjugate.

After introducing some scaling using a small parameter ϵ , the multiple scale method [3] can be used to derive approximated solutions to Eq.(1) under the form $x(t) = x_0(t) + \epsilon x_1(t) + \dots$. In this study, one supposes that the damping coefficient (μ), the variable part of the stiffness (g) and the variable part of the force (h_n) are of order ϵ (all the other terms remaining at order 1). The application of the multiple scale method up to order one, leads to two linear differential equations for x_0 and x_1 , and the cancellation of the secular terms inside the second equations allows to identify the coupling that can occurs between the different harmonics of the stiffness and the force, along with the computation of the approximated solution $x_0(t)$.

In this study, we consider the solution to Eq.(1) for three different kinds of forcing: i) harmonic forcing only ($h_0 = 0$), ii) constant forcing only ($h_n = 0$) and iii) combination of constant and variable forcing. In each cases, we describe the phenomenon of parametric amplification exposed by the multiple scale method and we use numerical methods to validate our results. Note that in this study, one will consider that the damping coefficient μ is sufficiently high to avoid parametric instabilities.

Results

Harmonic forcing only

Here we first consider that the system is forced harmonically ($h_0 = 0$ and $\hat{h}_n \neq 0$) close to its resonance ($n\Omega \approx \omega_0$). The cancellation of the secular terms shows that, at first order in ϵ , the $p = 2n$ -th harmonic of the stiffness interacts with the (n -th) harmonic of the force, leading to the following form for the approximated solution:

$$x(t) \approx \left(\frac{\hat{N}(\Omega)\hat{h}_n + \hat{h}_n^* \hat{\chi}_{2n}}{D(\Omega)} e^{in\Omega t} + c.c. \right), \quad (2)$$

with $\hat{N}(\Omega) \in \mathbb{C}$ and $D(\Omega) \in \mathbb{R}$. It can be seen that, for a given Ω (e.g. $n\Omega = \omega_0$), the amplitude of the solution can be made maximum (resp. minimum) if the phase between the complex numbers $\hat{N}(\Omega)\hat{h}_n$ and $\hat{h}_n^* \hat{\chi}_{2n}$ is zero (resp. is π). This phenomenon is known as the parametric amplification effect: by choosing conveniently the complex amplitude $\hat{\chi}_{2n}$ on can create an amplification, or an attenuation of the vibration amplitude for a given excitation frequency (usually around resonance) [4, 5].

Constant forcing only

Here, we consider that the system is only statically forced ($h_0 \neq 0$ and $\hat{h}_n = 0$), and that the fundamental pulsation of the periodic stiffness is such that $p\Omega \approx \omega_0$ (for a given $p \in \mathbb{N}$ such that $\hat{\chi}_p \neq 0$). The cancellation of the secular terms shows

that, at first order in ϵ , the p -th and the $2p$ -th harmonic of the stiffness interacts together, leading to the following form for the approximated solution:

$$x(t) \approx \frac{h_0}{\omega_0^2} \left[1 + \left(\frac{\hat{N}(\Omega)\hat{\chi}_p + \hat{\chi}_p^* \hat{\chi}_{2p}}{D(\Omega)} e^{ip\Omega t} + c.c. \right) \right], \quad (3)$$

again with $\hat{N}(\Omega) \in \mathbb{C}$ and $D(\Omega) \in \mathbb{R}$. It can be seen that, for a given Ω (e.g. $p\Omega = \omega_0$), the amplitude of variable part of the solution can be made maximum (resp. minimum) if the phase between the complex numbers $\hat{N}(\Omega)\hat{\chi}_p$ and $\hat{\chi}_p^* \hat{\chi}_{2p}$ is zero (resp. is π). This phenomenon appears to be very similar to the parametric amplification effect presented before: adjusting the phase between the p -th and $2p$ -th harmonic of the stiffness can lead to amplification or attenuation of the vibration level (see Fig.1). To our knowledge, this phenomenon is not often referred to (one explanation might be that, most of the time, researchers consider Mathieu's equation with only a single harmonic variable stiffness along with an harmonic forcing only), and we think it might be useful to understand and/or design gear systems.

Figure 1: Constant forcing only. Left plot: amplitude of the variable part of the solution in Eq.(3) for different value of the phase between the p -th and $2p$ -th harmonic of the stiffness. Right plot: Amplitudes at the resonance as a function of the phase difference, an amplification takes place at $\phi_1 = -\frac{\pi}{4}$ and an attenuation at $\phi_1 = \frac{\pi}{4}$. In this example $p = 1$ and $\phi_2 = 0$ (the second harmonic of the stiffness is the origin for the phase)

Constant and Harmonic forcing

Here, we consider that the system is statically and harmonically forced ($h_0 \neq 0$ and $\hat{h}_n \neq 0$) around its resonance ($n\Omega \approx \omega_0$) and that $\hat{\chi}_p \neq 0$ and $\hat{\chi}_{2p} \neq 0$. Due to the linearity of Eq.(1), the solution to this case can be obtained by summing the results of Eq.(2) and Eq.(3). This leads to interactions between the harmonics of the force and/or the stiffness resulting in parametric amplification or attenuation effect, depending on the relative phase between \hat{h}_n , $\hat{\chi}_n$ and $\hat{\chi}_{2n}$, that will be described in the presentation.

Conclusions

In this study, we have shown that parametric amplification in Mathieu's oscillators is possible for in the case of an harmonic forcing as well as in the case of a pure constant forcing. The parametric amplification is due to interaction between harmonics of the stiffness and/or of the forcing. This can be interesting for various fields of applications where the modification of the phases between the harmonics of the stiffness may cause a reduction in vibration levels. In particular, we think that this phenomenon might be of interest for understanding and/or designing geared systems.

Optimization Process for Ride Quality of a Nonlinear Suspension Model Based on Newton-Euler's Augmented Formulation

Mohamed Belhorma*, and Aboubakar S. Bouchikhi*

*The Mechanics of structures and solids Laboratory, BP 89, Cite Ben M'hidi, University of Sidi Bel Abbès, Sidi Bel Abbès 22000, Algeria.

Summary. This paper addresses modeling a Double A-Arm suspension, a three-dimensional nonlinear model has been developed using the multibody systems formalism. Dynamical study of the different components responses was done, particularly for the wheel assembly including the tire body and the knuckle. To validate those results, a similar model was constructed and simulated by RecurDyn; a professional multibody dynamics simulation software. The model has been used as an Objective function that generate an optimization algorithm for ride quality improvement.

Introduction

Modern systems are often very complex and consist of many components interconnected by joints and force elements. These systems are commonly called multibody systems (MBS). Vehicles can be considered as MBS and the dynamic equations that govern their motion are highly nonlinear which in most cases cannot be solved analytically. One must resort to the numerical solution of the resulting dynamic equations. Nikravesh work in [1] can be considered as an interesting reference about the Newton-Euler equations and its most suitable forms.

The aim of this study is the implementation of the augmented formulation in a dynamical model of the double A-Arms suspension. This system contains two lateral control arms to hold the wheel where the length between the upper and lower arms is not the same [2]. The upcoming sections represent a suspension mathematical model which can be used as an Objective function that generate an optimization algorithm for ride quality improvement.

Dynamic Equations of motion

From [1], The equation of motion for the mass center of a rigid body is directly obtained from Newton's second law as

$$\mathbf{M} \cdot \ddot{\mathbf{q}} = \mathbf{h} \quad (1)$$

For a system of n_b constrained bodies, we must revise Equation 1 by including the reaction (constraint) forces

$$\mathbf{M} \cdot \ddot{\mathbf{q}} = \mathbf{h} \rightarrow \mathbf{M} \cdot \ddot{\mathbf{q}} = \mathbf{h} + {}^{(c)}\mathbf{h} \quad (2)$$

Assume that the position constraints between the n_b bodies form n_c constraint equations that are expressed in general form as

$$\Phi(\mathbf{q}) = 0 \quad (3)$$

The velocity and acceleration constraints are expressed as

$$\dot{\Phi} = \Phi_q \cdot \dot{\mathbf{q}} = 0 \quad (4)$$

$$\ddot{\Phi} = \Phi_q \cdot \ddot{\mathbf{q}} - \alpha = 0 \quad (5)$$

Where Φ_q is the Jacobian matrix. According to the method of Lagrange multipliers, the array of reaction forces ${}^{(c)}\mathbf{h}$ can be presented as

$${}^{(c)}\mathbf{h} = \Phi_q^T \cdot \boldsymbol{\lambda} \quad (6)$$

$\boldsymbol{\lambda}$ is a vector of n_c Lagrange multipliers. Then Equation 2 is rewritten as

$$\mathbf{M} \cdot \ddot{\mathbf{q}} = \mathbf{h} + \Phi_q^T \cdot \boldsymbol{\lambda} \quad (7)$$

This system contains n_b equations and $n_b + n_c$ unknowns, accelerations and Lagrange multipliers.

THREE-DIMENSIONAL NONLINEAR MODEL OF DOUBLE A-ARM SUSPENSION

To well understand the selected approach, three-dimensional nonlinear model of double A-Arm suspension will be presented. The system contains four (04) moving bodies that are connected with each other by kinematic joints and driven by a set of forces, Figure 1. With this formulation the number of unknowns is $n + m$, since not only \mathbf{q} but also $\boldsymbol{\lambda}$ needs to be calculated.

$$\mathbf{q} = (\mathbf{q}_1 \ \mathbf{q}_2 \ \mathbf{q}_3 \ \mathbf{q}_4)^T \quad (8)$$

where

$$\mathbf{q}_i = (x_i \ y_i \ z_i \ \gamma_i \ \beta_i \ \varphi_i)^T \quad (9)$$

For validation, RecurDyn software is used. It provides realistic simulation of multibody dynamics.

Table 1: Constraints configuration of the double A-arm system.

OPTIMIZATION PROCESS

The chassis vertical acceleration is minimized, while the design constraints on the suspension working space and dynamic tire load should be satisfied. The RMS of the acceleration of a sprung mass \ddot{Z}_1 is frequently used to evaluate the riding quality of a vehicle. A rider's comfort improves as the acceleration decreases. Ride comfort is chosen to be the design criterion. The design optimization problem can be described as: Minimize $\ddot{Z}_1(m_1, m_2, m_3, m_4, K_s, N_s, K_t, N_t)$. We choose the *fmincon* function in MATLAB to execute this simple optimization process which .

Figure 2: Optimized and origin vertical accelerations.

Conclusions

This paper has focused on the vertical motion of the Nonlinear planar model of the Double A-Arm suspension. The comparison between the responses of the three-Dimensional nonlinear model and the one in the simulation software shows that a precise setting in the multibody modeling of mechanical systems can offer great results in short period of time with low processing capacity requirements.

As a final step in the process, this model was transformed to an Objectif function. The use of this function allowed us to generate an optimization algorithm capable of calculating the optimal suspension to improve vehicle ride quality. The vertical acceleration of the chassis was reduced but the process has some difficulties because of the set of the differential-algebraic equations and the constraints violation

Passive suppression of parametric excitation of cables using a nonlinear vibration absorber (NVA)

Pauline Kolb*, Vitor Schwenk† and Guilherme Rosa Franzini †

*Institute of Structural Mechanics and Design, Technische Universität Darmstadt, Darmstadt, Germany

†Universidade de São Paulo, Escola Politécnica, LMO, Brazil

Summary. The usage of non-linear vibration absorbers is a rather new but practical way to prevent a fatigue failure of a structure exposed to especially broad banded dynamic loading. In this work, a non-linear vibration absorber will suppress the response of a flexible rod under parametric excitation. Therefore, a mathematical model is derived using the extended Hamilton's principle. A reduced-order model (ROM) is obtained after the application of the Galerkin's method and is numerically integrated aiming at observing the Mathieu's instability and its suppression. This excitation scenario is common in offshore engineering where parametric excitation appears on risers of TLP tethers, slender structures linked to the seabed and the floating unit. Nonlinear vibration absorbers can be designed, built and installed with a relatively small effort compared to other methods and provide a positive effect on the sustainability of the rod [1]. The results show a suppression of the oscillation is possible to a certain degree, when the NVA reaches a sufficient mass ratio.

Introduction

Besides the academic interest, the studies of parametric excitation have a technological importance on off-shore and ocean engineering. Especially for the dynamic of risers and tendons of TLPs (Tension Leg Platforms), buoyant platforms held in place by a mooring system as can be seen in figure 1. Even though the considered structures are always under tension, the value varies with time due to the vertical movement of the platforms and the change of lifting force.

Figure 1: TLP [4] and system of flexible cable with NVA at $x = \bar{x}$

Parametric excitation

In contrast to external excitation, parametric excitation leads to *homogenous* differential equations with a parameter depending only on time on the left side. Of significance is that even a small parametric excitation produces a large response when the frequency of excitation Ω resembles twice the natural frequency ω of the system (*principle parametric resonance*)[2]. Therefore, an efficient suppression device is to be designed.

Non-linear suppression

A non-linear vibration absorber (NVA) as can be seen in figure 1 has the advantage to be able to react to a broad band loading. Due to the absence of a linearizable natural frequency, the NVA uses internal resonances for a spacial transfer of energy and its dissipation. This process is known as energy pumping, or TET (Targeted Energy Transfer). Further information can be found in papers by Lee [3] and Vakakis [5].

Mathematical model

Consider a flexible cable with a diameter D , mass per unit length μ and the structural damping ratio c . A rotative NVA (mass m , radius r) is attached to the cable at the height \bar{x} by a dashpot (c_θ), as can be seen in figure 1. The kinetic energy T and the potential energy V with $\epsilon = u' - zw'' + \frac{1}{2}w'^2$ are regarded for the Lagrangian, as well as the virtual work

for extended Hamilton's principle. Using Galerkin's method by considering one degree of freedom (1-DOF) and placing the NVA at midspan, the non-dimensional equations of motion can be written as seen in equation 1 for the system and equation 2 for the NVA.

$$\left(\frac{1}{2} + \hat{m}\right)\ddot{A}_1 + \zeta_s \dot{A}_1 + K_3 \dot{A}_1 |\dot{A}_1| + [K_0 + \bar{K} \cos \eta \tau] A_1 + K_2 A_1^3 = \hat{r} \hat{m} (\ddot{\Theta} \sin \Theta + \dot{\Theta}^2 \cos \Theta) \quad (1)$$

$$\ddot{\Theta} - \frac{1}{\hat{r}} \sin \Theta \ddot{A}_1 + 2\zeta_\Theta \dot{\Theta} = 0 \quad (2)$$

Results and discussion

After a numerical Runge-Kutta based integration with MATLAB, the behaviour of structure and NVA can be observed. In figure 2 the time histories can be divided in three main sections, where A and B show the typical behaviour of energy pumping, while C describes a more or less steady oscillation. Figure 2 also shows that depending on given parameters a NVA might also lead to an increase of the main amplitude. To give an overview over the choice of parameters \hat{m} and \hat{r} ,

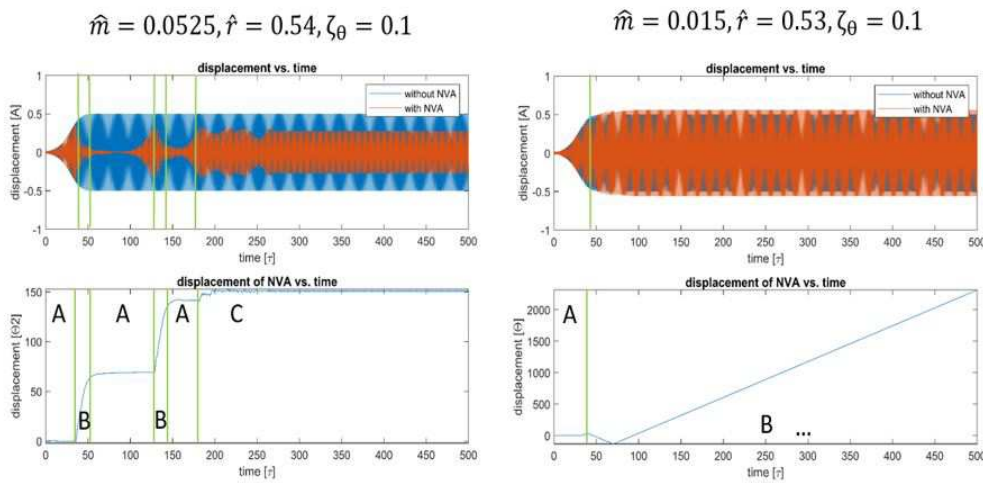

Figure 2: Time history and NVA sections with $\hat{m} = \frac{\text{mass NVA}}{\text{mass cable}}$, $\hat{r} = \frac{r}{D}$

the ratio of standard deviations with and without NVA can be seen in figure 3, where red areas show an increase and blue areas a significant reduction of the main structures vibration.

Summary. Synchronization networks play important roles in Engineering and Physical systems, allowing information distribution and exchange between the components of computation, communication and complex dynamical systems. In the recent decades the growing need for data communication led to the development of a world wide communication and data transmission network. The clock signal distribution network is an important part of these networks. The Phase-Locked Loop (PLL) is the circuit that synchronizes the local oscillator (clock) to a reference signal (phase and frequency scale). Usually, the PLL networks are build in Mutually-Connected or in Master-Slave topologies. In many cases the Master-Slave is used due to its simplicity and low cost. The nonlinear behavior of PLLs makes the design of clock signal distribution networks a difficult task, therefore, numerical simulation is an important tool. In this work, a Two-Way Master-Slave network is build using parallel computation, aiming to develop a more efficient simulation strategy, and to study the effects of the interacting PLLs running in a parallel computation system.

Introduction

Complex systems can be thought as a set of a large number of connected, usually simple, elements, exchanging signal (information), and producing new behaviors difficult to predicted from the components or boundary conditions. The study of dynamical systems arise from the need to understand phenomena, and to build mechanisms or circuits, such as the complex systems. Synchronization networks are complex systems with growing interest given the need for global communication systems [1, 2, 3].

The PLL is the fundamental component of clock signal distribution networks, and consists of a closed-loop control system that synchronizes a local oscillator, or clock, to a reference signal. The PLL block diagram, shown in Fig. 1, is composed of a Phase Detector (PD), of a Low-Pass Filter, and of a Voltage-Controlled Oscillator (VCO) [4].

Figure 1: PLL block diagram.

Given the input and output signals in Eqs. 1 and 2, the multiplier type PD generates an error signal $v_d(t)$ with the same sign of the phase difference $\theta_i(t) - \theta_o(t)$.

$$v_i(t) = v_i \sin(\omega_M t + \theta_i(t)) \quad (1)$$

$$v_o(t) = v_o \cos(\omega_M t + \theta_o(t)) \quad (2)$$

The LPF controls the VCO phase and frequency, according to the relation in 3, around the free-running frequency ω_M , tracking the input phase $\theta_i(t)$ and filtering noise, jitter and wander frequency fluctuations [2, 5, 6].

$$\frac{d}{dt} \theta_o(t) = k_o v_c(t) \quad (3)$$

Considering the foregoing relations the PLL mathematical model is given by Eq. 4,

$$L[\theta_o(t)] + GQ[\sin(\theta_o(t) - \theta_i(t))] = GQ[\sin(2\omega_M t + \theta_i(t) + \theta_o(t))], \quad (4)$$

where $G = \frac{1}{2} k_m k_o v_i v_o$ is the loop gain and the operators L and Q depend on the LPF transfer function [1, 2].

TWMS PLL network

There are many strategies for synchronization of clocks. Each strategy depend on the choice for the network topology. In Mutually-Connected networks all the nodes (PLLs) contribute to the phase and frequency scale of the network, however, in Master-Slave networks, the master clock dictates the phase and frequency scales for the whole network. In most cases the Master-Slave strategy is used due to its simplicity and low cost [2, 7].

In One-Way Master-Slave network the master node alone dictates the phase and frequency scales for the whole network. On the other hand, in the Two-Way Master-Slave strategy, the slave nodes also contribute to the determination of the phase and frequency scales of the network. In Fig. 2(a) the PLL block diagram for a TWMS network is shown. Differently from Fig. 1, the error signal depends on the average phase between the previous and of following nodes, as it shown in Fig. 2(b).

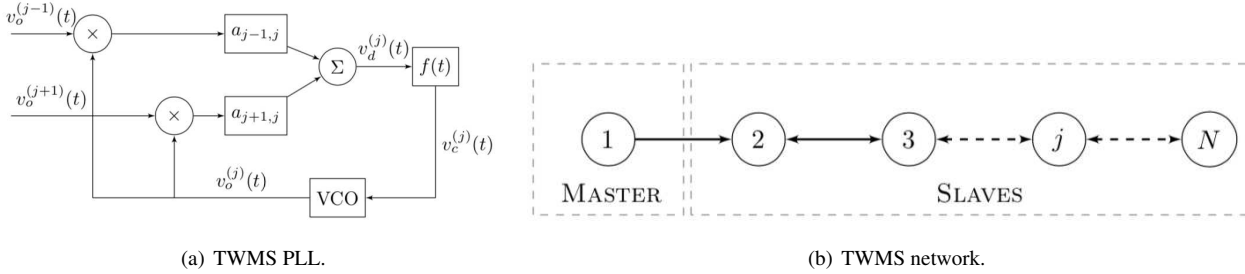

Figure 2: TWMS Clock signal distribution networks.

Following a procedure similar to the previous section the mathematical model of the slave-nodes in a TWMS network is given by

$$L^{(j)} \left[\theta_o^{(j)}(t) \right] + Q^{(j)} \left[\sum_{\substack{\ell=j-1 \\ \ell \neq j}}^{j+1} G^{(j,\ell)} \sin \left(\theta_o^{(j)}(t) - \theta_o^{(\ell)}(t) \right) \right] = Q^{(j)} \left[\sum_{\substack{\ell=j-1 \\ \ell \neq j}}^{j+1} G^{(j,\ell)} \sin \left(2\omega_M t + \theta_o^{(\ell)}(t) + \theta_o^{(j)}(t) \right) \right] \quad (5)$$

where $j = 2, 3, \dots, N$, $G^{(j,\ell)} = \frac{1}{2} a_{\ell,j} k_m^{(j)} k_o^{(j)} v_o^{(j)} v_o^{(\ell)}$ is the loop gain and the operators $L^{(j)}$ and $Q^{(j)}$ depend on each slave node LPF transfer function.

As it can be noticed from Fig. 2, the phase and frequency scales for the slave nodes depend on the master clock and on the parallel interaction of the slave nodes. Although this is a MS strategy, there is a mutual connection of the slave nodes. The nonlinear and simultaneous interactions generate complex dynamic behaviors. In this case parallel computing is helpful to study and to build more realistic synchronization networks models.

Parallel Programming

Parallel computation consists of solving parts of the system concurrently, that is, in parallel, and in different processors (or cores), in order to reduce the simulation time. In addition, this technique gives more flexibility to build the network [8].

MATLAB's Parallel Computing Toolbox (PCT) allows the developer to work with memory sharing and distributed memory architecture. Within this tool, the development of the "local" infrastructure is built inside a multi-core computer [9]. Generally speaking, hardware architectures are commonly two-, four-, or eight-core versions.

PCT delivers functions to MATLAB such as parallel loop execution, creation and/or manipulation as well as enabling the construction of animal arrays of parallel logic. PCT allows you to use even the cores of the machine on which they all run as they enable interactive development and debugging of code in parallel logic. As a possibility of expanding the work developed on this platform, the largest developed can scale to a number of cores using the MATLAB Distributed Computing Server [10]. Fig. 3 shows a division of the sections into desktop system and cluster computer.

Using MATLAB's PCT, a program with parallel logic can be expressed in three different ways [11]:

1. by the *parfor* feature, which executes a for loop in parallel;
2. by the *spmd* feature, which creates a synchronous process of cooperation;
3. by the *task* feature, which creates multiple, independent programs.

Among the PCT functions, *parfor* (parallel for)-loop stands out, which is very useful in situations that require several iterations in a loop, with a simple function being executed between these iterations, such as Monte Carlo simulations and image processing. In order to run the *parfor*, it is necessary to use PCT, adapting the original code to the new commands of that toolbox [12].

The iterations that run in *parfor* are independent and run in independent instances of MATLAB, running them separately from the operating system process. That way, the function that will be executed at each iteration cannot depend on results that are found in that loop. This is due to the construction of *parfor* inside the PCT, which does not share memory during execution. The application of this solution is feasible for different computers connected via the network because the PCT is able to transform each core of this network into a processing unit of *parfor* iterations [9, 12, 13].

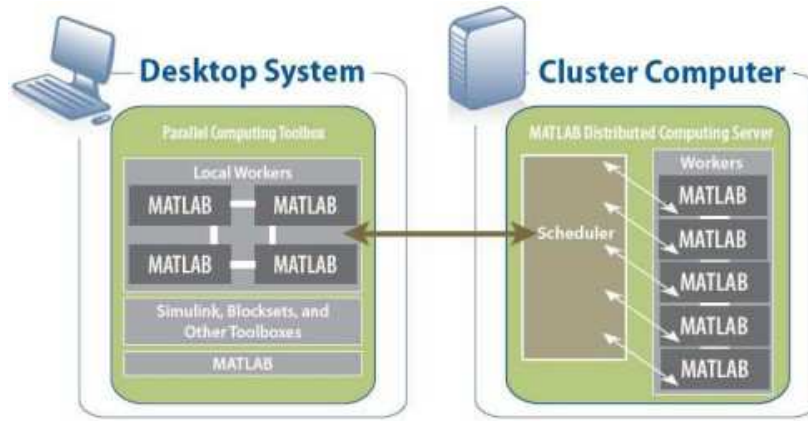

Figure 3: The Parallel Computing Toolbox and MATLAB Distributed Computing Server [10].

Proposed Algorithm

For the development of the work, the necessary calculation steps for the execution of the PLL were followed. Thus, in the first moment, the phase comparison of the input signal and the output signal of the VCO of the PLL itself was performed. This signal is called VD and it feeds the LPF filter of the PLL, in which the fourth-order Runge-Kutta integrative method is used, in which the implementation was based on [14]. Finally, the output signal from the LPF, called VC, is directed to the VCO, closing the loop. The proposed algorithm for running the simulations has three main sections:

1. Definition of initial and simulation parameters – the following questions are answered: What is the input signal; What is the size of the network; What is the start time, end time and sample rate of the simulation; What are the filter parameters;
2. TWMS network simulation – the calculations referring to the constructed TWMS network are performed, in which the calculation of the LPF output is performed in parallel;
3. Construction and presentation of the results obtained – creation of an output file with the simulation results and graphs of the system's behavior.

In this work, the development of parallelism via TPC was chosen through the function *parfor*. Basically in the PLL integration loop, the repetitive structure that advances in time according to the sample rate is a *for* structure. This structure directs the “round” the system is in, that is, it manages the integration step. In this case, we call it the main program. Within the main program, due to the LPF operation, we need an integration, so that the control signal for the VCO (which in this case is the LPF output) is found. In this step, the *parfor* was applied, that is, the calculation of all PLLS of the TWMS network is performed simultaneously.

Simulation features

The simulated TWMS network is formed by a PLL Master, a PLL Slave, called Slave 1, whose input signal $v_i(t)$ depends on both the Master and Slave 2, and another PLL Slave, called Slave 2, whose signal depends only on the output signal $v_o(t)$ of Slave 1, as described in [15].

Results to step

The simulated TWMS network contains a PLL Master, Slave 1 (having its input signal dependent on the output signals of the PLL Master and Slave 2) and Slave 2 (having its input signal dependent only on Slave 1). The simulations followed the models found in [4, 15, 16, 17].

When analyzing Fig. 4, we see that the PLL Master and Slave 2 are in sync with the input signal because the phase error of θ_o with respect to θ_i is zero. This fact is confirmed by observing Fig. 5 which are results of the steady state of the network. In this case, the Lissajous figure in the post-transient regime demonstrates that the PD input ($v_i(t)$) and the VCO output ($v_o(t)$) of Master and Slave 2 are signals periodic, with the same frequency and quadrature phase, implying synchronization.

Slave 1, in the studied interval, does not reset the phase error of the output in relation to the input. This fact evidenced by Fig. 4 and 5. The signal of Slave 1, when looking at the Lissajous graph, the behavior of the PD input ($v_i(t)$) and the VCO output ($v_o(t)$) Slave 1 has $\theta_o(t)$ equal to 180° , thus being out of phase in relation to $\theta_i(t)$, implying non-synchronization.

Figure 4: TWMS: Phase error of the step response.

Figure 5: TWMS: Lissajous of the step response.

Results to ramp

When we apply a ramp to the network and observe the behavior of the network, we see that in the TWMS model that the phase of θ_o in relation to θ_i follows the ramp. In Fig 9, we notice that the Master, Slave 1 and Slave 2 replicate the ramp applied to the PD ($v_i(t)$), causing the VCO output ($v_o(t)$) has the same behavior, not synchronizing any of the network PLLs.

Figure 6: TWMS: Master's response to ramp.

Figure 7: TWMS: Slave 1's response to ramp.

Figure 8: TWMS: Slave 2's response to ramp.

Figure 9: TWMS: Phase error of the ramp response.

Conclusion

In the TWMS network, composed of 3 PLLs, when we apply a step to the input signal phase, we notice that through the phase error and the Lissajous figures that the Master and Slave 2 synchronize with this signal, having a jitter due to the

characteristics of the simulated system. Slave 1 has as a response the non-synchronization with the input signal, a fact observed in the phase error and also by its Lissajous, whose arrangement indicates a phase delay in the order of 180° , as shown in [17].

When applying a ramp to the input phase, it is noted that both the Master and Slaves do not find a control voltage capable of tuning the output signal with the input applied. As shown in [15, 17], the ramp signal causes synchronization failures in all PLLs.

Stability Analysis of Rotary Drilling Systems Associated with Multiple State-Dependent Delays

He Zhang* and Emmanuel Detournay†

*Department of Civil, Environmental, and Geo-Engineering, University of Minnesota, Minneapolis, MN, USA, 55414;

Summary. This paper presents an algorithm to conduct numerical linear stability analyses of rotary drilling systems equipped with a realistic Polycrystalline Diamond Compact (PDC) bit. The interaction between a PDC bit and the rock introduces up to 100 state-dependent delays into the differential equations governing the rotary drilling system, here represented by a discrete multiple degrees of freedom model. A bit trajectory function is proposed to convert the time delays into their corresponding angular delays that are embedded in the PDC bit design. The proposed algorithm has the potential to be used for optimizing PDC bit design with the goal of postponing the occurrence of torsional stick-slips.

Introduction

Torsional stick-slip vibrations are destructive dynamic phenomena encountered during rotary drilling of oil and gas wells. The torsional stick-slips are characterized by alternating stick phases with the bit at rest for a period of time and slip phases, during which the angular velocity of the tool increases up to two times the nominal angular velocity. The root cause of the torsional stick-slip oscillations lies in the nature of bit-rock interaction as both laboratory and field measurement data have shown that PDC bit design has a significant influence on the torsional stick-slips. However, it is a challenging problem to model the interaction between a realistic PDC bit and the rock, which is associated with two major sources of nonlinearities: (i) the regenerative rock cutting process introduces up to 100 state-dependent delays due to the complex layout of PDC cutters; (ii) the unilateral nature of the frictional contact process introduces a discontinuity in the boundary conditions [1]. The search for the numerous state-dependent delays in numerical simulations is, however, CPU intensive, which renders the computational efficiency of conventional solution strategies unacceptable.

This difficulty has recently been overcome by Tian et al [1], who employed a bit trajectory function [2, 3], to reformulate the time delay-related variables. In this way, the state-dependent time delays are converted into the corresponding angular delays that are known from the PDC bit designs. The evolution of the bit trajectory function is governed by a partial differential equation (PDE), which is coupled by the system of ordinary differential equations (ODEs) that governs the dynamics of the discretized drillstring. By the application of the Galerkin method, the coupled system of PDE-ODEs are transformed into a system of ODEs, which can be efficiently integrated. The drillstring in [1] is, however, simplified as a low-dimensional (LD) discrete model that solely consists of two degrees of freedom (DOFs). This LD drillstring model considers only one torsional DOF, which is thus unable to capture the higher modes of torsional resonance that are usually responsible for the occurrence of torsional stick-slips [3].

This paper extends the LD drillstring model in [1] to a high-dimensional model (HD) with multiple DOFs. Instead of pursuing the time simulation of the HD model with strong nonlinearities, this paper focuses on its linear stability analysis, which provides useful information regarding the growth rate of torsional vibrations into stick-slip oscillations by the examination of unstable poles. The linear stability analysis thus has the potential application in the optimization of PDC bit designs in terms of postponing the occurrence of torsional stick-slips due to its high computational efficiency.

Numerical Stability Analysis

The PDC bit-rock interaction model is adopted from [1], while the HD drillstring model is the same as that in [3]. A combination of both leads to a system of nonlinear coupled PDE-ODEs governing the dynamics of the HD model. The reader is referred to the references [1, 3] for a full description of the derivation. Linearization of this nonlinear system is carried out around the equilibrium point by imposing small perturbations to the steady-state variables. The system of linear coupled PDE-ODEs that governs the perturbation of bit trajectory $\tilde{h}(\theta, \tau)$ function and state variables reads

$$\frac{\partial \tilde{h}}{\partial \tau} + \omega_0 \frac{\partial \tilde{h}}{\partial \theta} + \dot{\varphi}_b \frac{v_0}{\omega_0} = 0, \quad (1)$$

$$\hat{I} \ddot{\mathbf{u}} + \hat{C}_a \dot{\mathbf{u}} + \hat{K}_a \mathbf{u} = \hat{\mathbf{W}}, \quad (2)$$

$$\hat{I} \ddot{\boldsymbol{\varphi}} + \hat{C}_t \dot{\boldsymbol{\varphi}} + \hat{K}_t \boldsymbol{\varphi} = \hat{\mathbf{T}}, \quad (3)$$

where v_0 (ω_0) is the non-dimensional nominal axial (torsional) velocity; $\dot{\varphi}_b$ is the perturbed bit angular velocity; \hat{I} is the unit diagonal matrix; \hat{C}_a (\hat{C}_t) and \hat{K}_a (\hat{K}_t) are the dimensionless damping and stiffness matrices for axial (torsional) motion; \mathbf{u} , $\boldsymbol{\varphi}$, $\hat{\mathbf{W}}$, $\hat{\mathbf{T}}$ represent, respectively, the vectors of dimensionless axial and angular displacement, external axial force and torque. The perturbed bit trajectory function $\tilde{h}(\theta, \tau)$ can be approximated by

Figure 1: Stability map in the space of the operating parameters (weight-on-bit and rotary speed) for two PDC bit designs: (a) bit A and (b) bit B. The red color denotes the region of operating parameters with large real parts, while the green color represents the region with smaller real parts.

$$\tilde{h}(\theta, \tau) = \tilde{a}_0 \left(1 - \frac{\theta}{2\pi}\right) + \tilde{a}_1 \frac{\theta}{2\pi} + \sum_{k=1}^{N-1} \tilde{a}_{k+1} \sin\left(\frac{k\theta}{2}\right), \quad \theta \in [0, 2\pi), \quad (4)$$

Substituting the approximation (4) into the linearized PDE (1) and invoking the Galerkin method to minimize the resulting residual $\tilde{\mathcal{R}}$ yields a system of first-order ODEs that governs the evolution of the perturbed coefficients

$$\int_0^{2\pi} \tilde{\mathcal{R}} \frac{\theta}{2\pi} d\theta = 0, \quad \int_0^{2\pi} \tilde{\mathcal{R}} \sin\left(\frac{m\theta}{2}\right) d\theta = 0, \quad m = 1, \dots, N-1. \quad (5)$$

This systems of ODEs together with the system of ODEs in (2)-(3) can be written in the matrix-vector form as

$$\mathbf{A} \dot{\tilde{\mathbf{X}}} + \mathbf{B} \tilde{\mathbf{X}} = \mathbf{0} \quad (6)$$

where \mathbf{A} and \mathbf{B} are coefficient matrices and $\tilde{\mathbf{X}}$ comprises the perturbed state variables and coefficients \tilde{a}_i , $i = 1, 2, \dots, N$. The linear stability analysis of the system of coupled PDE-ODEs (1)-(3) has thus been replaced by the equivalent stability analysis of the linear system of ODEs (6). If the system is stable, the perturbed vector $\tilde{\mathbf{X}}$ converges to the null vector; otherwise, $\tilde{\mathbf{X}}$ grows exponentially. The instability of the linear system of ODEs (6) is indicated by positive real part of the eigenvalues of the matrix $\mathbf{A}^{-1}\mathbf{B}$.

Numerical results

Surface rotary speed (RPM) and weight-on-bit (WOB) are two operating parameters that are commonly adjusted to alleviate drillstring vibrations. Preliminary linear stability analyses have shown that the drillstring system is unstable within the practical ranges of the operating parameters (weight-on-bit and rotary speed). This indicates that the torsional vibrations will always degenerate into stick-slips given enough time.

Extensive simulation results have shown that the most unstable pole with the maximum real part of the system (6) corresponds to the axial dynamics of the drillstring. The magnitude of the real part of the most unstable pole determines the rate at which the axial dynamics evolves eventually to the axial stick-slips. Therefore, the values of the operating parameters that lead to smaller real parts of the most unstable poles will delay the occurrence of axial stick-slips. Figure 1 presents the distributions of maximum real parts of the eigenvalues for different combinations of operating parameters for two PDC bit designs. It is observed that different PDC bit designs have different optimum pairs of the operating parameters.

Furthermore, the unstable axial dynamics influences the torsional dynamics via the coupling caused by the bit-rock interaction. It is observed from the time simulation results that the axial stick-slips always precede torsional stick-slips. Therefore, the occurrence of torsional stick-slips can be possibly delayed by selecting PDC bit designs for which the most unstable pole has the smallest real part for prescribed values of the operating parameters.

Conclusions

This paper presents an algorithm for the stability analysis of a high-dimensional drillstring model in conjunction with PDC bit-rock interaction. It is shown that PDC bit designs affect the stability of the drillstring. By recognizing that the most unstable pole corresponds to the axial dynamics and that the axial stick-slips always precede torsional stick-slips, it is possible to delay the occurrence of torsional stick-slips by optimizing PDC bit design that leads to the smallest real part of the most unstable pole. The validity of this approach is currently being verified by time domain simulations.

Two-stroke single-cylinder engine with elastic hinges with preset force characteristics

A.N. Zotov, A.S. Sviridov, A.P. Tokarev

Ufa State Petroleum Technological University, Kosmonavtov Street 1, Ufa, 450062, Russian Federation

Abstract. The work is devoted to balancing a two-stroke single-cylinder engine by installing two elastic hinges with a given characteristic (the dependence of the restoring moment on the angle of rotation) between the strut and the crank and between the crank and the connecting rod. The hinge is an elastic element (spring or pneumatic spring) that moves between the guides of the calculated shape. The characteristic of the elastic hinge between the crank and the connecting rod is such that the lateral force acting on the piston decreases many times during engine operation. With certain parameters of the engine under consideration with a hinge between the crank and the connecting rod, the lateral force acting on the piston is zero at any angle of rotation of the crank. The characteristic of the elastic hinge between the strut and the crank is such that the angular velocity of the crank will be constant. In this case, you can either completely abandon the flywheel in the engine design or significantly reduce its weight. Flywheel inertia can now account for up to 80 percent of all moving parts in an engine. Such parameters of the proposed two-stroke single-cylinder engine are selected, at which it becomes fully balanced. At the moment, the considered problem has been solved for a certain constant angular velocity of the crank. For a different angular velocity, a different characteristic of the elastic hinge will be required. A possible solution to this problem can be the use of a pneumatic spring as an elastic element of the proposed hinges. By changing the pressure in the pneumatic spring in an appropriate way with a change in the angular velocity of the crank, it is possible to achieve the proper coefficient of uneven operation of the considered two-stroke engine. The approach proposed here for balancing a two-stroke single-cylinder engine can also be applied to balancing four-stroke engines.

The problem of balancing internal combustion engines (ICE) based on a crank mechanism (CM) has been the subject of many works, for example [1-4]. This work is devoted to a two-stroke single-cylinder engine (TSSCE) with two elastic hinges with preset force characteristics [5] located between the crank and connecting rod at point A (with characteristic $M_{12}(\varphi)$) and between the crank and connecting rod at point O with characteristic $M_1(\varphi)$ (Fig. 1, (a)). The dependence $M_{Cr}(\varphi)$ on the TSSCE crank shaft was taken from [6] and was approximated by the analytical function (1), where φ is in degrees.

$$\begin{aligned}
 M_{Cr}(\varphi) = & -2,693510959090909 \cdot 10^7 + 1009131,066530486 \cdot (\varphi \cdot \pi/180) - \\
 & -16831,236170949003 \cdot (\varphi \cdot \pi/180)^2 + 164,56930773216035 \cdot (\varphi \cdot \pi/180)^3 - \\
 & -1,0445902415421795 \cdot (\varphi \cdot \pi/180)^4 + 0,004497285554988163 \cdot (\varphi \cdot \pi/180)^5 - \\
 & -0,000013297457442994316 \cdot (\varphi \cdot \pi/180)^6 + 2,665200570792428 \cdot 10^{-8} \cdot (\varphi \cdot \pi/180)^7 - \\
 & -3,463864860887725 \cdot 10^{-11} \cdot (\varphi \cdot \pi/180)^8 + 2,636647972125913 \times 10^{-14} \cdot (\varphi \cdot \pi/180)^9 - \\
 & -8,947485203612654 \cdot 10^{-18} \cdot (\varphi \cdot \pi/180)^{10} + (2,693510959090909 \cdot 10^7 - \\
 & -1008993,066791191 \cdot (\varphi \cdot \pi/180) + 16823,278538256654 \cdot (\varphi \cdot \pi/180)^2 - \\
 & 164,3809582389641 \cdot (\varphi \cdot \pi/180)^3 + 1,0422601817406472 \cdot (\varphi \cdot \pi/180)^4 - \\
 & -0,0044809411801945455 \cdot (\varphi \cdot \pi/180)^5 + 0,000013232168767022518 \cdot (\varphi \cdot \pi/180)^6 - \\
 & -2,651459239985029 \cdot 10^{-8} \cdot (\varphi \cdot \pi/180)^7 + 3,452203947414538 \cdot 10^{-11} \cdot (\varphi \cdot \pi/180)^8 - \\
 & -2,636647972125913 \cdot 10^{-14} \cdot (\varphi \cdot \pi/180)^9 + 8,947485203612654 \cdot 10^{-18} \cdot (\varphi \cdot \pi/180)^{10} \cdot \text{Sign}[180 - \varphi].
 \end{aligned} \quad (1)$$

In this formulation of the problem, a CM with a counterweight on the connecting rod is considered. We consider that the weight of the counterweight is P_4 , and its length is ℓ_0 . Rod weight AC_4 was not taken into account (Fig. 1).

Fig. 1.

To determine the dependence $M_{12}(\varphi)$ in steady state, taking into account the operating resistance $M_{res.}$, the horizontal force $F^{pot.}$ acting on the piston from condition (2) was determined.

$$F^{pot.}(\varphi)dx = M_{Cr.}^{pot.}(\varphi)d\varphi, \quad (2)$$

where $M_{Cr.}^{pot.}(\varphi) = M_{Cr.}(\varphi) - \int_0^{2\pi} M_{Cr.}(\varphi)d\varphi/2\pi$ - potential component of the moment on the shaft of the ICE ($\int_0^{2\pi} M_{Cr.}^{pot.}(\varphi)d\varphi = 0$) in the steady state of the engine, taking into account the resistance (Fig. 1, (a)).

It is assumed that dependence (1) and, consequently, dependence (2) can be determined for any TSSCE. Figure 2 shows the dependencies $M_{Cr.}(\varphi)$ (dependence 1 according to formula (1)) and $M_{Cr.}^{pot.}(\varphi)$ (dependence 2) at one turn of the crank.

Fig. 2.

Omitting calculations for dependence (2), we write an expression for $F^{pot.}(\varphi)$ ($\oint F^{pot.}dx = 0$).

$$F^{pot.} = M_{Cr.}^{pot.}/((r_1 + r_2) \cdot \sin \varphi \cdot \left(1 + \lambda \frac{\cos \varphi}{\sqrt{1 - \lambda^2 \sin^2 \varphi}}\right)), \quad (3)$$

where r_1 – distance from point 0 to the center of mass of the crank; $(r_1 + r_2)$ – crank length; $\lambda = \frac{(r_1 + r_2)}{(\ell_1 + \ell_2)}$; ℓ_1 – distance from point A to the center of gravity of the connecting rod AB; $(\ell_1 + \ell_2)$ – crank length AB.

To determine the dependence $M_{12}(\varphi)$ (4), in which the lateral force R_{43} acting on the piston is equal to 0 at any angle of rotation of the crank (Fig. 1, (b)), the sum of the moments of active forces ($P_2, P_3, P_4, F^{pot.}$), inertia forces ($P_3 \cdot \ddot{x}_B/g, P_2 \cdot \ddot{x}_{C2}/g, P_2 \cdot \ddot{y}_{C2}/g, P_4 \cdot \ddot{x}_{C4}/g, P_4 \cdot \ddot{y}_{C4}/g$), torque inertia of the connecting rod ($I_{C_2}^{(2)} \cdot \varepsilon_2$) relative to point A. It was assumed that the angular velocity of the crank φ is constant. The direction of rotation of the crank is counterclockwise (Fig. 1, (a)).

$$\begin{aligned}
 M_{12} = & -P_4 \cdot h_5 + P_3 \cdot h_1 + P_2 \cdot h_3 + I_{C2}^{(2)} \cdot \varepsilon_2 + \frac{P_3}{g} \cdot \ddot{x}_B \cdot h_2 + F^{pot.} \cdot h_2 + \\
 & + \frac{P_2}{g} \cdot \ddot{x}_{C2} \cdot h_4 + \frac{P_2}{g} \cdot \ddot{y}_{C2} \cdot h_3 - \frac{P_4}{g} \cdot \ddot{x}_{C4} \cdot h_6 - \frac{P_4}{g} \cdot \ddot{y}_{C4} \cdot h_5,
 \end{aligned} \quad (4)$$

where $h_1 = (\ell_1 + \ell_2) \cdot (1 - 0,25\lambda^2 + 0,25\lambda^2 \cdot \cos 2\varphi)$; $h_2 = (\ell_1 + \ell_2) \cdot \lambda \cdot \sin \varphi$; $h_6 = \ell_0 \cdot \lambda \cdot \sin \varphi$;
 $h_3 = \ell_1 \cdot (1 - 0,25\lambda^2 + 0,25\lambda^2 \cdot \cos 2\varphi)$; $h_4 = \ell_1 \cdot \lambda \cdot \sin \varphi$ $h_5 = \ell_0 \cdot (1 - 0,25\lambda^2 + 0,25\lambda^2 \cdot \cos 2\varphi)$;
 $\varepsilon_2 = \lambda \cdot \dot{\varphi}^2 \cdot \sin \varphi \cdot (1 - (\lambda \cdot \cos \varphi / (1 - 0,25\lambda^2 + 0,25\lambda^2 \cdot \cos 2\varphi))^2) / (1 - 0,25\lambda^2 + 0,25\lambda^2 \cdot \cos 2\varphi)$;
 $\ddot{x}_B = -(r_1 + r_2) \cdot \dot{\varphi}^2 \cdot (\cos \varphi + \lambda \cdot \cos 2\varphi)$; $\ddot{x}_{C2} = -(r_1 + r_2) \cdot \cos \varphi \cdot \dot{\varphi}^2 - \ell_1 \cdot \lambda^2 \cdot \cos 2\varphi \cdot \dot{\varphi}^2$;
 $\ddot{y}_{C2} = -\ell_2 \cdot \lambda \cdot \dot{\varphi}^2 \cdot \sin \varphi$; $\ddot{x}_{C4} = -(r_1 + r_2) \cdot \cos \varphi \cdot \dot{\varphi}^2 + \ell_0 \cdot \lambda^2 \cdot \cos 2\varphi \cdot \dot{\varphi}^2$;
 $\ddot{y}_{C4} = -(r_1 + r_2 + \ell_0 \cdot \lambda) \cdot \sin \varphi \cdot \dot{\varphi}^2$.

In the absence of an elastic hinge at point A , the lateral force R_{430} will be determined by the dependence (5).

$$R_{430} = M_{12} / ((\ell_1 + \ell_2) \cdot (1 - 0,25 \cdot \lambda^2 + 0,25 \cdot \lambda^2 \cdot \cos 2\varphi)) \quad (5)$$

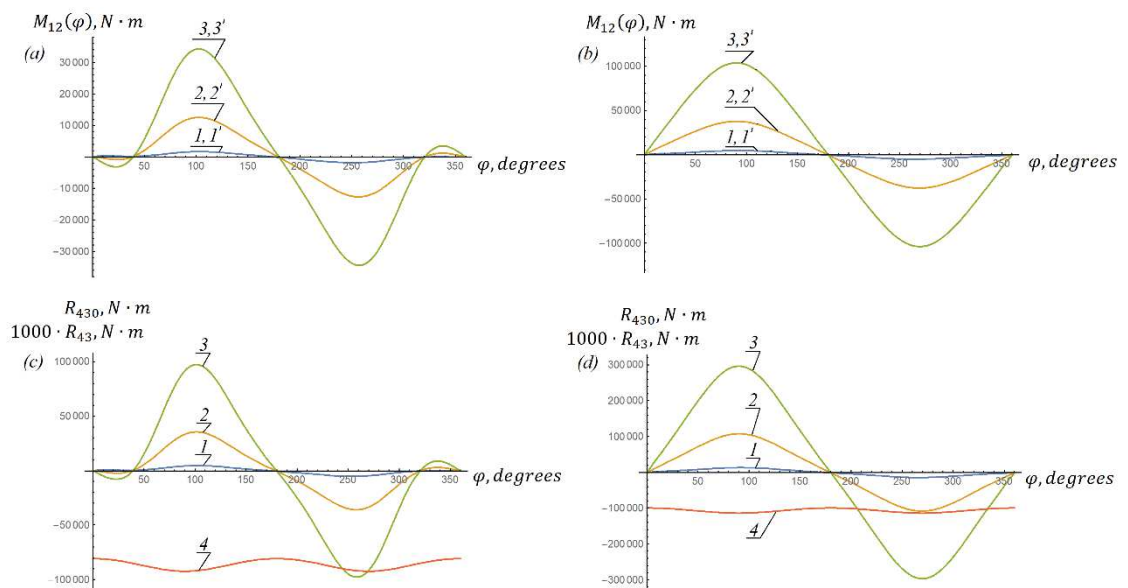

Dependence (4) turned out to be such that $\int_0^{2\pi} M_{12}(\varphi) d\varphi \neq 0$. It should be noted that $\int_0^{2\pi} M_{12}(\varphi) d\varphi$ does not depend on the angular velocity of the crank. To obtain such dependence $M_{12}^{pot.}(\varphi)$ that $\int_0^{2\pi} M_{12}^{pot.} d\varphi = 0$, dependence (6) can be used.

$$M_{12}^{pot.} = M_{12} - \int_0^{2\pi} M_{12} d\varphi / 2\pi \quad (6)$$

When the elastic hinge is located with characteristic (6), the lateral force acting on the piston $R_{43}(\varphi)$ (Fig. 1, (b)), is determined by the following expression.

$$R_{43} = \int_0^{2\pi} M_{12} d\varphi / (2\pi \cdot (\ell_1 + \ell_2) \cdot (1 - 0,25 \cdot \lambda^2 + 0,25 \cdot \lambda^2 \cdot \cos 2\varphi)) \quad (7)$$

Fig. 3 shows the dependencies $M_{12}(\varphi)$, $M_{12}^{pot.}$, $R_{430}(\varphi)$, $R_{43}(\varphi)$ obtained by dependences (4), (5), (6), (7), respectively. Options (a) and (c) were obtained with $P_4 = 0$ and $\ell_0 = 0$. Variants (b) and (d) were obtained with such values of P_4 and ℓ_0 ($P_4 = 20$ N, $\ell_0 = 0.4$ m) that the center of mass of the system “counterweight at point C_4 -rod-piston” is at point A .

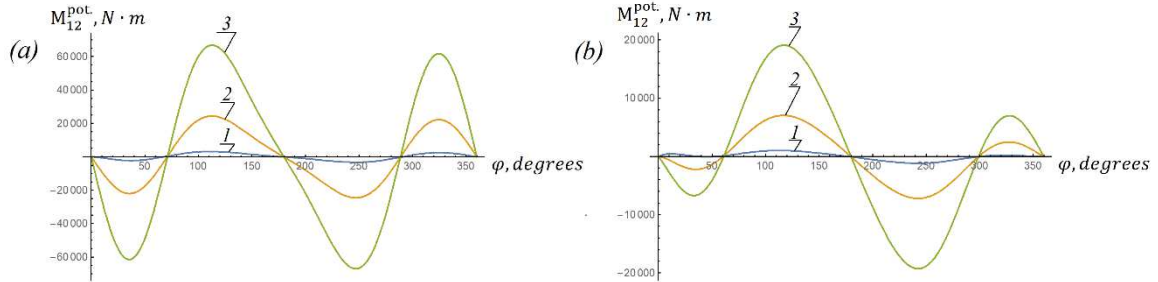

$$r_1 = 0,1 \text{ m}; r_2 = 0,1 \text{ m}; \ell_1 = 0,2 \text{ m}; \ell_2 = 0,2 \text{ m}; P_2 = 10 \text{ N}; P_3 = 15 \text{ N};$$

$$1 - \dot{\varphi} = 100 \text{ s}^{-1}; 2 - \dot{\varphi} = 300 \text{ s}^{-1}; 3 - \dot{\varphi} = 500 \text{ s}^{-1}; 4 - \text{dependence } R_{430}(\varphi) \text{ according to (5).}$$

Fig. 3.

As can be seen from Figure 3, the dependences $M_{12}(\varphi)$ (without a prime) and $M_{12}^{pot.}$ (with a prime) practically coincide. Installing an elastic hinge with a given characteristic between the crank and the connecting rod reduces the lateral force acting on the piston $R_{43}(\varphi)$ hundreds of times. It should be noted that the reaction $R_{43}(\varphi)$ is practically independent of the angular velocity of the crank for these parameters. It was possible to select such parameters of the system under consideration, in which the lateral force $R_{43}(\varphi)$ is equal to zero at any angle of rotation of the crank. Figure 4 shows such dependencies. Option (a) obtained with $P_4 = \ell_0 = 0$. Option (b) with $P_4 = 10 \text{ N}$ и $\ell_0 = 0.1 \text{ m}$. For the case when the center of mass of the system “counterweight at point C₄-rod-slider” is at point A, select such parameters for which $R_{43}(\varphi) = 0$ at any angle φ , failed.

$$r_1 = 0,1 \text{ m}; r_2 = 0,1 \text{ m}; 1 - \dot{\varphi} = 100 \text{ s}^{-1}; 2 - \dot{\varphi} = 300 \text{ s}^{-1}; 3 - \dot{\varphi} = 500 \text{ s}^{-1};$$

$$a) \ell_1 = 0,2 \text{ m}; \ell_2 = 0,2 \text{ m}; P_2 \approx 54,40 \text{ N}; P_3 = 79 \text{ N};$$

$$b) \ell_1 = 0,4 \text{ m}; \ell_2 = 0,4 \text{ m}; P_2 = 10 \text{ N}; P_3 \approx 18,16 \text{ N}.$$

Fig. 4.

The case was considered when the angular velocity of the crank is constant. To determine the characteristics of the elastic hinge at point 0 ($M_1(\varphi)$, Fig. 1, (a)) the Lagrange equation of the second kind was compiled.

$$\frac{d}{dt} \left(\frac{\partial T}{\partial \dot{\varphi}} \right) - \frac{\partial T}{\partial \varphi} = Q_{\delta \varphi}, \quad (8)$$

where $T = \frac{1}{2} I_{\text{giv.}} \cdot \dot{\varphi}^2$ – kinetic energy of the mechanism in Fig. 1, (a));

$$\begin{aligned} I_{\text{giv.}} = & I_0^{(1)} + \frac{P_2}{g} \cdot (r_1 + r_2)^2 \cdot \left[(\sin \varphi - \frac{\ell_1 \cdot \lambda}{2(\ell_1 + \ell_2)} \cdot \sin 2\varphi)^2 + \frac{\ell_2^2 \cdot \cos^2 \varphi}{(\ell_1 + \ell_2)^2} \right] + I_{C_2}^{(2)} \cdot \frac{\lambda^2 \cdot \cos^2 \varphi}{(1 - \frac{1}{4} \lambda^2 + \frac{1}{4} \lambda^2 \cos 2\varphi)^2} + \\ & + \frac{P_3}{g} \cdot (r_1 + r_2)^2 \cdot (\sin \varphi + \frac{1}{2} \lambda \cdot \sin 2\varphi)^2 + \frac{P_4}{g} \cdot \frac{\lambda^2 \cdot \cos^2 \varphi}{(1 - \frac{1}{4} \lambda^2 + \frac{1}{4} \lambda^2 \cos 2\varphi)^2} \cdot ((\ell_0 + \ell_1 + \ell_2)^2 + \\ & + 2(\ell_0 + \ell_1 + \ell_2) \cdot ((r_1 + r_2) \cdot \cos \varphi + (\ell_1 + \ell_2) \cdot (1 - \frac{1}{4} \lambda^2 + \frac{1}{4} \lambda^2 \cos 2\varphi)) \cdot \text{tg} \varphi \cdot \lambda \cdot \sin \varphi) + \frac{P_5}{g} \cdot r_0^2; \end{aligned}$$

 & - 0,25\lambda^2 + 0,25\lambda^2 \cdot \cos 2\varphi)^2)
 \end{aligned}$$

$$Q_{\delta\varphi} = F^{pot.} \cdot \left((r_1 + r_2) \cdot \sin \varphi + \frac{(r_1 + r_2)^2 \cdot \sin 2\varphi}{2 \cdot (\ell_1 + \ell_2)} \right) + M_1 - P_1 \cdot r_1 \cdot \cos \varphi + P_5 \cdot r_0 \cdot \cos \varphi - \frac{P_2 \delta y_{C_2} + P_4 \delta y_{C_4} + M_{12} \delta(\varphi + \psi)}{\delta \varphi};$$

P_1, P_2, P_4, P_5 – the weights respectively of the crank, connecting rod, counterweight at point C_4 and counterweight at point C_5 ;

r_1 is the coordinate that determines the position of the center of mass of the crank;

r_0 is the coordinate that determines the position of the counterweight at point C_5 ;

y_{C_2}, y_{C_4} – ordinates of points C_2 and C_4 respectively (Fig. 1); $\delta y_{C_2} = \ell_2 \cdot \lambda \cdot \cos \varphi \delta \varphi$;

$\delta y_{C_4} = (r_1 + r_2) \cdot \cos \varphi \delta \varphi + \ell_0 \cdot (r_1 + r_2) / (\ell_1 + \ell_2) \cdot \cos \varphi \delta \varphi$;

$\delta \psi = (r_1 + r_2) \cdot \cos \varphi \delta \varphi / (\ell_1 + \ell_2) \cdot (1 - 0,25 \cdot (\frac{r_1 + r_2}{\ell_1 + \ell_2})^2 + 0,25 \cdot (\frac{r_1 + r_2}{\ell_1 + \ell_2})^2 \cdot \cos 2\varphi)$;

$$\begin{aligned}
 Q_{\delta\varphi} = F^{pot.} \cdot \left((r_1 + r_2) \cdot \sin \varphi + \frac{(r_1 + r_2)^2 \cdot \sin 2\varphi}{2 \cdot (\ell_1 + \ell_2)} \right) - P_1 \cdot r_1 \cdot \cos \varphi + \\
 + P_5 \cdot r_0 \cdot \cos \varphi + M_1 - P_2 \cdot \ell_2 \cdot \frac{r_1 + r_2}{\ell_1 + \ell_2} \cdot \cos \varphi - P_4 \cdot (r_1 + r_2) \cdot \cos \varphi + \\
 + \ell_0 \cdot \frac{r_1 + r_2}{\ell_1 + \ell_2} \cdot \cos \varphi - M_{12} -
 \end{aligned}$$

$$-M_{12} \cdot \frac{(r_1 + r_2) \cdot \cos \varphi}{(\ell_1 + \ell_2) \cdot (1 - 0,25 \cdot (\frac{r_1 + r_2}{\ell_1 + \ell_2})^2 + 0,25 \cdot (\frac{r_1 + r_2}{\ell_1 + \ell_2})^2 \cdot \cos 2\varphi)};$$

Let us rewrite equation (8) in the following form.

$$I_{giv.} \cdot \ddot{\varphi} + I_{giv.} \cdot \ddot{\varphi} - \frac{1}{2} \dot{\varphi}^2 \cdot \frac{\partial I_{giv.}}{\partial \varphi} = Q_{\delta \varphi}. \quad (9)$$

From equation (9) we obtain the dependence of the moment on the crank on its angle of rotation ($\ddot{\varphi} = 0$).

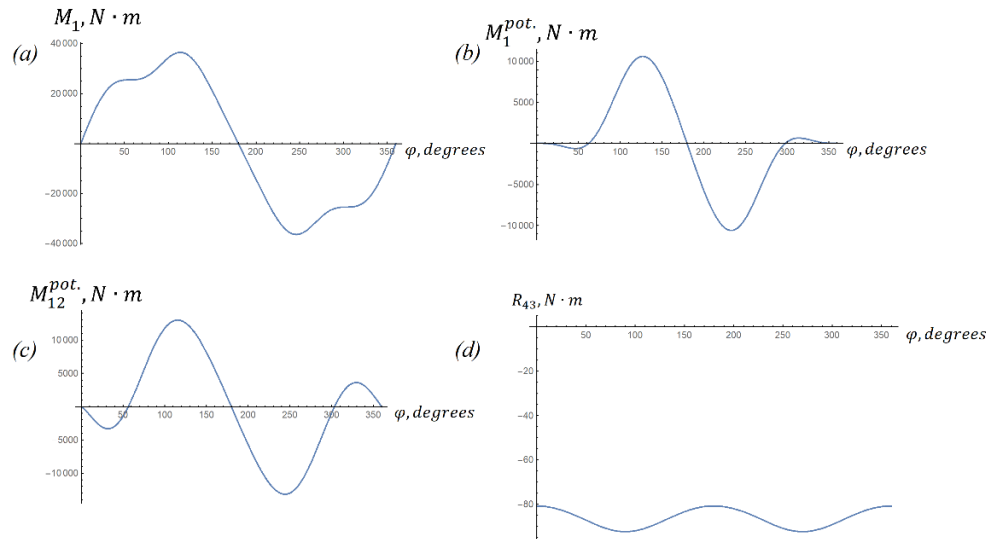

$$\begin{aligned} M_1 = I_{giv.} \cdot \ddot{\varphi} - \frac{1}{2} \dot{\varphi}^2 \cdot \frac{\partial I_{giv.}}{\partial \varphi} - F^{pot.} \cdot \left((r_1 + r_2) \cdot \sin \varphi + \frac{(r_1 + r_2)^2 \cdot \sin 2\varphi}{2 \cdot (\ell_1 + \ell_2)} \right) + \\ + P_1 \cdot r_1 \cdot \cos \varphi - P_5 \cdot r_0 \cdot \cos \varphi + P_2 \cdot \ell_2 \cdot \frac{r_1 + r_2}{\ell_1 + \ell_2} \cdot \cos \varphi + P_4 \cdot ((r_1 + r_2) \cdot \cos \varphi - \\ - \ell_0 \cdot \frac{r_1 + r_2}{\ell_1 + \ell_2} \cdot \cos \varphi) + M_{12} + \\ + M_{12} \cdot (r_1 + r_2) \cdot \cos \varphi / (\ell_1 + \ell_2) \cdot (1 - 0,25 \cdot (\frac{r_1 + r_2}{\ell_1 + \ell_2})^2 + 0,25 \cdot (\frac{r_1 + r_2}{\ell_1 + \ell_2})^2 \cdot \cos 2\varphi). \end{aligned} \quad (10)$$

Variants were considered in which $M_{12} = M_{12}^{pot.}$, that is, in the presence of an elastic hinge with the characteristic $M_{12}^{pot.}(\varphi)$ between the crank and the connecting rod. It turned out that not for all parameters of the considered system $\int_0^{2\pi} M_1 d\varphi = 0$. For example, for the data on which Fig. 3, (b), $\int_0^{2\pi} M_1 d\varphi \approx 14193.2 J$ under the condition of vertical balancing (Fig. 5, (a), - according to equation (10)). Vertical balancing of the CM in Fig. 1, (a) was determined by the following equation

$$P_5 \cdot r_0 \cdot \sin \varphi = P_1 \cdot r_1 \cdot \sin \varphi + P_2 \cdot \ell_2 \cdot \sin \psi + P_4 \cdot (\ell_1 + \ell_2 + \ell_0) \cdot \sin \psi. \quad (11)$$

The weight P_5 from equation (11) is given by the following expression

$$P_5 = \left(P_1 \cdot r_1 + P_2 \cdot \ell_2 \cdot \frac{r_1 + r_2}{\ell_1 + \ell_2} + P_4 \cdot (\ell_1 + \ell_2 + \ell_0) \cdot \frac{r_1 + r_2}{\ell_1 + \ell_2} \right) / r_0 \quad (12)$$

$$\dot{\varphi} = 300 \text{ s}^{-1}; I_0^{(1)} = 0,2 \text{ kg} \cdot \text{m}^2; r_1 = 0,1 \text{ m}; r_2 = 0,1 \text{ m};$$

$$a) r_0 = 0,1 \text{ m}; \ell_0 = 0,4 \text{ m}; \ell_1 = 0,2 \text{ m}; \ell_2 = 0,2 \text{ m};$$

$$P_1 = 5 \text{ N}; P_2 = 10 \text{ N}; P_3 = 15 \text{ N}; P_4 = 20 \text{ N}; P_5 = 47,50 \text{ N};$$

$$b), c), d) r_0 = 0,4 \text{ m}; \ell_0 = 0,2 \text{ m}; \ell_1 = 0,4 \text{ m}; \ell_2 = 0,45 \text{ m};$$

$$P_1 = 20 \text{ N}; P_2 = 30 \text{ N}; P_3 = 30 \text{ N}; P_4 = 30 \text{ N}; P_5 = 31,47 \text{ N}.$$

Fig. 5.

For option (b) $\int_0^{2\pi} M_1 d\varphi = 0$, while $\int_0^{2\pi} M_{12}^{pot.} d\varphi = 0$ ((c), - according to (4)). As can be seen from the figure 5, the lateral force acting on the piston ((d), - according to (7)), is quite small.

The condition for finding the center of mass of the system in fig. 1, (a) at point 0 the following

$$P_5 = ((P_2 + P_3 + P_4) \cdot (r_1 + r_2) + P_1 \cdot r_1) / r_0, \quad (13)$$

where $P_4 = (P_3 \cdot (\ell_1 + \ell_2) + P_2 \cdot \ell_1) / \ell_0$ (the condition for finding the central mass of the system “counterweight at point C₄-rod-posun” at point A, Fig.1).

Figure 6, (a) shows the dependence $M_1(\varphi)$ in the case when the center of mass of the system in Fig.1, (a) is at point 0 (condition (13) is satisfied). Figure 6, (b) shows the dependence of the lateral force acting on the piston on the angle of rotation (in the presence of an elastic hinge at point A, Fig. 1, b).

$$r_0 = 0,4 \text{ m}; r_1 = 0,1 \text{ m}; r_2 = 0,1 \text{ m}; \dot{\varphi} = 300 \text{ s}^{-1}; \ell_0 = 0,2 \text{ m}; \ell_1 = 0,4 \text{ m}; \ell_2 = 0,45 \text{ m};$$

$$I_0^{(1)} = 0,2 \text{ kg} \cdot \text{m}^2; P_1 = 20 \text{ N}; P_2 = 30 \text{ N}; P_3 = 30 \text{ N}; P_4 = 187,50 \text{ N}; P_5 = 128,75 \text{ N}.$$

Fig. 6.

An elastic hinge with a given characteristic is an elastic element, a spring or a pneumatic spring, moving between the guides of the given form (Fig. 7). For option (a), the elastic element is a spring; for option (b) the elastic element is a pneumatic spring. The shape of the guides is such that the reactions N_1 and N_2 create a calculated restoring moment depending on the angle of rotation of the elastic element relative to the guides α . For an elastic hinge at point 0, the angle α is equal to the angle of rotation of the crank φ . For a hinge at point A: $\alpha = \varphi + \psi$, or $\alpha = \varphi + \arcsin(\lambda \cdot \sin\varphi)$. The method for calculating the shape of the guides of an elastic hinge is presented in the article [7]. At first, the guides are calculated assuming that the radius of the rollers in contact with the guides is zero. Then equidistant guides are built to the obtained ones, taking into account the radius of the rollers. For example, according to the dependences $M_{12}^{pot.}(\varphi)$ and $M_1(\varphi)$ derived in this article, it is possible to calculate the guides of the elastic hinges, which will be located between the crank and the connecting rod and between the strut and the crank, respectively. For the steady-state operation of the engine at different constant angular velocities of the crank, elastic hinges with different characteristics are required. From this point of view, elastic hinges are preferable, in which a pneumatic spring is used as an elastic element. Then, with a small change in the magnitude of the angular velocity of the crank, it is possible to achieve the proper coefficient of uneven operation of the considered engine by calculating the pressure change in the air spring [7].

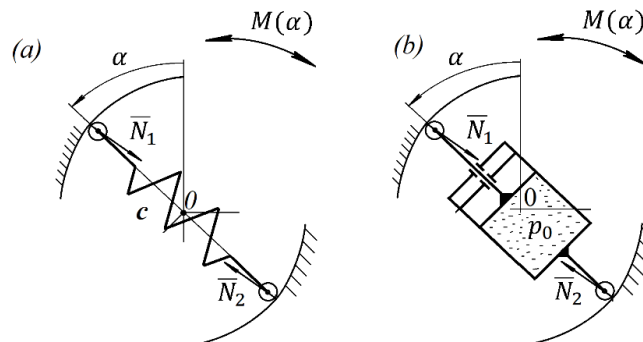

Fig. 7.

Conclusions.

1. Installation of an elastic hinge with a given characteristic between the crank and the TSSCE connecting rod can reduce the lateral force acting on the piston by hundreds of times. For certain parameters of the system under consideration, the lateral force acting on the piston during the operation of the TSSCE is equal to zero at any angle of rotation of the crank.
2. Installation of an elastic hinge with a given characteristic between the strut and the crank, in the presence of an elastic hinge between the crank and the connecting rod, makes it possible to obtain a constant angular velocity of the TSSCE crank with a minimum lateral force acting on the piston.
3. For CM with counterweights on the connecting rod and crank with elastic hinges located between the strut and the crank and between the crank and the connecting rod, it is possible to obtain a fully balanced TSSCE with a constant angular velocity of the crank

When friction and vibro-impact makes music: physical model of the tromba marina

Frédéric Ablitzer, Joël Gilbert, François Gautier

Laboratoire d'Acoustique de l'Université du Mans, CNRS UMR 6613, Le Mans, France

Figure 1: Representation of a tromba marina (adapted from [1]).

The tromba marina (Fig.1) is a bowed string ancient instrument able to imitate the sound of a brass instrument [2, 3]. The functioning of the instrument takes advantage of two non-linear phenomena: dry friction, which allows the emergence of self-sustained oscillations, and vibro-impact mechanism, which makes the “brassy” sound. In this study, a physical model of tromba marina is developed to investigate the phenomenon of spectral enrichment caused by the collisions between one foot of the bridge and the soundboard.

The model consists of a perfectly flexible string fixed at both extremity, vibrating in the plane parallel to the soundboard (Fig. 2a). The string is coupled to a soundboard through the bridge (Fig. 2b). The foot of the bridge located under the string is considered rigidly linked to the soundboard, whereas the other foot is free to move independently of the soundboard, except when they are in contact. The dynamic behavior of the assembly is represented by a set of $N_s + N_b$ modal equations. The N_s modes of the string are known analytically, whereas the N_b modes of the body (soundboard and bridge) are obtained with a finite element model.

Figure 2: (a) Top view of the simplified instrument. (b) Front view of the bridge. P_1 is the coupling point with the string. P_2 and P_3 are the points likely to enter into contact during playing.

The contact law used to produce the vibro-impact mechanism is the Hunt & Crossley model [4]. The model contains three parameters (stiffness coefficient k , non-linear power exponent n and damping coefficient λ) and expresses the contact force as

$$F_c = \begin{cases} k\delta^p + \lambda\delta^p\dot{\delta} & \text{if } \delta > 0 \\ 0 & \text{if } \delta \leq 0, \end{cases} \quad (1)$$

where $\delta = u_3^{z(b)} - u_2^{z(b)} - \varepsilon$ is the indentation between the two bodies in contact (ε is a control parameter which represents the initial gap between the bridge foot and the soundboard, see Fig. 2b). The friction law describing the interaction between the bow and the string assumes that the string perfectly sticks to the bow during sticking phases and that the friction coefficient during sliding phases depends on the relative velocity as

$$\mu(\Delta v) = \mu_d + \frac{\mu_s - \mu_d}{1 - \Delta v/v_0}, \quad (2)$$

where Δv is the relative velocity between the bow and the string, μ_s is the coefficient of static friction, μ_d the asymptotic coefficient of dynamic friction and v_0 a parameter controlling the shape of the friction curve.

Time-domain simulations are performed using an explicit numerical scheme of the form

$$\mathbf{x}(t_{i+1}) = \mathbf{A}\mathbf{x}(t_i) + \mathbf{B}\mathbf{f}(t_i), \quad (3)$$

where \mathbf{x} is a vector containing all modal coordinates and their time derivatives and \mathbf{f} is a vector containing the modal forces. The coefficients in \mathbf{A} and \mathbf{B} are obtained using a piecewise constant approximation of the right-hand side of modal equations. At each time step, the contact force F_c is calculated using the available solution at t_i . The other unknown forces (coupling force F_{bridge}^y between the string and the body, reaction force F_{finger}^y of the finger stopping the string, friction force F_T exerted by the bow on the string) are obtained by enforcing constraints: continuity of displacement

between the string and the body, zero displacement at finger location, sticking or sliding condition. Finally, the pressure radiated by the soundboard is calculated using Rayleigh integral, assuming that it is surrounded by an infinite baffle.

To highlight the phenomenon of spectral enrichment, a *crescendo* is simulated by bowing the open string with linear increase of the bow speed, after a short phase intended to establish a periodic regime, the Helmholtz motion [5, 6]. Figure 3 illustrates the results of the simulation. During a first phase of the simulation, no collision occurs. After $t = 1.6$ s, the body response has sufficient amplitude so that the free foot of the bridge enter into contact with the soundboard. Figure 4a shows the sound pressure radiated by the instrument for the same gesture and Figure 4b the corresponding spectrogram. As expected, the occurrence of collisions from $t = 1.6$ s is accompanied by a strong spectral enrichment. To highlight this, the evolution of the spectral centroid is shown on the same figure. The emergence of high rank harmonics during the *crescendo*, making the sound perceived as “brassy”, is a common feature with brass instruments. However, the effect appears suddenly in the case of the tromba marina, as seen by the abrupt increase in spectral centroid at $t = 1.6$ s, whereas a progressive spectral enrichment is typically observed when a *crescendo* is played on a brass instrument. This significant difference is due to the fact that different physical phenomena are at the origin of the spectral enrichment: non-linear wave propagation in the air column contained in the brass instrument [7], vibro-impact mechanism for the tromba marina.

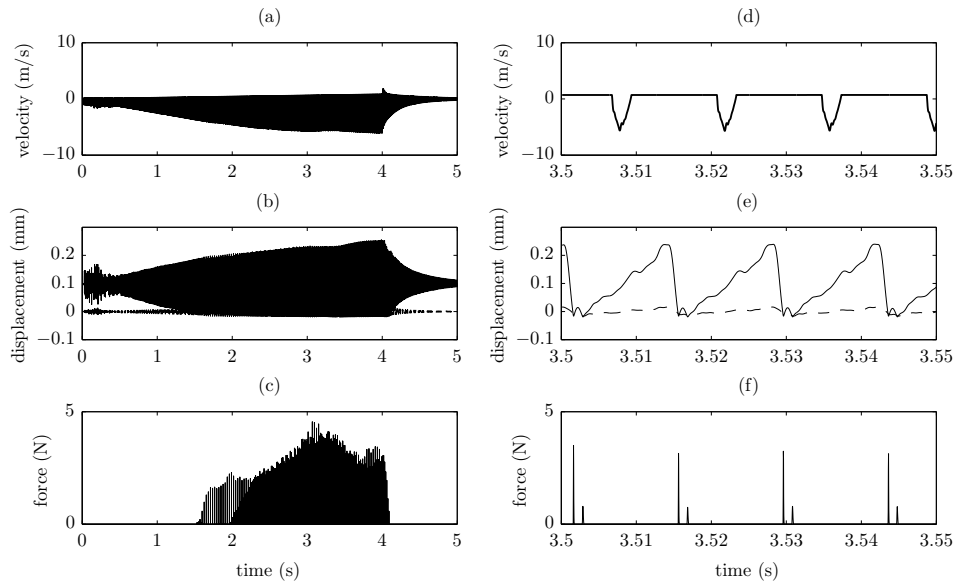

Figure 3: (a)-(d) Velocity of the string at bowing point, (b)-(e) displacement of point P_2 and P_3 (see Fig. 2b), (c)-(f) contact force F_c .

Figure 4: (a) Sound pressure (normalized) radiated during a *crescendo* and (b) its spectrogram. The superimposed red curve is the spectral centroid.

Summary. We are interested in understanding the control mechanism employed by the central nervous system during stick balancing on the fingertip. Although this is a relatively simple balancing task, the underlying control law is still not yet fully understood. In this research, predictor feedback is applied in the mechanical model of stick balancing by taking into account the dead zone of human perception of the stick's state and the reaction delay. Using these assumptions, we derive a switched control model whose behaviour is then investigated as the function of the system parameters.

Introduction

In recent years, the interest on studying human balancing from an engineering point of view is constantly growing [1]. The results of this research can be beneficial in helping people living with balance disorders and in the therapeutic motor control development of children. Stick balancing on the fingertip represents the key features of dynamic balancing, namely, an unstable equilibrium should be stabilized in the presence of reaction time delay and sensory uncertainty. Therefore, in this paper the stick balancing task is studied by developing the mechanical model and performing numerical analysis using the semidiscretization method for time-delay systems [2]. There are several control concepts to model the balancing mechanism, e.g. delayed PD controller [3], PDA controller [4], intermittent controller [5]. Measured time signals of stick balancing tasks suggest that nonlinearities due to switching-type control may be a key feature of human balancing [6]. Here, a switching-type predictor controller is applied to model the control force exerted by human subjects.

Mechanical model and applied controller

Our research group has developed a device, in order to have a simplified measurement setup, where planar stick balancing can be carried out by human subjects. The stick is mounted on a cart via a pin joint and the cart is only allowed to move along a 1-meter-long rail. Subjects sit in a chair so their shoulders are parallel to the rail, therefore, the balancing occurs in the subject's medio-lateral plane [7]. It is assumed, that humans move only their forearm in this balancing task and not their upper arm. The mechanical model of the system is shown in Fig. 1a), where the forearm of the subject is modelled by a truncated cone [8]. The inertia of the forearm and hand can be modelled by a cart of equivalent mass m_a which is added to the mass of the cart m_c and thus, the system is reduced to a two-degree-of-freedom pendulum-cart model shown in Fig. 1b), where $m_e = m_a + m_c$.

Figure 1: a) Schematic 3D figure of the stick balancing task. The cart is linearly driven on a rail and the stick is pinned onto the cart via a planar joint. The subject controls the cart with their hand using a handle that is rigidly fixed to the cart. b) Reduced mechanical model of the stick balancing task.

By taking the generalised coordinates x - the position of the cart - and φ - the angular deviation of the stick -, the equation of motion can be derived for the 2 DoF system. However, x is a cyclic coordinate, and therefore can be eliminated from the equation. After linearisation, the equation of motion reads

$$\ddot{\varphi}(t) = \frac{6g}{cl} \varphi(t) - \frac{6F(t)}{(m + m_e)cl}, \quad (1)$$

where $c = 4 - 3m/(m + m_e)$, m is the mass of the stick, l is the length of the stick, m_e is the equivalent mass of the cart, g is the gravitational acceleration and $F(t)$ is the control force applied by the human. When applying predictor feedback, it is assumed that the internal model of the human is exact, that is it matches the actual system parameters as a result of a

long enough learning process. In this case, the feedback of the predicted state eliminates the delay from the control loop [4] and the control force of the switching-type model predictor feedback is:

$$F(t) = \begin{cases} 0 & \text{if } |\varphi(t - \tau)| < \Pi_\varphi \text{ and } |\dot{\varphi}(t - \tau)| < \Pi_{\dot{\varphi}}, \\ P\varphi(t) & \text{if } |\varphi(t - \tau)| \geq \Pi_\varphi \text{ and } |\dot{\varphi}(t - \tau)| < \Pi_{\dot{\varphi}}, \\ D\dot{\varphi}(t) & \text{if } |\varphi(t - \tau)| < \Pi_\varphi \text{ and } |\dot{\varphi}(t - \tau)| \geq \Pi_{\dot{\varphi}}, \\ P\varphi(t) + D\dot{\varphi}(t) & \text{if } |\varphi(t - \tau)| \geq \Pi_\varphi \text{ and } |\dot{\varphi}(t - \tau)| \geq \Pi_{\dot{\varphi}}, \end{cases} \quad (2)$$

where it is assumed, that the angular deviation and the angular velocity of the stick is sensed by the human perception and the prediction is made based on these measured values. The human sensory dead zone is also accounted for in the model of the control force, hence the switching. Different sensory dead zones are applied for the angle and angular velocity of the stick denoted by Π_φ and $\Pi_{\dot{\varphi}}$, respectively. The switching of the control force occurs with a time delay τ , since it takes a finite time for the human to detect that the stick is out of the dead zone, which is equal to the reaction delay of the subject. Substituting $F(t)$ into Eq. (1) gives a nonlinear model of human balance control.

Numerical study

A numerical study on the stability of the system is carried out using the semidiscretization method [2] as a function of the system parameters P , D and τ . The values of $m_e = 1.73$ [kg], $m = 0.1$ [kg] and $l = 0.9$ [m] are held constant during the analysis. The equivalent mass is determined by anthropometric data from [9] and by measuring $m_e = 0.12$ [kg]. Because of the model predictor feedback, the discrete map corresponds to a sampled output system without any feedback delay, where the stability diagram depends on the sampling time Δt . The sampling time was set to $\Delta t = 0.01$ [s]. Fixed value of sensory dead zone is applied for the angle $\Pi_\varphi = 1$ [deg] and the sensory threshold for the angular velocity is varied between $\Pi_{\dot{\varphi}} = 0.02 \dots 2$ [deg/s].

Conclusions

The parametric study leads to the detection of solutions converging to pseudo-equilibria that lies on the switching line determined by the size of the dead zone for the angle if the sensory dead zone of the angular velocity is sufficiently small and $\tau = 0$ [s]. However, if the size of the dead zone of the angular velocity is large, a stable periodic orbit determined by both sensory dead zones can be observed for the parameter combination $P = 30$ [N], $D = 5$ [Ns] and $\tau = 0$ [s]. Nevertheless, $\tau = 0$ [s] is not physiologically feasible for the case of human balancing. For a feasible value of time delay a stable symmetric orbit with a long period is found for the control gains $P = 30$ [N], $D = 5$ [Ns], and $\tau = 0.3$ [s].

Figure 2: a) Numerical solution for control parameters $\tau = 0.3$ [s], $P = 30$ [N], $D = 5$ [Ns]. b) Stable symmetric orbit in phase plane for the numerical solution.

Summary. Stability and bifurcation analysis of a non-rigid robotic arm controlled with a time delayed feedback loop is addressed in this work. The study aims at revealing the dynamical mechanisms leading to the appearance of limit cycle oscillations existing in the stable region of the trivial solution of the system, which are related to the combined dynamics of the robot control and its structural nonlinearities. An analytical study of the bifurcations occurring at the loss of stability enables the development of strategies to eliminate this undesired bistable phenomenon by the implementation of special additional nonlinearities in the control force.

Introduction

Robots are increasingly adopted in modern manufacturing facilities, thanks to their versatility and relatively low cost [1]. Milling operation is one of the operations robots are intended to be used for, where complicated tool trajectories can be realized in a large workspace, with a relatively low cost. The relative vibrations between workpiece and tool are a troublesome phenomenon in milling that is mainly caused by the so-called regenerative vibration. The main solution to avoid them is to increase stiffness and damping and try to disturb time delays introduced by the regenerative effect [2]. Generally, increasing the stiffness is hardly achievable, since robotic arms are naturally slender and not especially stiff structures [3]. This makes them particularly prone to vibrations. The main method to mitigate these vibrations should consist of implementing an active controller working collaboratively in the robot original feedback loop. This envisioned controller online reads the acceleration of the end effector (EE, see Fig. 1a) as input and sends a proportional signal to the robot controller in order to counteract and suppress the arising oscillations. This signal is combined to the signal of the position controller of the robot required to make the robotic arm follow the prescribed path during machining.

Although this procedure is rather straightforward to be implemented, there are several aspects that can undermine the effectivity of such combined system if the followings are not properly accounted for: (i) Robotic arms are naturally slender and they cannot be assumed to be rigid, especially if they are subject to strong periodic forces, as in the case of machining. (ii) Since the actuators are placed at the joints of the arm, the system is underactuated. Depending on the position of the sensors, either near the motor or near the EE, the system can be considered as collocated or non-collocated, which have relevant consequences on the system stability [4, 5]. (iii) Robot configuration changes continuously during operation and the drive components of the robot generate non-negligible nonlinearities; as we will illustrate in this study, these nonlinearities might have important consequences on the system robustness. (iv) Robot's controller is unavoidably subject to time delay in the feedback loop. Although this is often negligible, if large control gains are required to counteract strong forces, time delay can still generate instabilities.

This study is motivated by the appearance of unexpected vibrations in a real industrial robotic arm in milling operation. This robot is equipped with a built-in controller (most probably a proportional-derivative controller) for its correct positioning and with an additional controller proportional to the EE acceleration, to counteract machining vibrations (Fig. 1a). Although the control parameters of the system were set such that the system was stable (Fig. 1b), when subject to very small external forcing, in some occasions the robotic arm exhibited either large or small oscillations, which suggests that it was in bistable conditions (see Fig. 1c). The objective of this work is to define and study a general simplified model of this system in order to understand the origin of the bistability and define methods to avoid it. From a broader prospective, this seed research aim at providing a reliable modelling of robotic manufacturing.

Mathematical model

The mathematical model adopted is a two degrees of freedom (DoF) system (Fig. 1a), consisting of two lumped masses m_1 and m_2 , connected by a linear damper c , and a nonlinear spring k_{nl} . The two DoF of the system represent the two dominant DoFs measured for the actual robotic arm in a certain frequency bandwidth. The nonlinearity models a stiffness nonlinearity observed during measurement, most probably originated in the joints. This simplified equivalent mechanical model captures the most important features of the real robotic arm considered in the study. The model is equivalent since during a simple dynamic measurement on the EE the source of the stiffness, damping and nonlinearities are hard to be traced. A prescribed reference trajectory x_d is programmed, such that, in ideal circumstances, an identical constrained motion x_r is imposed to m_1 via a spring of stiffness k with a certain time delay τ_r . This enables the robot to follow the prescribed path. The equations of motion has the following form:

$$\begin{aligned} m_1 \ddot{x}_1 + c(\dot{x}_1 - \dot{x}_2) + k_{nl}(\Delta x)(x_1 - x_2) + kx_1 &= kx_r, \\ m_2 \ddot{x}_2 + c(\dot{x}_2 - \dot{x}_1) + k_{nl}(\Delta x)(x_2 - x_1) &= 0, \end{aligned} \quad (1)$$

where $k_{nl}(\Delta x) = k_2 + \kappa \Delta x^2$ ($\Delta x := x_2 - x_1$). Apart from the position controller integrated in the robot, an additional signal x_f , proportional to the acceleration of the EE, is added to x_r . This generates a final constrained motion $x_r(t) =$

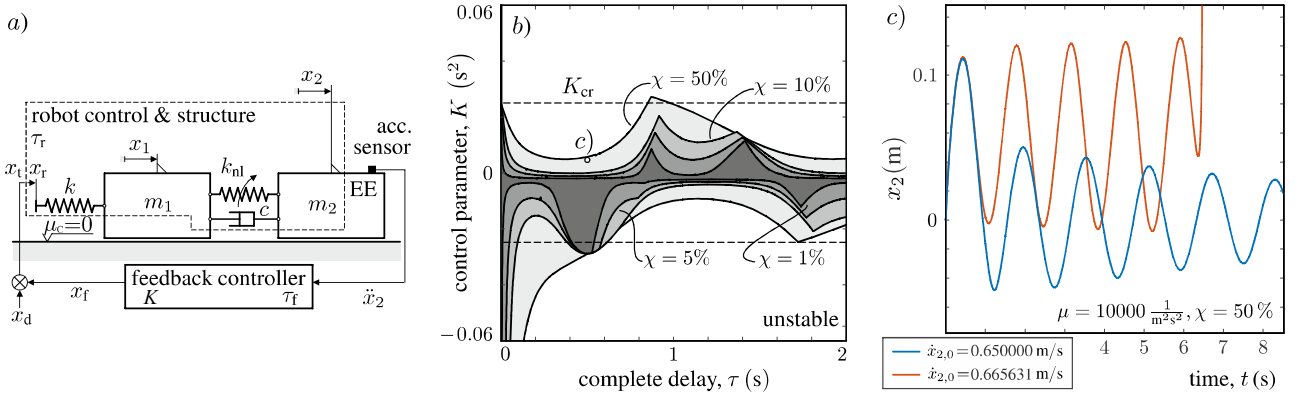

Figure 1: a) shows the sketch of the 2 DoF model with the additional acceleration feedback control ; b) stability chart in the (τ, K) space for $\omega_1 = \omega_2 = 2\pi$ rad/s, $r = 1$, $\chi = (50, 10, 5, 1)\%$, $K_{cr} = 0.0253 s^2$, c) time evolutions for different initial conditions.

$x_d(t - \tau_f) + K\ddot{x}_2(t - \tau_f)$, where τ_f is the delay of the acceleration feedback. In order to focus on the instabilities generated by the acceleration feedback control, in this work we assume constant desired position, that is, $x_d(t) := x_d$, which results in the equilibrium $(\bar{x}_1, \bar{x}_2) = (x_d, x_d)$. By introducing the perturbations $x_1 := \bar{x}_1 + u_1$ and $x_2 := \bar{x}_2 + u_2$, the stability of the local equilibrium can be studied. Via a standard non-dimensionalization procedure, the equations of motion around the equilibrium are reduced to the equation, where $r := m_2/m_1$, $\omega_1^2 := k_1/m_1$, $\omega_2^2 := k_2/m_2$, $\chi := c/(2m_2\omega_2)$, $\mu := \kappa/m_2$, $\ddot{u}_{2\tau} := \ddot{u}_2(t - \tau)$ and $\tau := \tau_f + \tau$.

$$\begin{aligned} \ddot{u}_1 + 2\chi r \omega_2 (\dot{u}_1 - \dot{u}_2) + \omega_2^2 r (u_1 - u_2) + \mu r (u_1 - u_2)^3 + \omega_1^2 u_1 &= \omega_1^2 K \ddot{u}_{2\tau}, \\ \ddot{u}_2 + 2\chi \omega_2 (\dot{u}_2 - \dot{u}_1) + \omega_2^2 (u_2 - u_1) + \mu (u_2 - u_1)^3 &= 0, \end{aligned} \quad (2)$$

Stability and bistable behavior

By linearising (2) and setting $\chi := 0$, the linear stability of the corresponding neutral equation can be investigated (see Fig. 1b). A naive necessary condition of stability for neutral equation is to have the neutral coefficient (here $\omega_1^2 K$) less than one in its magnitude with $|K_{cr}| \leq \omega_1^{-2}$. However, the investigated robotic arm is non-collocated; therefore, the neutral condition is always fulfilled, thus, the stability domains overtakes K_{cr} . In the case of small damping, repeating lobe structure significantly erodes the stable region, which is limited to a narrow region around $K = 0$.

Apart from the local stability of the trivial solution, time simulations show that the nonlinearity of the system has significant impact on its global stability. In particular, if the system is subject to a stiffening nonlinearity ($\mu > 0$) simulations for parameter values within the stable region tend to diverge if initial conditions are sufficiently large. This phenomenon is caused by the subcritical characteristic of the bifurcations occurring at the stability limit and it is probably directly related to the bistable behaviour observed in real robotic arms. The detailed analysis of the bifurcation behaviour of the system enables us to design additional nonlinearities to be included in the control force algorithm to enforce supercritical behaviour; therefore, eliminating the bistable behavior in the stable region.

Conclusions

The stability and bifurcation analysis of a simplified model of the robotic arm subject to acceleration feedback was performed. Results illustrated that the stability chart is characterized by a critical value of the control gain, which is a necessary condition to guarantee stability, and by a repeating stability limit pattern, which strongly depends on the time delay and on system damping. The mechanism connecting bistable behavior and hardening nonlinearity was also identified. The full understanding of this mechanism enables the development of a control algorithm, based on nonlinear functions, which forces the bifurcation to be supercritical, suppressing bistable behaviour in the stable region.

Summary. We investigate theoretically the multi-frequency dynamics observed experimentally in an excitable microlaser subject to delayed optical feedback. We perform a bifurcation analysis of a suitable mathematical model using advanced numerical methods. This demonstrates that the modulated dynamics can be interpreted as quasiperiodic oscillations on a stable torus and that it originates in the interplay between the delay time and the internal slow timescales of the microlaser.

As sources of short, high-amplitude light pulses, self-pulsing lasers are central to many applications, including telecommunications and neuromorphic photonic computing. We consider a semiconductor micropillar laser with integrated saturable absorber subject to delayed optical feedback [2]. The solitary microlaser is excitable [1]: it is in its non-lasing state, but displays an all-or-none response to external perturbations, in the form of a short, high-amplitude light pulse, depending on whether or not the perturbation amplitude exceeds the so-called excitable threshold [3]. In the presence of a feedback loop, recent theoretical and experimental work demonstrated that a first excitable pulse can regenerate itself when reinjected in the laser after the delay time [5, 4]. As such, a single external perturbation can trigger a train of pulses whose repetition rate is close to the delay time. It has recently been shown [4] that several pulse trains can be triggered and sustained simultaneously: in such a case, a very slow convergence is typically observed towards a pulsing pattern where the pulses are equidistant in the laser cavity. In other words, the system is slowly attracted towards one of the stable pulsing periodic solutions with periods close to submultiples of the delay time.

Here, we show theoretically and experimentally that the delayed feedback can also induce complex multifrequency dynamics. In particular, we provide experimental evidence of the existence of pulsing regimes with a strong modulation of the pulse amplitude on a slow timescale compared to the delay time.

Figure 1: Experimental intensity time series, represented over reduced time (top) and in the pseudo-space (bottom) where the x-axis represents one delay time and the y-axis represents the number of roundtrips in the laser external (feedback) cavity.

We focus on the theoretical investigation of such multifrequency dynamics and perform a numerical bifurcation analysis of the Yamada model with feedback. This system of three delay-differential equations (DDEs) for the gain G , the absorption Q and the intensity I is written as follows in the dimensionless form:

$$\begin{aligned}\dot{G} &= \gamma_G(A - G - GI); \\ \dot{Q} &= \gamma_Q(B - Q - aQI); \\ \dot{I} &= (G - Q - 1)I + \kappa I(t - \tau).\end{aligned}\tag{1}$$

Here, A is the pump parameter, B is the non-saturable absorption, a is the saturation parameter and γ_G and γ_Q are the carrier recombination rates in the gain and absorber media, respectively. The values of γ_G and γ_Q are typically small, and the model (1) is then a slow-fast dynamical system with two slow variables (the gain G and the absorption Q) and one fast variable (the laser field intensity I). The optical feedback is described by the delayed term in the intensity equation, where κ is the feedback strength and τ is the feedback delay. This model has been shown to describe accurately the dynamics observed experimentally [6, 4].

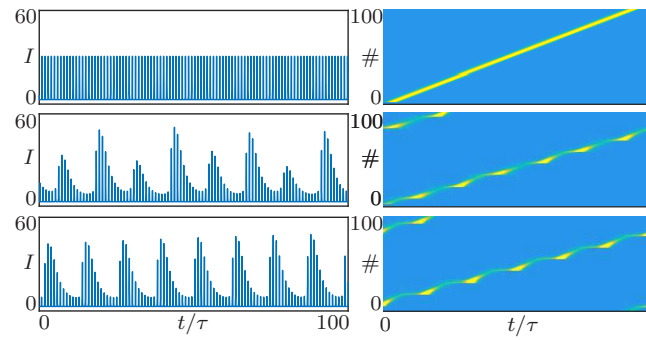

Figure 2: Simulated intensity time series represented over reduced time (left) and in the pseudo-space (right), for $\kappa = 0.39$ (top), $\kappa = 0.3805$ (middle), and $\kappa = 0.38$ (bottom). The delay is $\tau = 965$.

Time domain simulations of the Yamada model with feedback, in figure 2, demonstrates its ability to reproduce the modulated pulsing dynamics observed in the experiment. We perform an in-depth bifurcation analysis of the model (1) with advanced numerical methods [7], considering both the feedback strength κ and feedback delay τ as bifurcation parameters. It demonstrates that the modulated dynamics can be interpreted as quasiperiodic oscillations on a stable torus. The bifurcation analysis unveils an interplay between the delay time and the internal timescales of the microlaser (related to the carrier recombination rates in the gain and absorber sections) as the main reason behind the emergence of such multifrequency dynamics. Moreover, time-domain simulations of the Yamada model with delay show that chaotic dynamics exists in small regions of the parameter space.

Overall, our results provide a better understanding of pulsing dynamics in an excitable laser with delayed feedback. As such, they constitute a step toward an all-optical control of pulse trains, which may prove useful for optical memories or neuromorphic photonic computing. Despite its simplicity, the Yamada model with feedback describes accurately the complex dynamics observed in the experiment and displays complex dynamics, including chaotic behaviour. Importantly, the only ingredients, excitability and feedback, are very general [1]. Therefore, we believe our results may be of interest beyond the scope of laser dynamics.

Summary. The stability analysis of generic retarded differential equations is a difficult question since their asymptotic behavior depends on a non-trivial way on parameters and delays. From a control point of view, the main difficulty is that one has infinitely many spectral roots but only finitely many parameters in the system. A natural question is then to design techniques of assigning a finite number of roots guaranteeing that the rightmost root is among the ones assigned. One such a technique is to place roots of maximal multiplicity, which are often also dominant, a property known as *multiplicity-induced-dominancy* (MID). This paper proves that the MID property holds for some classes of systems by using a priori bounds on the imaginary part of roots on the right half-plane, a suitable factorization of the characteristic equation in integral form, and the analysis of crossing imaginary roots.

Introduction

This paper is interested in linear time-invariant differential equations with delays which can be written under the form

$$y^{(n)}(t) + \sum_{j=0}^N \sum_{k=0}^{n-1} \alpha_{j,k} y^{(k)}(t - \tau_j) = 0, \quad (1)$$

where n and N are positive integers, $\alpha_{j,k} \in \mathbb{R}$, and $\tau_j \geq 0$. With no loss of generality, we assume $0 = \tau_0 < \tau_1 < \dots < \tau_N$. Equation (1) is said to be *retarded* since the highest order derivative only appears in the non-delayed term $y^{(n)}(t)$. The stability analysis of time-delay systems has attracted much research effort and is an active field [4, 5, 8, 9, 11]. The asymptotic behavior of (1) can be studied through spectral methods by considering the complex roots of the corresponding characteristic function $\Delta : \mathbb{C} \rightarrow \mathbb{C}$ defined for $s \in \mathbb{C}$ by

$$\Delta(s) = s^n + \sum_{j=0}^N e^{-s\tau_j} \sum_{k=0}^{n-1} \alpha_{j,k} s^k. \quad (2)$$

Functions such as Δ that can be written under the form $Q(s) = \sum_{j=0}^{\ell} P_j(s) e^{\lambda_j s}$ for some non-zero polynomials with real coefficients P_0, \dots, P_{ℓ} and pairwise distinct real numbers $\lambda_0, \dots, \lambda_{\ell}$ are called *quasipolynomials*. The integer $D = \ell + \sum_{j=0}^{\ell} d_j$ is called the *degree* of Q , where d_j denotes the degree of P_j . A classical result on quasipolynomials provided in [10, Problem 206.2] implies that the multiplicity of any root of Q does not exceed D .

A root s_0 of Δ is said to be (*strictly*) *dominant* if every other root of Δ has a real part (*strictly*) smaller than $\operatorname{Re} s_0$. It has been observed in several works that real roots of maximal multiplicity tend to be dominant, a property known as *multiplicity-induced-dominancy* (MID) (see, e.g., [1, 3] for the case $N = 1$ and $n = 2$ using approaches based on factorization and Cauchy's argument principle). The interest in considering multiple roots does not rely on the multiplicity itself, but on its connection with dominance and its implications for stability analysis and control design.

Main results

The main results of this paper prove that the MID property holds for some classes of systems under the form (1).

Theorem 1 Consider the quasipolynomial Δ given by (2) in the case $N = 1$. Let $s_0 \in \mathbb{R}$. The number s_0 is a root of multiplicity $2n$ of Δ if and only if, for every $k \in \{0, \dots, n-1\}$,

$$\begin{cases} \alpha_{0,k} = \binom{n}{k} (-s_0)^{n-k} + (-1)^{n-k} n! \sum_{j=k}^{n-1} \binom{j}{k} \binom{2n-j-1}{n-1} \frac{s_0^{j-k}}{j! \tau_1^{n-j}}, \\ \alpha_{1,k} = (-1)^{n-1} e^{s_0 \tau_1} \sum_{j=k}^{n-1} \frac{(-1)^{j-k} (2n-j-1)! s_0^{j-k}}{k! (j-k)! (n-j-1)! \tau_1^{n-j}}. \end{cases} \quad (3)$$

Moreover, if (3) is satisfied, then s_0 is a strictly dominant root of Δ .

Thanks to the change of variables $z = \tau_1(s - s_0)$ transforming $\Delta(s)$ into $\hat{\Delta}(z) = \tau^n \Delta(s_0 + \frac{z}{\tau_1})$, it suffices to prove Theorem 1 in the case $s_0 = 0$ and $\tau_1 = 1$. Its first part can be obtained by solving the system of linear equations $\hat{\Delta}^{(\ell)}(0) = 0$ for $\ell \in \{0, \dots, 2n-1\}$. As for the second part, when (3) is satisfied and $z = 0$ is a root of multiplicity $2n$ of $\hat{\Delta}$, one can factorize $\hat{\Delta}$ as $\hat{\Delta}(z) = z^{2n} I(z)$, where $I(z)$ is an entire function which can be written as an integral, for

instance $I(z) = \int_0^1 t(1-t)^2 e^{-zt} dt$ when $n = 2$. A direct study of I , making use of the a priori information that roots z of $\hat{\Delta}$ in the closed right half-plane \mathbb{C}_+ must satisfy $|\operatorname{Im} z| \leq 2\pi$, shows that it cannot have roots in \mathbb{C}_+ . A detailed proof is provided in [6].

Theorem 2 Consider the quasipolynomial Δ given by (2) in the case $N = 1$ and $n = 2$. Let $s_0 \in \mathbb{C}$, $\sigma_0 = \operatorname{Re} s_0$, and $\theta_0 = \operatorname{Im} s_0$ and assume that $\theta_0 \neq 0$. The numbers s_0 and \bar{s}_0 are roots of multiplicity 2 of Δ if and only if

$$\begin{cases} \alpha_{0,0} = \sigma_0^2 + 2\sigma_0\theta_0 \frac{\tau_1\theta_0 - \sin(\tau_1\theta_0)\cos(\tau_1\theta_0)}{\tau_1^2\theta_0^2 - \sin^2(\tau_1\theta_0)} + \theta_0^2 \frac{\tau_1^2\theta_0^2 + \sin^2(\tau_1\theta_0)}{\tau_1^2\theta_0^2 - \sin^2(\tau_1\theta_0)}, \\ \alpha_{0,1} = -2\sigma_0 - 2\theta_0 \frac{\tau_1\theta_0 - \sin(\tau_1\theta_0)\cos(\tau_1\theta_0)}{\tau_1^2\theta_0^2 - \sin^2(\tau_1\theta_0)}, \\ \alpha_{1,0} = 2\theta_0 e^{\sigma_0\tau_1} \left(\sigma_0 \frac{\sin(\tau_1\theta_0) - \tau_1\theta_0 \cos(\tau_1\theta_0)}{\tau_1^2\theta_0^2 - \sin^2(\tau_1\theta_0)} - \frac{\tau_1\theta_0^2 \sin(\tau_1\theta_0)}{\tau_1^2\theta_0^2 - \sin^2(\tau_1\theta_0)} \right), \\ \alpha_{1,1} = 2\theta_0 e^{\sigma_0\tau_1} \frac{\tau_1\theta_0 \cos(\tau_1\theta_0) - \sin(\tau_1\theta_0)}{\tau_1^2\theta_0^2 - \sin^2(\tau_1\theta_0)}. \end{cases} \quad (4)$$

Moreover, if (4) is satisfied, then s_0 and \bar{s}_0 are a pair of strictly dominant roots of Δ .

Similarly to Theorem 1, one may reduce the proof of Theorem 2 to the case $\sigma_0 = 0$ and $\tau_1 = 1$, with (4) being again proved by solving a linear system of equations. As $\theta_0 \rightarrow 0$, (4) converges (3) with $n = 2$, and one can thus prove dominance of the complex conjugate pair $\pm i\theta_0$ by proving that, as θ_0 increases from 0, no roots of $\hat{\Delta}$ may lie on the imaginary axis other than $\pm i\theta_0$, and hence no roots can cross to the right half-plane. See [7] for a detailed proof.

Theorem 3 Consider the quasipolynomial Δ given by (2) in the case $N = 2$ and $n = 1$. Let $s_0 \in \mathbb{R}$. The number s_0 is a root of multiplicity $2n$ of Δ if and only if

$$\alpha_{0,0} = -s_0 - \frac{1}{\tau_1} - \frac{1}{\tau_2}, \quad \alpha_{10} = e^{s_0\tau_1} \frac{\tau_2}{\tau_1(\tau_2 - \tau_1)}, \quad \alpha_{20} = -e^{s_0\tau_2} \frac{\tau_1}{\tau_2(\tau_2 - \tau_1)}. \quad (5)$$

Moreover, if (5) is satisfied, then s_0 is a strictly dominant root of Δ .

One obtains (5) using the same arguments from Theorems 1 and 2. The second part of the statement can be proved by considering the limit $\tau_2 \rightarrow \tau_1$ and proving that s_0 is dominant for the limiting quasipolynomial and that, as τ_2 increases, no roots other than s_0 may have real part s_0 , excluding the possibility of any other root becoming dominant.

Conclusion

We further explored the MID property for generic single-delay retarded systems of arbitrary order, showing that a real spectral value with maximal multiplicity is necessarily dominant. For a scalar equation with two delays, it is shown that the MID property still applies. Further, in the second-order case, we contributed by extending the MID property for complex conjugate pairs of spectral values.

In recent studies, the applicability of the MID property in reduced-complexity delayed controller design was shown, where the attenuation of the dominant vibrating modes of flexible mechanical structures was considered [2]. In future work, the MID property will be further exploited in the problem of vibration quenching.

Playing dominoes with lasers: Excitability and pulsed solutions of the Yamada model for a semiconductor laser with saturable absorber and delayed optical feedback

[‡]*Department of Physics, The University of Auckland, New Zealand*

Summary. We are concerned with the generation of periodic light pulses in semiconductor lasers with saturable absorber through delayed re-injection of the pulse via a reflecting mirror. More specifically, we consider the Yamada model with delayed feedback and study the generation of periodic pulse trains via repeated self-excitation after passage through the delayed feedback loop. We employ numerical continuation and analytical methods for delay differential equations to characterize these periodic solution and their bifurcations.

Surely everyone is familiar with chain reactions of falling domino tiles. After careful preparation of upright rectangular tiles along some path and in close proximity to one another, toppling the first tile leads to a chain reaction that hopefully causes all dominoes to fall. Such setups shall serve as an analogy for directed networks of delay-coupled excitable systems. Here, a sufficiently large perturbation (toppling the first tile) is capable of producing an excitation, in the form of a pulse, a spike or some kind of localized change in a physical quantity (momentum in the case of dominoes), which propagates to a subsequent node in the network and itself serves as a perturbation. If this perturbation is again large enough, a secondary excitation is created and the process continues. The speed of this propagation is finite and can be modeled via time delays between the nodes. Specific examples of this kind of relay are networks of semiconductor lasers with saturable absorber; another is the human brain consisting of millions of connected neurons, which are hard to study both experimentally and analytically.

Motivated by experiments with a micropillar semiconductor laser with saturable absorber and a reflecting mirror [1], we are concerned with the simplest network motif allowing for sustained re-excitation: a single node with delayed self-coupling. We modify the Yamada model [2] for an excitable or self-pulsating laser to incorporate delayed optical self-feedback [3]. Although seemingly simple, this setup allows for the generation of periodic light pulses that constitute the basis for modern telecommunication, material processing and high energy physics.

Here, we present an analytical tool that characterizes the onset and termination of such light pulses as a bifurcation in this system of delay differential equations (DDE). In dimensionless form, the model reads

$$G'(t) = \gamma (A - G(t)[1 + I(t)]), \quad (1)$$

$$Q'(t) = \gamma (B - Q(t)[1 + aI(t)]), \quad (2)$$

$$I'(t) = [G(t) - Q(t) - 1] I(t) + \kappa I(t - \tau). \quad (3)$$

Equations (1)–(3) describe the time evolution of the laser output intensity $I(t)$, as well as the gain $G(t)$ and absorption $Q(t)$ of photons in the laser cavity. The parameter A is the pump strength (the amount of energy provided to the laser), $B, a, \gamma > 0$ describe physical properties of the laser; and they differ from device to device. The time delay τ reflects the distance from the mirror to the laser cavity and the feedback strength κ accounts for the losses along that feedback loop. We fix parameters $A = 6.5, B = 5.8, a = 1.8$, and $\gamma = 0.04$ as in [4] and refer the interested reader to [1, 2] for the physical details.

The excitability of Eqs. (1)–(3) is governed by a homoclinic bifurcation [4]. For the considered parameter values, the stable manifold of a steady state locally separates the state space of the system [5]. The laser is essentially off, yet a sufficiently large perturbation that brings the system above this manifold, causes a fast increase in I that is followed by fast relaxation. Such an orbit is referred to as a pulse in the context of lasers; see Fig. 1(a, black) for an example. At the homoclinic bifurcation, the stable and unstable manifold of the equilibrium intersect transversally and give rise to a periodic orbit [4].

In the following, we focus on the full system (1)–(3) and study the effects of delayed feedback to the system in the excitable configuration. A detailed bifurcation analysis of Eqs. (1)–(3) has been carried out earlier by some of the authors [6], and we present here a refined analysis with regard to periodic orbits that are generated by sustained self-excitation after one delayed feedback loop. To illustrate our results, we fix $\tau = 5000$ and $\kappa = 0.52$ and prepare the pulse in Fig. 1(a) as the initial condition for system (1)–(3). We observe sustained pulsation: each pulse travels along the delayed feedback loop and triggers a subsequent pulse after approximately one delay interval. Remarkably, the pulsed solution reached from this initial condition has a higher peak intensity than the original pulse of the solitary system, and we observe a different profile; see Fig. 1(b, blue). Our formal analysis reveals that these solutions correspond to different periodic orbits, which coexist for the chosen parameter values. In fact, there is a third type of small pulsed solution present for the chosen parameter values; see Fig. 1(c, red).

We employ numerical continuation to reveal that these solutions correspond to different branches (black, blue, red) of periodic orbits when the time delay is varied as a parameter; see Fig. 1(d). The branches of periodic orbits share a

Figure 1: Panels (a)–(c) show the I -component of coexisting pulsed solutions with large period for large delay $\tau = 5000$. Panel (d) is the corresponding bifurcation diagram for small values of the delay; shown are the period of the periodic orbits (solid curves), points of Hopf bifurcations (circles), and indicated loci of Homoclinic bifurcations (squares). Other parameters are $A = 6.5$, $B = 5.8$, $a = 1.8$, $\gamma = 0.04$, and $\kappa = 0.52$.

remarkable property: their period scales effectively linearly with the delay. More precisely, the period T along a given family satisfies $T = \tau + \delta$, where $\delta \ll \tau$ and $\delta/\tau = T/\tau - 1 \rightarrow 0$ as $\tau \rightarrow \infty$. The intuition is clear: the I -component of the pulsed solutions is close to zero throughout most of their period. Therefore, a pulse that is emitted at time t , travels the length of the delay loop and only affects the system at time $t + \tau$. Additionally, there is a certain response time δ of the system to build up in intensity and to produce a subsequent pulse. Such periodic solutions are also referred to as Temporal Dissipative Solitons (TDS) in DDEs [7]. Each branch of pulsed periodic orbits in system (1)–(3) corresponds to a family of periodic solutions of the so-called profile equation, given by Eqs. (1)–(2) and

$$I'(t) = [G(t) - Q(t) - 1] I(t) + \kappa I(t + \delta), \quad (4)$$

which undergoes a homoclinic bifurcation. Figure 1(d) shows that for each branch of periodic orbits (black, blue, black) with $T > \tau$, for $\tau > 0$, there is a branch (red, blue, black) of periodic orbits with $\tau < 0$ exhibiting a homoclinic bifurcation. This correspondence can be seen by using the concept of reappearance of periodic orbits for DDEs [8]. Hence, we study the pulsed solutions of Eqs. (1)–(3) indirectly via bifurcations and codimension-two points of homoclinic orbits in Eqs. (1),(2) and (4). We show that the onset and termination of such pulse trains correspond to a bifurcation of countably many saddle-node periodic orbits with infinite period; moreover, we show these bifurcations coincide with codimension-two points along the family of homoclinic orbits as κ is varied as a parameter. This approach allows us to compute the corresponding critical coupling strengths that give rise to pulsed solutions in Eqs. (1)–(3). Our methodology is relevant for the rigorous analysis of delay-coupled excitable systems in general. Future applications will include recurrent networks of lasers and neurons, which are in a similar excitable configuration when at rest.

Ploughing-limited post-critical dynamics under chatter in turning. Harmonic balance based investigation

Mikhail Guskov*

*PIMM, Arts et Metiers Institute of Technology, CNRS, Cnam, HESAM University,
151 boulevard de l'Hopital, 75013 Paris (France)

Summary. At chatter onset, as many works show, vibrations magnitudes grow until the tool exits the continuous cutting. Another magnitude limitation mechanism, namely ploughing is investigated in the present contribution, in a harmonic balance + continuation framework

Chatter problematics

Regenerative chatter instability in metal cutting processes such as turning is known to possess subcritical behaviour [1], inducing bistable regions in the vicinity of the bifurcation. Investigations of post-critical vibrations have shown growing magnitude until the tool exit [2]. Once the cut becomes intermittent due to tool exit, the dynamics are much more complex due to the interrupted surface regeneration. Nevertheless, in some cases magnitude is limited by other mechanisms, such as ploughing [3]. In the present work we investigate post-critical dynamics of a 1 degree of freedom (DOF) with a piecewise linear ploughing model via a harmonic balance method (HBM) framework coupled with arclength continuation.

1DOF cutting system

The investigation is carried out on a system schematized on Fig. 1, giving place to the following equation of motion:

$$m\ddot{X} + c\dot{X} + kX = F_c(h) + F_p(\dot{X}), \quad (1)$$

$$F_c = -F_{c0} \left(\frac{h}{f} \right)^\alpha, \quad h = f + X - X_D, \quad X_D = X(t - D), \quad (2)$$

$$F_p = -H(\Delta\Gamma) F_{p0} \Delta\Gamma, \quad \Delta\Gamma = \frac{\dot{X}}{V_c} - \Gamma, \quad (3)$$

with m mass, c damping, k stiffness, f feed, V_c cutting velocity, D delay period, F_c and F_p cutting and ploughing force, F_{c0} , F_{p0} , α , Γ respective tool-workpiece interaction parameters, H Heaviside step function.

Cutting force definition (2) is based on the assumption of uninterrupted cut. The ploughing force model (3) features a unilateral penalty term corresponding to a closure of effective clearance angle $\Delta\Gamma$ at high magnitude oscillations.

Figure 1: Cutting system model illustration

By introducing, for a given oscillation frequency ω , time and length scaling $\tau = \omega t$ and $x = X/f$, the equation (1) can be rewritten in adimensional form:

$$\Omega^2 x'' + 2\Omega\zeta x' + x + \kappa(x - x_D + 1)^\alpha + Z_p \Pi_p(\Omega x' - \phi) = 0, \quad \Pi_p = H(\Omega x' - \phi) \quad (4)$$

In the present work, the system is based on a case described in literature [4], with chatter onset parameters $\zeta = 0.01$, $\Omega = \omega/\sqrt{k/m} = \sqrt{1 - 2\zeta}$, $\omega D = 3\pi/2$, $\alpha\kappa_0 = 0.02$, the cutting law being a power law with exponent $\alpha = 3/4$.

HBM approach with continuation

The HBM approach used in this work is a variant of trigonometric collocation [5]. The solution is sought in the form of a trigonometric polynomial or order N (N -truncated Fourier series):

$$x(\tau) = \mathbf{T}(\tau)\mathbf{x}, \quad \mathbf{T} = \left[\frac{1}{2}, \cos \tau, \sin \tau, \dots, \cos N\tau, \sin N\tau \right], \quad \mathbf{x} = [a_0, a_1, b_1, \dots, a_N, b_N]^T \quad (5)$$

In the case of chatter, constituting an auto-oscillation of a priori unknown frequency Ω , a phase condition is used ($b_1 = 0$). For variation of κ in the vicinity the chatter onset configuration at a given delay D , the following continuation condition ("arclength") is used for neighbouring points:

$$\|\Delta \mathbf{x}\|^2 + \Delta \Omega^2 + \Delta \kappa^2 = s^2 \quad (6)$$

with s a given (small) step distance.

Investigation of ploughing parameters

The postcritical oscillations were analyzed in a range $\kappa \in [0, 2\kappa_0]$ for a wide set of ploughing parameters Z_p and ϕ was simulated, with $N = 7$ and time discretization of 1024 points. The response is essentially mono-harmonic and thus are shown as the magnitude of the fundamental component on fig. 2. As for other variables, it can be noticed that Ω remains very close to 1 and the static component a_0 shows a slight variation with κ .

The upper limits of the plots are due to the cut interruption. The left branch of the plots, especially in cases of high ploughing thresholds $\phi \geq 0.7$, corresponds to a "no ploughing" behavior. The ploughing term comes in at $a_1 \approx \phi/\Omega$. As a general trend, the oscillation magnitudes tend to be lower for higher ploughing coefficient Z_p and for small ϕ . In particular, for the lowest values of Z_p combined with big ϕ , the tool gets to exit the cutting process in the given range of κ (top limits of the plots). At the extreme opposite, one can notice for $Z_p \geq 3$ a quasi-constant oscillation magnitude is maintained.

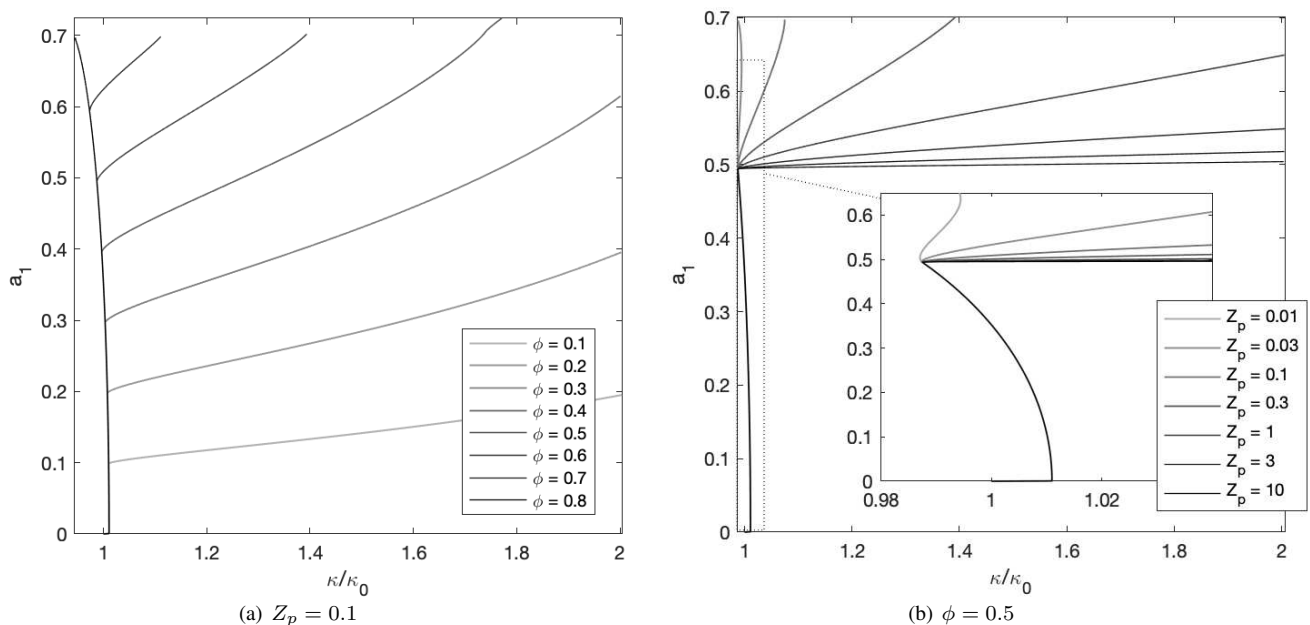

Figure 2: Postcritical response of (4) for $\kappa \in [0, 2\kappa_0]$

Summary. Collective oscillations and their suppression by external stimulation are analyzed in a large-scale neural network consisting of two interacting populations of excitatory and inhibitory quadratic integrate-and-fire neurons. In the limit of an infinite number of neurons, the microscopic model of this network can be reduced to an exact low-dimensional system of mean-field equations. Bifurcation analysis of these equations reveals three different dynamic modes in a free network: a stable resting state, a stable limit cycle, and bistability with a coexisting resting state and a limit cycle. We show that in the limit cycle mode, high-frequency stimulation of an inhibitory population can stabilize an unstable resting state and effectively suppress collective oscillations. We also show that in the bistable mode, the dynamics of the network can be switched from a stable limit cycle to a stable resting state by applying an inhibitory pulse to the excitatory population. The results are confirmed by numerical simulation of the microscopic model.

Introduction

Synchronization processes in large populations of interacting dynamical units are the focus of intense research in physical, technological and biological systems. In neural networks, synchronization can play a dual role. Under normal conditions, synchronization is responsible for cognition and learning, while excessive synchronization can cause abnormal brain rhythms associated with neurological diseases such as Parkinson's disease, epilepsy, and others. Various algorithms have been developed to suppress unwanted synchronized network oscillations. A therapeutic procedure clinically approved for the treatment of Parkinson's disease is a high-frequency (HF) deep brain stimulation (DBS). The mechanism of action of DBS is still poorly understood. Clinical observations show that the effects of lesions and DBS of the same target area are similar. This suggests that HF stimulation suppresses neuronal activity in the target area. In this context, the effect of HF stimulation can be explained in terms of stabilization of neuron's resting state [1]. However, there is no clear theoretical understanding of how HF stimulation affects synchronization processes in neural networks.

Recent advances in dynamical systems theory have allowed us to better understand the effects of synchronization in large-scale oscillatory networks. A major breakthrough in these studies was achieved by Ott and Antonsen [2], who showed that the microscopic model equations of globally coupled heterogeneous phase oscillators (Kuramoto model) can be reduced to a low-dimensional system of ordinary differential equations that accurately describe the macroscopic evolution of the system in the infinite-size (thermodynamic) limit. Later this approach was extended to a particular class of heterogeneous neural networks composed of all-to-all pulse-coupled quadratic integrate-and-fire (QIF) neurons [3]. In thermodynamic limit, a low-dimensional system of mean-field equations was derived for biophysically relevant macroscopic quantities: the firing rate and the mean membrane potential. The approach has been further developed in recent publications to analyze the occurrence of synchronized macroscopic oscillations in networks of QIF neurons with a realistic synaptic coupling [4], in the presence of a delay in couplings [5] and in the presence of noise [6].

Here, we demonstrate that mean-field equations are useful not only for understanding the occurrence of collective oscillations in large-scale neural networks, but also for understanding the effect of stimulation on synchronization processes [7]. As an example, we consider a network of two interacting populations of excitatory and inhibitory QIF neurons.

Microscopic model and low-dimensional mean-field equations in the thermodynamic limit

The microscopic state of the QIF network is determined by the set of $2N$ neurons' membrane potentials $\{V_j^{(E,I)}\}_{j=1,\dots,N}$, which satisfy the following system of $2N$ ordinary differential equations:

$$\tau \dot{V}_j^{(E,I)} = (V_j^{(E,I)})^2 + \eta_j^{(E,I)} + \mathcal{I}_j^{(E,I)}, \quad \text{if } V_j^{(E,I)} \geq V_p \text{ then } V_j^{(E,I)} \leftarrow V_r. \quad (1)$$

Here, τ is the membrane time constant and $V_j^{(E,I)}$ is the membrane potential of neuron j in either the excitatory (E) or the inhibitory (I) population. For simplicity, we set the number of neurons N and the time constant τ the same for both populations. The heterogeneous parameter of excitability $\eta_j^{(E,I)}$ is a current that specifies the behavior of each isolated neuron and the term $\mathcal{I}_j^{(E,I)}$ defines the synaptic coupling between neurons as well as external stimulation. The isolated neurons ($\mathcal{I}_j^{(E,I)} = 0$) with the negative value of the parameter $\eta_j^{(E,I)} < 0$ are at rest, while the neurons with the positive value of the parameter $\eta_j^{(E,I)} > 0$ generate instantaneous spikes, which are approximated by the Dirac delta function.

The spikes are emitted at the moments when the membrane potential $V_j^{(E,I)}$ reaches a peak value V_p . Immediately after the spike emission the membrane potential is reset to a value V_r . We assume $V_p = -V_r \rightarrow \infty$. The values of the heterogeneous parameter $\eta_j^{(E,I)}$ for both populations are independently taken from the Lorentzian distributions: $g_{E,I}(\eta) = \Delta_{E,I} / \{\pi[(\eta - \bar{\eta}_{E,I})^2 + \Delta_{E,I}^2]\}$, where $\Delta_{E,I}$ and $\bar{\eta}_{E,I}$ are respectively the width and the center of the

distribution for the excitatory (E) and inhibitory (I) populations. The last term $\mathcal{I}_j^{(E,I)}$ in Eqs. (1) describes synaptic coupling and an external stimulation. For the excitatory and inhibitory populations, this term respectively is

$$\mathcal{I}_j^{(E)} = -J_{IE}S_I(t) + I_E(t), \quad \mathcal{I}_j^{(I)} = J_{EI}S_E(t) - J_{II}S_I(t) + I_I(t). \quad (2)$$

Here, $S_E(t)$ and $S_I(t)$ determine the mean synaptic activation of E and I populations:

$S_{E,I}(t) = \frac{\tau}{N} \sum_{j=1}^N \sum_{k \in (t_j^k)_{E,I} < t} \delta(t - (t_j^k)_{E,I})$, where $(t_j^k)_{E,I}$ is the time of the k th spike of the j th neuron in either E or I population and $\delta(t)$ is the Dirac delta function. The positive parameters J_{EI} , J_{IE} and J_{II} define synaptic weights. The current $-J_{IE}S_I(t)$ inhibits E neurons due to synaptic activity of I population, while the current $J_{EI}S_E(t)$ excites I neurons due to synaptic activity of E population. The term $-J_{II}S_I(t)$ determines recurrent inhibition of neurons within I population. The currents $I_E(t)$ and $I_I(t)$ represent external homogeneous stimulation of the excitatory and the inhibitory populations, respectively.

In the thermodynamic limit $N \rightarrow \infty$, the microscopic model (1) can be reduced to the exact system of four ODEs [3]:

$$\tau \dot{r}_E = \Delta_E/\pi + 2r_E v_E, \quad \tau \dot{v}_E = \bar{\eta}_E + v_E^2 - \pi^2 r_E^2 - J_{IE}r_I + I_E(t), \quad (3a)$$

$$\tau \dot{r}_I = \Delta_I/\pi + 2r_I v_I, \quad \tau \dot{v}_I = \bar{\eta}_I + v_I^2 - \pi^2 r_I^2 + J_{EI}r_E - J_{II}r_I + I_I(t), \quad (3b)$$

where $r_{E,I}(t)$ and $v_{E,I}(t)$ are respectively the spiking rates and the mean membrane potentials of E and I populations.

Results and conclusions

Relatively simple mean field Eqs. (3) make it possible to conduct a thorough bifurcation analysis of various dynamic modes of a free network and to reveal the mechanisms of action of various stimulation algorithms. We performed a bifurcation analysis of a free network depending on the coupling strengths J_{EI} and J_{IE} of the bidirectional interaction between excitatory and inhibitory populations and the coupling strength J_{II} , which determines the interaction within the inhibitory population. We also built a bifurcation diagram in the plane of the parameters $(\bar{\eta}_I, \bar{\eta}_E)$, which determine the centers of the distributions $g_{E,I}(\eta)$ of the excitability parameter η for I and E populations. As a result of this analysis, three different modes were established. Depending on the values of the parameters, the system can have a single stable fixed point, a single stable limit cycle, or be in a bistable mode with these two coexisting attractors.

As the next step in our analysis, we looked at the problem of controlling network synchronization. Some neurological diseases are successfully treated with high-frequency stimulation. Here, we tested the effectiveness of the HF algorithm for suppressing synchronous spiking in the network of excitatory and inhibitory QIF neurons. We have shown that HF stimulation of the inhibitory population is very effective, whereas HF stimulation of the excitatory population cannot suppress the oscillations. The mechanism of action of HF stimulation is explained using mean-field equations averaged over the stimulation period. The averaged mean-field equations are equivalent to the free mean-field equations, but with a modified parameter $\bar{\eta}_I$ or $\bar{\eta}_E$, depending on which inhibitory or excitatory population is stimulated. When HF stimulation is applied to the inhibitory population, changing the $\bar{\eta}_I$ parameter increases the proportion of spiking neurons in that population. This leads to the stabilization of the state of rest of the network. The averaged mean-field equations made it possible to obtain an analytical expression for the threshold amplitude of HF stimulation, which stabilizes the resting state. This amplitude is proportional to the frequency of stimulation.

HF stimulation of the excitatory population is ineffective, since changing the $\bar{\eta}_E$ parameter increases the proportion of spiking neurons in the excitatory population and cannot stabilize the resting state of the network. Nevertheless, stopping the network oscillation by controlling the excitatory population can still be achieved if the system parameters are in the bistable area. By applying a rectangular inhibitory pulse to this population, the network state can be switched from the stable limit cycle to the stable state of rest.

To test the performance of the above stimulation algorithms for finite-size networks, we numerically simulated the equations of the microscopic model. Modeling networks with 2000 excitatory and 2000 inhibitory QIF neurons gave results that are in good agreement with the results obtained from the mean-field equations. Based on our research, we believe that mean-field equations derived from the microscopic dynamics of interacting QIF neurons can serve as an effective tool for developing various stimulation algorithms to control synchronization processes in large-scale neural networks.

Synchronization of a Self-Excited Inertia-Wheel Pendula Array

Gilad Yakir and Oded Gottlieb

Dept. of Mechanical Engineering, Technion – Israel Institute of Technology, Haifa, 32000, Israel

Summary. We investigate synchronization of a self-excited inertia wheel pendula array. The dynamical system exhibits asymptotically stable equilibria, periodic limit cycle oscillations, and non-stationary rotations. The analysis reveals that synchronous periodic oscillators are in-phase whereas quasiperiodic oscillators are out-of-phase. Furthermore, the non-stationary rotations exhibit combinations of oscillations and rotations of the individual elements which are asynchronous.

Introduction

Self-excited synchronous oscillations in multibody dynamical systems have been documented since the middle of the seventeenth century with the observation of Christiaan Huygens that two pendulum clocks hanging from a common flexible support swung together periodically approaching and receding in opposite motions[1]. Examples of synchronization in rigid-body and continuous dynamical systems have been documented for coupled mechanical metronomes[2], coupled pendula suspended from a moving beam[3], and a nano mechanical cantilever array[4]. We examine the complexity of coexisting synchronous and asynchronous self-excited oscillations in an array of three planar pendula augmented with rotating inertia wheels governed by a linear feedback mechanism. We formulate the dynamical system using a Lagrangian approach (Fig. 1 left). A linear stability map analysis of the zero equilibria yields a transition from an asymptotically stable region (Fig. 1 right-red) to a region of self-excited oscillations (Fig. 1 right-blue), culminating with a region of rotations (Fig. 1 right-white). We note that the saddle-node bifurcation ($\Gamma_3 = 0$) for both a stationary array ($x \in \mathbb{R}^5$) is identical to that of a moving array ($x \in \mathbb{R}^{11}$). However, the Hopf bifurcation between a stable zero equilibria and periodic oscillations reveals a slightly larger region of self-excited limit cycles (Fig. 1 right-dashed).

Figure 1: Definition sketch (left), stability map (right) of the inertia wheel feedback gains ($\Gamma_3(\Gamma_1)$) for a stationary (solid) and moving (dashed) array

Results

By enforcing the analytical constraints[7] we find the Hopf threshold (Fig. 1 right-solid) of the stationary array. The Hopf threshold of the moving pendulum array is obtained numerically for varying values of the gain Γ_1 (Fig. 1 right-circles). Area I_A yields asymptotic stability for the moving array, and area I_B together with I_A yields asymptotic stability for the stationary array. We simulate the dynamics of the array for gain values Γ_3 both near and far from the Hopf threshold $\Gamma_{3H}(\Gamma_{1H})$ for an arbitrary constant gain parameter $\Gamma_1 = \text{const}$. For gains Γ_3 near the Hopf threshold we obtain periodic motion of the array elements which reveals in-phase synchronization (Fig. 2 left). As the gain Γ_3 increases we obtain quasiperiodic dynamics of the individual elements and out-of-phase synchronization (Fig. 2 center). The quasiperiodic motion leads to asynchronous chaotic oscillations (Fig. 2 right). The behavior of the dynamical system was examined through Poincaré maps (Fig. 2 bottom) portrayed by the system conjugate momenta $(p_\psi, p_{\theta_i}, p_{\phi_i})$ and sampled every positive zero crossing of the central inertia wheel velocity which is bounded.

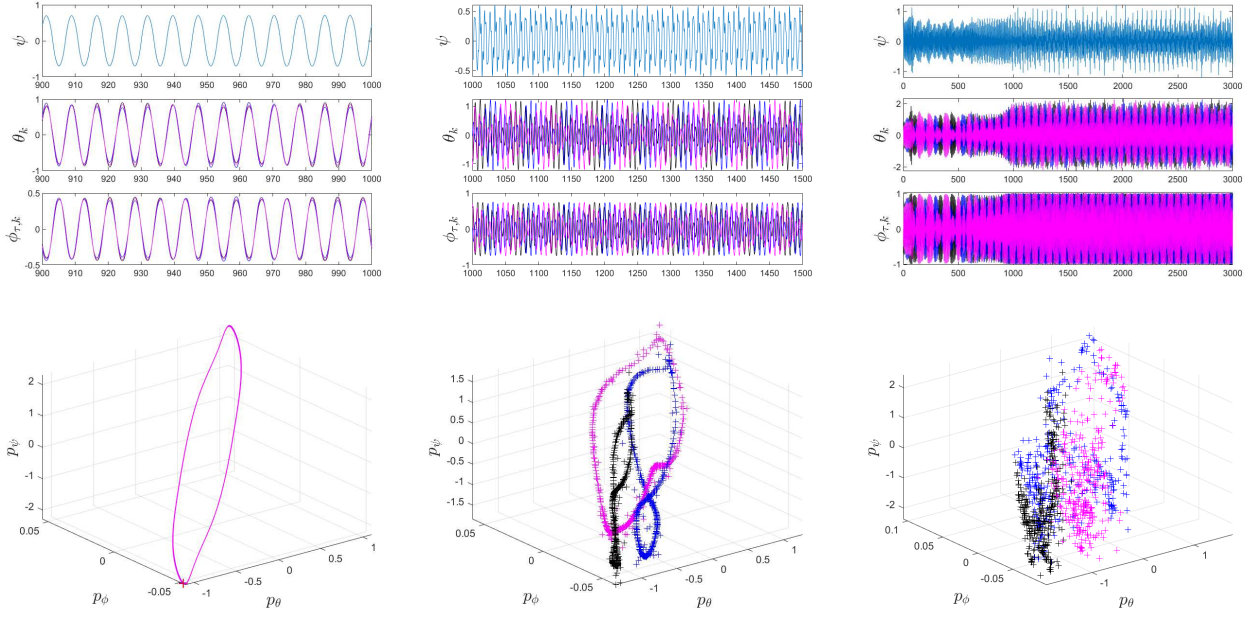

Figure 2: Time histories (upper) and conjugate momenta Poincaré maps (lower) for an in-phase periodic response (left) and an out-of-phase quasiperiodic response (center), and asynchronous chaotic oscillations (right)

Discussion

Non-stationary rotations occur first in the periphery pendula (Fig. 3 left), while the center pendulum exhibits chaotic oscillations. After a threshold gain value $\hat{\Gamma}_{3R}$ all three pendula rotate while the base oscillates chaotically (Fig. 3 center). The chaotic oscillations of the base culminate with rotations of all system elements (Fig. 3 right). We note that the linear feedback governing inertia wheel dynamics was synchronized with the pendula array periodic (out-of-phase) and quasiperiodic/chaotic (in-phase) oscillations, the non-stationary rotations were found to be asynchronous.

Figure 3: Time histories for non-stationary rotations combined with oscillations of the array elements (left) and (center), and non-stationary rotations of all elements (right)

* *Dept. of Geoscience and Petroleum, NTNU, Trondheim, Norway*

[†] *Dept. of Mechanical Engineering, Eindhoven Univ. of Tech., The Netherlands*

[‡] *Dept. of Civil, Environmental, and Geo- Engineering, Univ. of Minnesota, USA*

Summary. In this work we present a method for controlled synchronization of networked nonlinear systems based on nonlinear integral couplings. For a class of nonlinear systems and network topologies, this method allows one to design synchronizing nonlinear couplings with noticeably lower coupling gains (understood in a nonlinear sense) than for the case of linear diffusive couplings. This results in lower control values and energy consumption needed for synchronization as well as lower sensitivity to measurement noise. The method is illustrated by application to synchronization of Hindmarsh-Rose oscillators.

Synchronization and nonlinear integral couplings

In this abstract we consider N identical nonlinear systems of the form

$$\dot{x}_i = f(x_i) + Bu_i, \quad y_i = Cx_i, \quad i = 1, \dots, N, \quad (1)$$

with $x_i \in \mathbb{R}^n$, $y_i, u_i \in \mathbb{R}$, C^1 function $f(x)$ and matrices B and C of appropriate dimensions. The problem of controlled synchronization considered in this abstract is to find control laws for each u_i such that for any initial conditions of the closed-loop system, state vectors $x_i(t)$, $i = 1, \dots, N$ are bounded and

$$|x_i(t) - x_j(t)| \rightarrow 0, \quad \text{as } t \rightarrow \infty, \quad \forall i, j. \quad (2)$$

For each system i , u_i is allowed to depend on the system's output y_i and on the outputs y_j of the systems $j \in \mathcal{N}_i$, where \mathcal{N}_i is the set of systems that can communicate to system i . The sets \mathcal{N}_i specify the communication graph \mathcal{G} for the network (there is an edge from node j to node i if $j \in \mathcal{N}_i$). It is required that for identical outputs $y_1 = y_2 = \dots = y_N$, the controls satisfy $u_1 = u_2 = \dots = u_N = 0$, such that in exact synchrony the systems exhibit dynamics of the unforced (with zero input) system (1).

In this work we propose synchronizing control laws u_i in the form of nonlinear integral couplings:

$$u_i = \sum_{j \in \mathcal{N}_i} \int_{y_i}^{y_j} \lambda(s) ds, \quad i = 1, \dots, N, \quad (3)$$

where $\lambda(s) \geq 0$, $\forall s$, is a nonlinear coupling gain—the main design parameter in this scheme. Note that (3) is a generalization of conventional linear diffusive coupling, which is obtained from (3) with constant $\lambda(s) \equiv C$.

Contrary to the linear diffusive coupling, nonlinear integral coupling (3) allows one to differentiate the coupling strength depending on the location of the system's outputs in space, applying higher coupling gains only where the systems' nonlinearities counteract synchronization, while employing lower (or even zero) coupling gains where the nonlinearities do not have significant negative effects on synchronization. From the closed-loop performance point of view, the immediate consequences of this flexibility can be lower average synchronizing gains, lower coupling actions and energy needed to achieve and maintain synchronization and, consequently, lower sensitivity to measurement noise in outputs y_i . From the analysis point of view, this can provide better estimates of what should be the minimal coupling needed for synchronization. As couplings in physical, engineering and biological networked systems can have nonlinear nature (with their linear approximation studied in diffusive coupling), such estimates can shed more light on how synchronization is or can be achieved in such systems.

Main result

Let us first formulate notions and assumptions that delineate the considered class of systems (1) and the class of network topologies. The first assumption specifies the class of systems (1).

Assumption 1 *There exist $P = P^T > 0$, $R = R^T > 0$ and a scalar continuous function $\gamma(s)$ such that*

$$P \frac{\partial f}{\partial x}(x) + \frac{\partial f^T}{\partial x}(x)P - 2C^T C \gamma(Cx) \leq -R, \quad PB = C^T, \quad \forall x \in \mathbb{R}^n, \quad (4)$$

These conditions are satisfied for a class of incrementally minimumphase nonlinear systems [1]. Next, we formulate conditions on the communication graph \mathcal{G} . The conditions are linked to the notion of relaxed balanced coloring of the nodes of \mathcal{G} .

Definition 1 A coloring of the nodes with $k \in \{1, \dots, N\}$ colors c_1, \dots, c_k is called a relaxed balanced coloring if each node is assigned a color, and every c_i -colored node receives an equal number of edges from c_j -colored nodes for all $j \in \{1, 2, \dots, k\} \setminus \{i\}$.

A communication graph can be colored according to relaxed balanced coloring in multiple ways. The two trivial colorings are given by a) assigning each node an individual color and b) by assigning all nodes the same color. We call the graph *sequentially decolorable* if there exists a sequence of $N - 1$ relaxed balanced colorings, starting from the coloring a) and ending with coloring b), such that each coloring is obtained from the previous one by taking two groups of nodes with two different colors and assigning them the same color. Examples of sequentially decolorable graphs include graphs with two nodes with bi- and unidirectional couplings; bi-directionally coupled rings with 3 and 4 nodes, a graph with N nodes with all-to-all couplings. There are algorithms that allow one to verify whether a graph is sequentially decolorable in a computationally efficient way. Now we can formulate our main result.

Theorem 1 Consider N systems of the form (1) satisfying Assumption 1 and interconnected through nonlinear integral coupling (3) with a sequentially decolorable communication graph \mathcal{G} . Suppose the coupling gain function $\lambda(s)$ satisfies

$$\lambda(s) \geq \max(0, \gamma(s)), \quad \forall s \in \mathbb{R}, \quad \int_{-\infty}^{+\infty} \lambda(s) ds \leq +\infty. \quad (5)$$

Then all solutions of the closed-loop system (1), (3) are bounded and satisfy (2).

Remark: The condition (5) can be relaxed by taking into account quantitative characteristics of communication graph. For example, for a graph with N nodes and all-to-all interconnections, the first condition in (5) can be substituted by $\lambda(s) \geq \max(0, \gamma(s)/N)$.

Synchronization of Hindmarsh-Rose oscillators

We demonstrate our results with synchronization of Hindmarsh-Rose oscillators, which represent a simplified model of neuron dynamics [2]:

$$\dot{z}_1 = c - dy^2 - z_1, \quad \dot{z}_2 = \varepsilon(m(y + y_0) - z_2), \quad \dot{y} = -ay^3 + by^2 + z_1 - z_2 + I + u, \quad (6)$$

where y , z_1 and z_2 represent various states of a neuron and external stimulation is provided by input u . All other parameters are positive constants. Analysis of synchronization in a network of such oscillators with *linear* coupling is presented in [3]. For numerical simulations we choose the following values of system parameters: $a = 1$, $b = 3$, $c = 1$, $d = 5$, $m = 4$, $I = 2.8$, $y_0 = 1.618$, $\varepsilon = 0.005$ [3]. In this abstract, we consider 4 systems interconnected in the following way: $\mathcal{N}_1 = \{2, 4\}$, $\mathcal{N}_2 = \{3\}$, $\mathcal{N}_3 = \{2, 4\}$, $\mathcal{N}_4 = \{1\}$. System (6) satisfies Assumption 1 with some $P = P^T > 0$, $R = R^T > 0$ and $\gamma(s) = \epsilon - 3as^2 + 2bs + \frac{(1-\delta s)^2}{2(\delta-\epsilon)}$, for any sufficiently small $\epsilon > 0$ and, for the chosen system parameters, with $\delta = 0.2$, [1]. Thus, if we select $\lambda(s) = \max(0, \gamma(s))$, the function $\lambda(s)$ will satisfy (5) and, by Theorem 1 synchronization will be achieved. Simulations results are shown in Figure 1. The results demonstrate the synchronizing system states y_i , z_{1i} , z_{2i} and control inputs u_i , $i = 1, \dots, 4$. The last plot shows variable gain $g_{12}(t)$ of the nonlinear integral coupling defined as $g_{12}(t) = \int_{y_1(t)}^{y_2(t)} \lambda(s) ds / (y_2(t) - y_1(t))$, [1]. According to the simulations, the gain varies from 3 down to 0. The higher coupling gain is applied whenever it is needed to achieve synchronization. It is reduced and even set to zero in accordance with system's dynamics while maintaining synchronization. The average gain over the simulation of 500s equals 1.09 (shown as red dashed line in Figure 1). The lower coupling gains (instantaneous and average) is a distinctive feature of the proposed method over linear diffusive couplings. The best estimate of the linear diffusive coupling gain that we are aware of is 3, which can be computed using the results of [4].

Vibration control of underactuated 3-DOF systems inspired by tuned vibration absorbers: the non-linear Euler-Lagrange controller

Jasper Juchem* and Mia Loccufier*

*Department of Electromechanical, Systems and Metal Engineering, Ghent University, Ghent, Belgium

Summary. The concept of the non-linear Euler-Lagrange controller aims to combine the advantages of passive and active vibration control. The flexibility and adaptability of active control is combined with the intuitive design of a passive tuned vibration absorber. To verify this statement, an intuitive tuning procedure, which is inspired by the tuned vibration absorber, is stated. An energy-inspired approach is used to proof (asymptotic) stability using Lyapunov's direct method. A three-link planar manipulator with one actuator at the base is controlled to mitigate vibrations in the unactuated links. The controller contains a non-linear damper. Finally, some different experiments should give insight whether it is necessary to capture all modes, with the disadvantage that the number of controller parameters increases drastically. Also, a non-linear damper is compared to a linear one.

System description

The system that needs to be controlled, also referred to as the process, is a planar three-link manipulator. The joints are assumed to be frictionless. Between the links a spring creates a restoring force. At the base of the first link no spring is attached. The equation of motion is given by the general differential equation:

$$D(q)\ddot{q} + C(q, \dot{q})\dot{q} + K(q) = -Mu \quad (1)$$

with the generalized coordinates the relative angles between the links $q = [q_1 \ q_2 \ q_3]'$ and \cdot' the transpose. The inertia matrix $D(q) = D(q)' > 0 \in \mathbb{R}^{n_p \times n_p}$ with $n_p = 3$ the number of generalized coordinates of the process, $C(q, \dot{q}) \in \mathbb{R}^{n_p \times n_p}$ the coriolis/gyroscopic and damping terms, stiffness matrix $K(q) \in \mathbb{R}^{n_p}$, and $u \in \mathbb{R}^{n_p}$. The matrices for this system can be found in [3].

The controller consists of two blocks that are placed in parallel: a proportional controller $u_1 = K_p M' q$ and an Euler-Lagrange controller

$$\begin{cases} D_0 \ddot{z} + \frac{\partial F}{\partial \dot{z}}(\dot{z}) + K_0(z) = -N_1 M' q - N_2 M' \dot{q} \\ u_2 = \nu_1 z + \nu_2 \dot{z} \end{cases} \quad (2)$$

with $z \in \mathbb{R}^{n_c}$ the generalized coordinates of the controller, $D_0 \in \mathbb{R}^{n_c \times n_c}$ the inertia matrix, $\partial F / \partial \dot{z} \in \mathbb{R}^{n_c}$ non-linear damping function, $K_0(z) \in \mathbb{R}^{n_c}$ stiffness matrix of the controller, $N_1, \nu_1' \in \mathbb{R}^{n_c \times n_p}$ the amplification of the position coupling with the process in the input and output equation respectively, and $N_2, \nu_2' \in \mathbb{R}^{n_c \times n_p}$ the amplification of the velocity coupling with the process in the input and output equation respectively.

The controller effort in (1) is then given by $u = u_1 + u_2$. Notice the similarity with adding a mechanical structure to the system. However, the difference with adding a tuned vibration absorber is the way of connecting the controller and the process. Furthermore, in the differential equations $M = \text{diag}(\{0, 1\}) \in \mathbb{R}^{n_p \times n_p}$ forces a collocated control strategy. For the compound system to be an Euler-Lagrange system, the following must hold: $\nu_1 = N_1'$.

Asymptotic stability: Lyapunov's direct method

The stability is proven using Lyapunov's direct method. Let x_e be an equilibrium point for

$$\dot{x}(t) = f(x(t)) \quad (3)$$

where $f : D \rightarrow \mathbb{R}^n$ is a locally Lipschitz map from a domain $D \subset \mathbb{R}^n$ into \mathbb{R}^n , with $x_e \in D$. Let $V_L : D \rightarrow \mathbb{R}$ be a continuously differentiable function, such that

$$V_L(x_e) = 0, V_L(x) > 0 \text{ in } D \setminus \{x_e\}, \dot{V}_L(x) \leq 0 \text{ in } D, \text{ and } \dot{V}_L(x) < 0 \text{ in } D \setminus \{x_e\} \quad (4)$$

with $\dot{V}_L(x) = \frac{\partial V_L(x)}{\partial x} f(x)$. Then x_e is asymptotically stable.

Here, the Hamiltonian \mathcal{H} is chosen to be the Lyapunov function. This leads to four conditions for the controller parameters that need to be fulfilled:

1. $\frac{dK_0}{dz}$ should be continuous, invertible and positive definite,
2. $\frac{dK(q)}{dq} + MK_p - M\nu_1 \frac{dK_0(z)}{dz}^{-1} \nu_1' M' > 0$,
3. $\nu_2' = -N_2$, and
4. $\left(\frac{\partial F}{\partial \dot{z}}\right)' \dot{z} \geq 0$.

Controller tuning

This research focusses on mitigating vibrations due to impulse impacts on the third link. After impact, the open-loop system will vibrate infinitely, as there is no damping present. It is not possible to apply a controlled torque to the second or third joint, what complicates diminishing these vibrations. The topology of the controller allows the introduction of tuning techniques from passive vibration control. One can try to make the controller sensitive to the main system, such that easy energy transfer occurs from the process to the controller. Once the energy is transferred, it can be dissipated in this controller [1].

Eigenfrequency matching

To facilitate an easy energy flow from the process to the controller, eigenfrequency matching is well-known strategy [2]. In this work, this is done in two steps. Firstly, the eigenfrequencies of the substructures are matched by tuning K_p in the case that $\nu_1 = \nu_2 = 0$. Secondly, the eigenfrequency of the process and controller are matched. Let $\Omega^2 = \text{diag}(\omega_1^2, \omega_2^2, \omega_3^2)$ with ω_i an eigenfrequency of the process. Now, the controller is tuned to have the same eigenfrequency

$$K_0(z) = D_0 \Omega^2 z \quad (5)$$

Notice that depending on n_p the number of modes that are captured can be altered. To achieve stability, $\omega_i \neq 0$, as all conditions on $\frac{dK_0}{dz}$ are then fulfilled. The second condition leads to the expression $k_{p,1} - \nu_{11}^2/\omega_1 - \nu_{12}^2/\omega_2 - \nu_{13}^2/\omega_3 > 0$

with $K_p = \text{diag}(k_{p,1}, k_{p,2}, k_{p,3})$ and $\nu_1 = \begin{bmatrix} \nu_{11} & \nu_{12} & \nu_{13} \\ \nu_{21} & \nu_{22} & \nu_{23} \\ \nu_{31} & \nu_{32} & \nu_{33} \end{bmatrix} = \begin{bmatrix} \nu_{11} & \nu_{12} & \nu_{13} \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}$, which is equivalent as only the first link can be actuated.

Optimization

Without loss of generality it can be assumed that D_0 is an identity matrix [4]. This leaves us with three unknown matrices: ν_1, ν_2 , and $\frac{\partial F}{\partial \dot{z}}$. As ν_2 introduces a conservative coriolis force and due to non-linear damping, the analysis is too complex to be carried out analytically [5, 6]. Therefore, the remaining parameters will follow from an optimization. The optimization algorithm will use four objective functions:

$$f_1 = T_{s,1}\omega_1; f_2 = T_{s,2}\omega_1; f_3 = T_{s,3}\omega_1; f_4 = \int \frac{\mathcal{H}(t)}{\max \mathcal{H}} dt \quad (6)$$

with settling time $T_{s,i}$ of link i the time after which the time signal stays within 5% of the maximal deviation around equilibrium, and ω_1 the slowest eigenfrequency.

As mentioned before, the controller's damping will be a non-linear function

$$\frac{\partial F}{\partial \dot{z}} = c_1 \dot{z} + c_2 \arctan\left(\frac{c_0 - c_1}{c_2} \dot{z}\right) \approx \begin{cases} c_0 \dot{z} & \text{if } \dot{z} \approx 0 \\ c_1 \dot{z} + cst & \text{if } |\dot{z}| \rightarrow \infty \end{cases} \quad (7)$$

with $c_i > 0$. Then $(\frac{\partial F}{\partial \dot{z}})' \dot{z} > 0$ if $c_0 > c_1$.

Results

In this section different controllers are compared. First of all, increasing the number of generalized coordinates of the controller, n_c , leads to capturing all modes of the process. However, it also increases the number of controller parameters drastically, thus increasing the optimization time. Next to that, a non-linear Euler-Lagrange controller will be compared to a linear one. All simulations will be the result of an impulse on the tip of the third link.

Conclusions

A planar underactuated three-link manipulator will be controlled with a non-linear Euler-Lagrange controller. Next to stability, a tuning strategy based on tuned vibration absorbers will be validated. The number of generalized coordinates of the controller (n_c) will be varied from one to three to observe whether the increase in tuning parameters leads to an significantly improved result. Also, the difference between linear and non-linear damping is examined.

Summary. Two sampled based methods, i.e. the basin stability and basin entropy used to describe the dynamics of multistable systems will be presented. Both methods are based on integrating the system's equations of motion for a large set of different initial conditions and classifying the solutions based on final attractors. The main difference between the two approaches is the different sample methods of initial conditions for each trial. In the first one, we use the random initial conditions. In contrast, for the second one, the phase space should be uniformly divided into boxes of equal size. We show under which conditions it is possible to calculate the basin entropy using random samples of initial conditions. Moreover, the basin entropy method assumes the identical size of the investigated box in all directions of multidimensional phase space. In many real-life systems, it is impossible to achieve; hence we introduce the scaling of the box to overcome this problem. To summarize, we show under which conditions we can accomplish the reliable value of basin entropy using random initial conditions and rescaled size of the box.

Introduction

Non-linear ODEs describing dynamical systems can be solved analytically, but it often requires simplifying equations or imposing strong assumptions on the solution. Hence, nowadays, most non-linear ODEs are tackled with numerical methods. There are several approaches that allow to investigate the multi-stability of the systems. The problem appears for higher dimensional systems, where we can present only two-dimensional cross-sections of multidimensional phase space. Again, it is possible to overcome that, with a method proposed by Menck et al. [1] called basin stability. It can be used to characterize the volume of basins of attraction in the multidimensional phase space. To estimate the basin stability measure, one has to perform a large number of Bernoulli trials each time, drawing initial conditions randomly and checking which attractor is reached. This method is rather new, but was already successfully applied in a numerous different scenarios. The main advantages of this method are that it can be applied to all types of systems, and it is a straightforward procedure, thus a person who is not an expert on non-linear dynamics can use it to estimate the risk of unwanted behaviour. In 2017, the experimental validation of the basin stability approach has been performed [2] and results proved that the accuracy of basin stability approach is comparable with classical methods.

The disadvantage of the basin stability approach, is that it does not take into consideration the structure of the analysed basins. In 2016 Daza et al. [3] proposed a new method that include the information about the structure of the phase space. It is called a basin entropy measure and it provides information about the unpredictability of the dynamical system. To obtain basin entropy, one has to build a grid on the phase space and, in each part, estimate basin stability. Then, this value is used to obtain Gibbs entropy for every part of the grid. Summing the entropies, leads to a quantitative measure of the uncertainty associated with the state space.

The motivation is to combine these two metrics for an analysis of a dynamical system. The aim is to show, that it is possible to estimate the basin entropy accurately without distinct simulation for every part of the grid. To prove that, we will show that the basin entropy calculated using the data obtained during the estimation of basin stability is a good approximation of the one calculated classically.

Basin stability

Basin stability is defined for a n -dimensional dynamical system with N attractors in an analysed region of the state space $\Omega \subset R^n$. Then, integrating the system equation of the motion multiple times with random initial conditions from Ω allows to estimate the probability of reaching each attractor. The proportion of initial conditions that reach certain attractor to the overall number of trials is the estimation how the attractor is stable, and called basin stability $B_s(A)$ of attractor A . The application of the method is presented on an archetypal model of externally excited oscillator, the Van der Pol-Duffing system:

$$\ddot{x} - \alpha(1 - x^2)\dot{x} + x^3 = F\sin(\omega t),$$

where α , F and ω are positive constants.

Basin entropy

Basin entropy is defined for a n -dimensional dynamical system with N attractors in an analysed region of the state space $\Omega \subset R^n$. We then cover Ω with $k \in N$ disjoint n -dimensional hypercubes of linear size ϵ in each dimension. Each of

these boxes, in principle contains infinitely many trajectories. Moreover, each of such trajectory lead to one of N attractors mentioned before. For such a formulation, the basin entropy is given by

$$S_b = \frac{1}{N} \sum_{i=1}^k S_i = \frac{1}{N} \sum_{i=1}^k \sum_{j=1}^{N_A} p_{i,j} \log \left(\frac{1}{p_{i,j}} \right)$$

Where $p_{i,j}$ is the basin stability of a j -th attractor numbered $j \in \{1, \dots, N_A\}$ calculated in i -th box. The application of the method is again presented on the Van der Pol-Duffing system. Furthermore, it is shown that the value of basin entropy is not affected by scaling the state space. This is helpful in the cases, where the ranges of initial values for some state variables differ significantly from the other ones.

Estimating basin entropy with sample based methods

Basin entropy requires the initial conditions to be distributed over the state space, so that every box created during the calculation of basin entropy contains the same amount of trials. On the other hand, the basin stability initializes all trials at random, thus it cannot be ensured that the basin entropy calculated on such data matches the one equally distributed. The analysis of the relative error of basin entropy for a single multidimensional box was performed, followed by the comparison of basin entropy calculated with three different types of input data: two types of equal distribution of points per box (25 points and 100 points) and random sampling using 4,000,000 trials. It is summarized that one can accurately estimate the value of basin entropy using the random sampling method.

Trial based basin entropy for a double pendulum model

The idea behind basin stability type metrics, is to evaluate the asymptotic behaviour of a general system, where one cannot in principle visualize the results. Hence, in this section we present previously discussed metrics for a double pendulum model which is a paradigmatic example in nonlinear dynamics. We based on the real experimental rig which has been designed, constructed and tested in our laboratory. This rig was also used to experimentally validate the basin stability approach [2]. The physical model of the system is shown in Figure 1

Figure 1: The physical model of the double pendulum system and its realization in laboratory.

Conclusions

The basin stability and the modified basin entropy was then used to analyse the double pendulum system. Due to the described modifications, we were able to calculate the basin entropy on the scaled state space, using the randomized trials obtained with the procedure of calculating basin stability. To choose the proper number of simulations, we performed the analysis of entropy for randomized subsets of the state space. The values of basin stability for the main attractors of the system were also presented. We detected two most stable periodic attractors, both with period 1. Finally, we calculated the basin entropy, concluding that the analysed basins are neither fractal, nor regular.

Dynamics and Control of a Rotating Beam with Active Element

Jerzy Warminski*, Andrzej Mitura*, Lukasz Kloda*

**Department of Applied Mechanics, Lublin University of Technology, Lublin, Poland*

Summary. Dynamics of a rotating flexible beam with an embedded active element is studied in the paper. The beam model is based on Bernoulli-Euler theory but it is extended taking into account beam's extensionality and large transversal deformations with nonlinear curvature. The macro fibre composite (MFC) embedded into the structure is applied to control or reduce externally excited vibrations. The model of MFC element is considered in a few variants of simplifications. The complete model takes into account electromechanical properties of MFC element including hysteresis and also properties of a voltage amplifier. The influence of the MCF model simplifications on the effective vibration control is presented.

Introduction

Rotating structures are of interest in many engineering applications. One of the classical examples are rotors of helicopters [1], drones or wind turbines. The blades of such rotors can be subjected to various loadings, for example can be excited by aerodynamic forces leading to flutter oscillations, and then large amplitude vibrations may arise. In order to avoid unwanted vibrations a special design of blades is proposed. The good possibility to obtain specific properties of the blade can be achieved by application of modern composite materials which enable creating specific mechanical features of the blade as presented in paper [2]. An additional option of a vibration reduction is to apply actuators embedded into the rotating blade which may reduce unwanted vibrations by use of dedicated control algorithms. The effectiveness of selected linear and nonlinear algorithms tested numerically and experimentally for a cantilever composite beam with active Macro Fibre Composite (MFC) elements was presented in paper [3]. The nonlinear saturation control and the positive position feedback control were demonstrated as the most powerful methods to suppress beam vibrations. However, the methods were tested for a fixed (non-rotating) structure. The proportional (P) and derivative (D) control method for the rotating beam was proposed in [4]. A pair of piezoelectric actuators/sensors were used to reduced vibrations of the structure. The analysis showed that typical P control method did not reduce vibration but only PD algorithm enhanced vibration damping of the rotating beam. The goal of this paper is to study dynamics of a rotating structure which takes into account more precise nonlinear model of the rotating beam (the plant) together with nonlinear properties of the emended MFC actuator. Then, the model will be used to propose and test a proper control algorithm, including linear and nonlinear control strategies.

Model formulation and results

A model of the rotating structure is composed of a rigid hub and a flexible blade oscillating in the rotating frame (x, y) which has position defined by a preset angle θ measured from the axis Z_0 of the rotating hub (Fig. 1a). A lumped mass m_t is added to the beam tip which allows to study more general case with dynamic boundary conditions. The beam with a rectangular cross-section is made of material having isotropic and linear properties. The beam is assumed to be thin and its model is based on Bernoulli-Euler beam theory. However, due to possible large deformations a nonlinear curvature and furthermore its extensionality is taken into account which, in case of rotating structure may play an important role. At the present study it is assumed that the hub rotates with constant angular speed $\dot{\psi}(t) = \Omega$ and, in addition, the beam is excited periodically by periodic loading distributed along the beam's span.

Figure 1: Model of the rotating hub-beam structure with tip mass (a) and schematic model of the MFC actuator (b).

The equations governing the beam dynamics are given as a set of partial differential equations (PDE) with associated

dynamic boundary conditions. The equations have been solved analytically by the multiple time scale method. The resonance curves obtained analytically for the first and the second bending mode are presented in Fig. 2. The curves are computed for rotating structure for $\Omega = 10$ rad/s and selected preset angles $\theta = 30^\circ$, $\theta = 45^\circ$ and $\theta = 60^\circ$. The rotating beam demonstrates nonlinear behaviour with hardening effect for the first mode (Fig. 2a) and softening for the second (Fig. 2b). The first resonance curve is sensitive for varied preset angle while the influence for the second is minor, almost invisible.

Figure 2: Resonance curves against frequency detuning parameter σ_v around the first (a) and the second (b) bending mode. Angular velocity $\Omega = 10$ rad/s and preset angle: $\theta = 30^\circ$ - black, $\theta = 45^\circ$ - red, $\theta = 60^\circ$ - blue.

To control the rotating beam and reduce vibrations the active MFC elements are embedded into the beam structure. The model of piezoelectric MFC element and its amplifier is presented schematically in Fig. 1b. In the scheme two elements k_{amp} and R describe amplifier properties. The gain k_{amp} is related to voltage $U_{control}$, resistor R models the output resistance of the amplifier. The piezoelectric actuator is represented by a capacitor with capacity C_{MFC} . The direct and indirect (converse) piezoelectric effect transform the actuator deformation into charge q_{EM} and actuator voltage U_{MFC} into mechanical force F_{EM} , respectively. The model also takes into account nonlinear properties of the piezoelectric actuator including the hysteresis phenomenon which schematically is represented by H element. The nonlinear and hysteretic piezo-element is added to the main structure (the plant) and the obtained combined electro-mechanical system is studied in order to select the most effective control algorithm enabling active vibration suppression for selected resonance states. Linear and nonlinear control strategies are tested and some of them are verified in laboratory.

Conclusions

The developed model of the nonlinear rotating beam which takes into account influence of angular velocity and preset angle is studied in the paper. Due to nonlinear geometrical nonlinearities hardening or softening effects are observed for the first and the second bending modes, respectively. It has been shown that varied preset angle affects mainly the first mode resonance observed by a shift of the resonance zone. The second mode resonance is almost not affected, just a very minor change is present. Apart from the nonlinear rotating beam model (the plant) also the model of active MFC element is proposed. The model takes into account two-way electromechanical coupling as well as hysteresis of the active element. The control strategy for active vibration damping with linear and nonlinear control algorithms is analysed.

Utilizing Noise to Manipulate Energy Localization in a Circular Oscillator Array

Gizem Dilber Acar*, Abdulrahman Alofi* and Balakumar Balachandran *

*Department of Mechanical Engineering, University of Maryland, College Park, 20742, USA

Summary. In this work, energy localization in an array of Duffing oscillators with periodic boundary conditions is studied. Each oscillator in this array can exhibit multi-stable behavior, and the localized mode of the forced array exists in a certain frequency range. For a specific excitation frequency, Gaussian noise is applied in addition to the harmonic forcing to move the system response from the localized mode to a low-amplitude mode. Through this study, the authors shed light on how noise can be used to design the desired dynamics of coupled oscillator arrays, such as a circular array of rotor blades.

Introduction

Coupled oscillator arrays represent numerous mechanical systems including multi-bladed rotors and micro- electro- mechanical resonators [1]. Understanding nonlinear behavior of oscillator arrays is important for designing such systems. Energy localization is a nonlinear phenomenon that can be observed in oscillator arrays, wherein the system's energy is spatially focused in one or more oscillators. Although spatial energy localization can happen in discrete systems due to imperfections, it can be observed in homogeneous discrete systems due to nonlinearity [2]. Depending on the application, spatial localization of energy can be desirable or harmful.

Cyclically symmetric, discrete systems can exhibit localization behavior when the coupling between the discrete elements is weak [3]. In this study, the responses of an array subjected to a harmonic forcing and harmonic forcing with noise are numerically examined. The system exhibits multi-stable behavior in a particular frequency range, and depending on the initial conditions, one of these responses can correspond to energy localization. The array has a circular configuration (i.e., periodic boundary conditions), and each oscillator is coupled with two neighbors. Furthermore, energy can flow through the boundaries without interruptions. Here, the system is excited with a harmonic forcing so as to excite a localized mode. Then, Gaussian noise is added to the harmonic forcing in order to steer the system to a non-localized response. By using the numerical studies, the authors show that the Gaussian input can be used to move the system from the localized mode to a low-amplitude mode, wherein all the oscillator move with the same amplitude, and the energy is uniformly distributed across the array. For different noise intensities, the authors explore the possibility of using noise to destroy energy localization.

Numerical Experiments

A circular array of six identical hardening Duffing oscillators are considered, wherein each oscillator has associated linear stiffness, cubic stiffness, and linear damping. Each oscillator is coupled with the neighbors through linear springs, as shown in Figure 1a. The system is cyclically symmetric with periodic boundary conditions. The localized mode of the system is found using the anti-continuous limit method [4], according to which the localized mode is first found for the system with zero coupling stiffness. Then, by gradually increasing the coupling in small steps, and using the numerical shooting method at each step, the localized mode of the coupled system is found. The array is excited with a harmonic forcing that can induce energy localization in the system. A representative amplitude profile of the localized mode is shown in Figure 1b. The localized mode is symmetric about the high-amplitude oscillator, and each oscillator moves out-of-phase with its two neighbors. In this analysis, the authors chose the 3rd oscillator for the localization. It is noted that with a different choice of initial conditions, the system energy can be localized in another oscillator. Although energy localization can be observed in systems with smaller numbers of degrees of freedom, the authors analyzed an array with six oscillators to show that the amplitude of oscillations varies drastically around the localization, and it decreases as one moves away from the high-amplitude oscillator. For arrays with larger numbers of oscillators, the amplitude profile may become more uniform across the oscillators that are away from the high-amplitude oscillator.

In order to analyze the system behavior under noise, a Gaussian input is added to the harmonic forcing, as shown below.

$$\ddot{x}_n + c\dot{x}_n + k_1x_n + k_3x_n^3 + k_c(2x_n - x_{n-1} - x_{n+1}) = F_0 \cos(\omega t) + \sigma \dot{W}(t), \quad (1)$$

for $n = 1, \dots, N$, where the periodic boundary conditions imply that the $N + 1$ oscillator coincides with the first oscillator. The incremental noise is represented with $\sigma \dot{W}(t)$. In this study, each oscillator is excited with the same forcing function to avoid inducing asymmetry into the system through forcing. The system equations with noise are put into Langevin form, and the Euler Maruyama method is used to numerically integrate the noise-influenced system equations [5]. For three different noise intensity levels, the obtained energy distribution in the oscillator array is shown in Figure 2. For each chosen noise intensity, the energy distribution plots are provided by using an average of the responses of the oscillator array to 400 different noise vectors. Although depending on the noise vector, it might take longer or shorter for the noise to suppress localization, the averaged dynamics show that for higher noise intensities ($\sigma = 0.01$ and $\sigma = 0.006$), the Gaussian input can destroy the energy localization, and push the system to a state with uniform energy distribution. However, for a smaller noise intensity ($\sigma = 0.002$), one is not able to use the noise to the unison amplitude mode, and the localization persists.

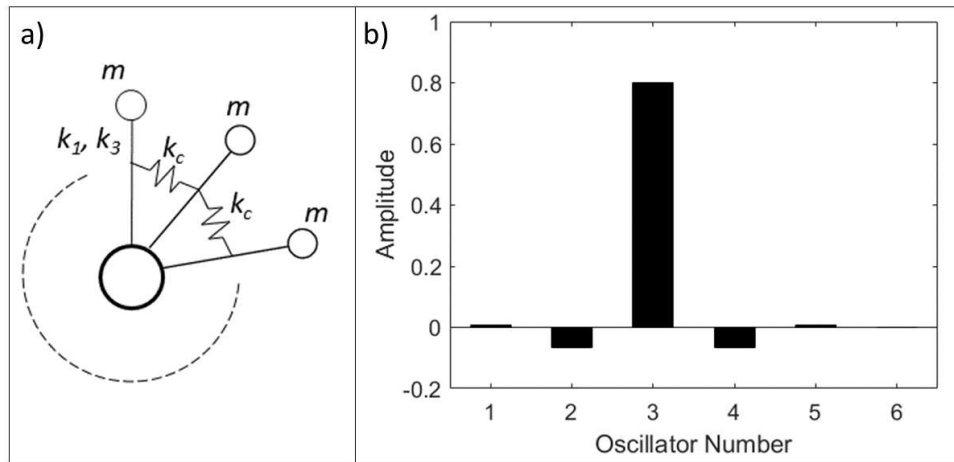

Figure 1: a) Coupled circular Duffing oscillator array with periodic boundary conditions. b) Amplitude profile of the localized mode: The energy is localized in the 3rd oscillator, and the amplitude profile is symmetric about the oscillator with the highest amplitude.

Figure 2: Energy distribution in a circular Duffing oscillator array averaged over 400 simulations. In all three cases, the energy is localized in the 3rd oscillator in the beginning. Addition of noise with intensity $\sigma = 0.01$ and $\sigma = 0.006$ can suppress the energy localization, and lead to a uniform energy distribution in the array. However, a lower noise intensity ($\sigma = 0.002$) is found to be inadequate for pushing the system to the unison-amplitude mode.

Conclusions

In this study, energy localization in a circular array of hardening Duffing oscillators with weak, linear coupling was investigated. The system was first excited with a harmonic forcing frequency, for which the array can oscillate in a localized mode. Then, various levels of Gaussian noise were applied along with the harmonic forcing, to explore the effects of noise on energy localization. Through numerical studies, it was found that above a certain noise level, the localization can be suppressed. The findings may provide a basis for suppressing energy localization in arrays of turbine blades. The studies will be extended to larger systems in order to explore the effects of number of oscillators on the noise required to drive the system between solutions with different energy distributions.

Evaluating the Resistant Force of a Vibro-Impact Self-Propelled Capsule Moving in the Small Intestine

Summary. In this work, we study a mathematical model for evaluating the resistant force of a vibro-impact capsule self-propelling in the small intestine with a consideration of its anatomy. Circular fold is the main source of intestinal resistance that needs to be overcome during the endoscopic procedure. Our model is able to calculate the resistance of such folds in different dimensions. Finite element analysis and experimental testing are presented to validate the proposed model. Our investigation shows that the resistance reaches its maximum immediately after the capsule is driven against the fold, and drops off gradually during the crossing motion.

Introduction

Diseases of surface lining of the small intestine are highly challenging to diagnose and treat. To develop new endoscopic devices capable of self-propelling in the small intestine, endoscopic engineers need to take the complex anatomy of the small intestine into account, in particular the circular fold of the small intestine, when evaluating the performance of their designs. The purpose of the present work is to develop a mathematical model for accurately predicting the resistant force of the capsule-type devices moving in the small intestine and use the model to test the vibro-impact self-propelled capsule developed in the Applied Dynamics and Control Lab at the University of Exeter [1, 2].

According to the movement of the small intestine, most of the research works (e.g., [5, 4]) assume that the capsule distends the intestine in the radial direction when assessing the intestinal resistance. However, this assumption is only valid for a very short time interval during the intestinal movement. For most of the time of diagnosis, the capsule is in one-sided contact with the intestinal wall, so the resistance from the hoop pressure does not apply. For this reason, Guo et al. [7, 8] estimated the intestinal resistance for a self-propelled capsule by considering both partial and full capsule-intestine contacts. In the present work, we use the cylindrical capsule as an example and take the circular fold of the small intestine into consideration to study the required driving force for self-propulsion and the capsule's dynamics in clinical scenario.

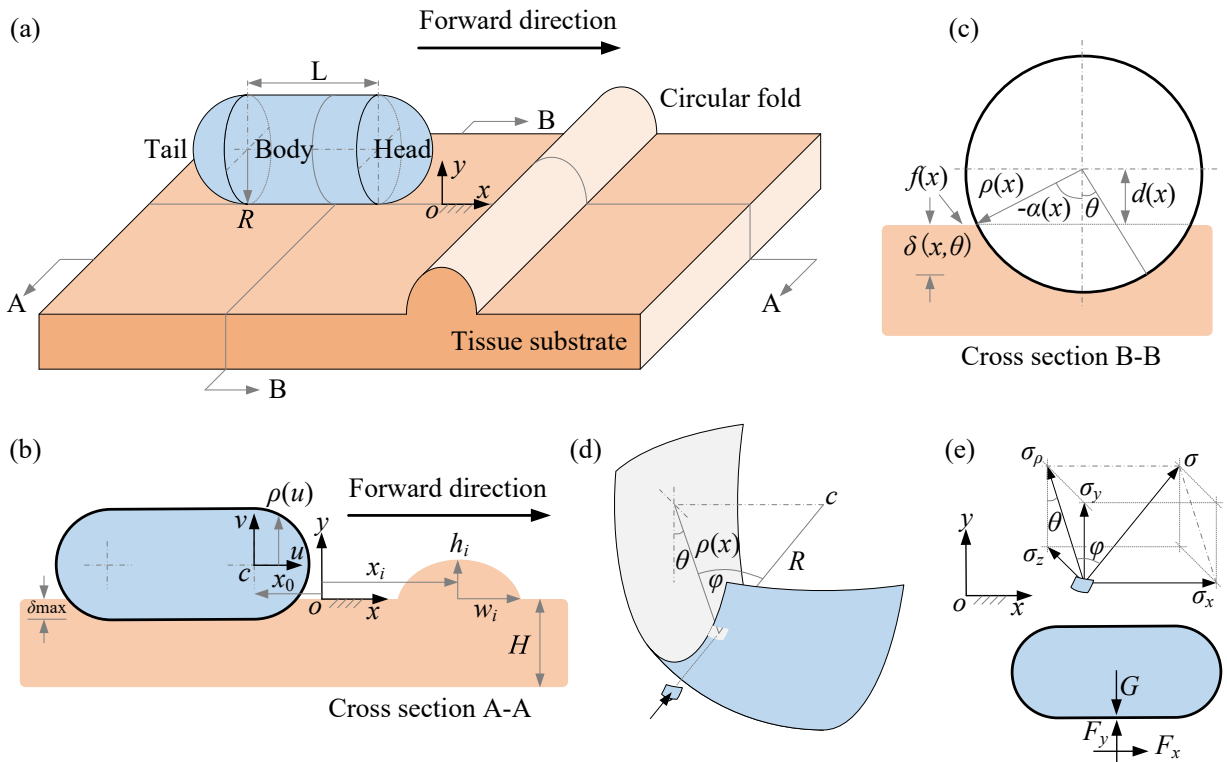

Figure 1: (a) 3D schematic of an endoscopic capsule moving towards a circular fold on a flat tissue substrate. (b) Cross section A-A shows the horizontal and vertical location of the capsule by x_0 and δ_{\max} , and the location, width and height of the i th fold by x_i , w_i and h_i . (c) Cross section B-B shows the capsule-substrate contact angle, $\theta \in [-\alpha(x), \alpha(x)]$. (d) The stress, $\sigma(x, \theta)$, is exerted on the capsule shell as a normal pressure. (e) Integrating the x and y components of the pressure yields the horizontal and vertical reactions, where F_y is balanced by the capsule's gravity, G , and F_x resists the capsule's motion.

Mathematical modelling and validation

The interaction between the capsule and a tissue substrate is schematically illustrated in Fig. 1. As seen, the capsule's hemispheric head and tail is connected by a cylindrical body with a length of L and a radius of R . When the capsule moves horizontally in x -direction, it engages with the circular fold of the small intestine, resulting in complex interactive forces and capsule motion. The detailed modelling procedure can be found in [9].

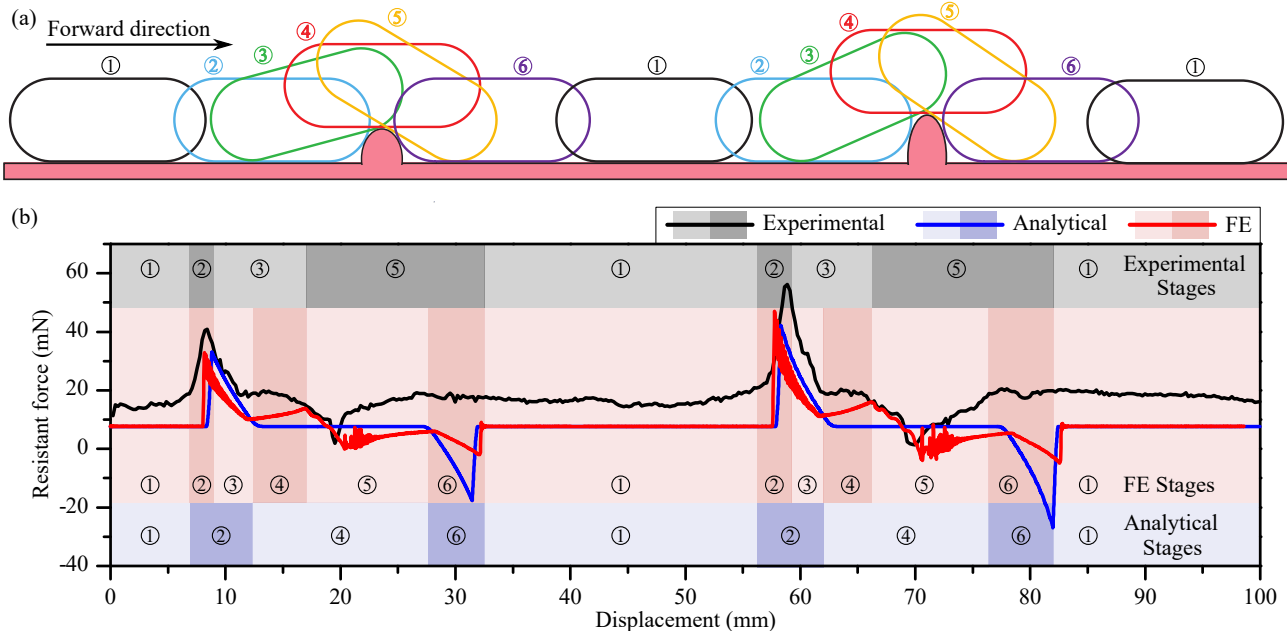

Figure 2: (Colour online) Resistant force acting on the capsule as a function of capsule's displacement when the capsule was pulled on a cut-open synthetic small intestine consisting of two different circular folds in a constant speed of 8 [mm/s] obtained from the mathematical model (blue line), the FE model (red line) and the experiment (black line). FE model can capture all of the six stages of the capsule's motion. Due to the limitations, experiment missed Stages ④ and ⑥, and the mathematical model cannot capture Stages ③ and ⑤. Parameters for the mathematical and FE models were chosen as $E = 100$ [kPa], $G = 33.96$ [mN], $\mu = 0.2293$, $R = 5.50$ [mm], $L = 15$ [mm], $H = 0.69$ [mm], $x_1 = 12.66$ [mm], $h_1 = 1.67$ [mm], $w_1 = 1.665$ [mm], $x_2 = 62.66$ [mm], $h_2 = 2.34$ [mm] and $w_2 = 1.545$ [mm], which were identified from the experimental setup in [8].

In order to validate the analysis, the mathematical and finite element (FE) models adopted the parameters corresponding to the experimental setup described in [8]. Under the same position, the one-to-one correspondence between the capsule's posture and the resistant force is shown in Fig. 2. According to the FE result, the process of capsule's crossing over a circular fold can be divided into six stages. Although some stages were missed by the mathematical model and the experiment due to their limitations, here we are interested with the maximum resistant force experiencing by the capsule when it crosses over the fold.

Conclusions

In conclusion, the FE model captured all of the crossing stages, but the computation was so time-consuming that we only adopted a 2D FE model to sacrifice its accuracy. Nonetheless, all these three (analytical, FE and experimental) methods yielded consistent results for evaluating the maximum resistant force.

Work-loop techniques for optimising nonlinear forced oscillators

Arion Pons^{* ** †}, and Tsevi Beatus^{* ** ‡}

^{*}*Institute of Life Sciences, Hebrew University of Jerusalem, Israel*

^{**}*School of Computer Science and Engineering, Hebrew University of Jerusalem, Israel*

Summary. Linear and nonlinear resonant states can be restrictive: they exist at particular discrete states in frequency and/or elasticity, under particular (*e.g.*, simple-harmonic) waveforms. In forced oscillators, this restrictiveness is an obstacle to system design and control modulation: altering the system elasticity, or modulating the response, would both appear to necessarily incur a penalty to efficiency. In this work, we describe an approach for bypassing this obstacle. Using novel work-loop techniques, we prove and illustrate how certain classes of resonant optimisation problem lead to non-unique solutions. In a structural optimisation context, several categories of energetically-optimal elasticity are non-unique. In an optimal control context, several categories of energetically-optimal frequency are non-unique. For these classes of non-unique optimum, we can derive simple bounds defining the optimal region. These novel theoretical results have practical implications for the design and control of a range of biomimetic propulsion systems, including flapping-wing micro-air-vehicles: using these results, we can generate efficient forms of wingbeat modulation for flight control.

1. Introduction

A wide range of biological and engineering systems utilize nonlinear structural elasticity to shape and control an oscillatory forced response. Insects rely on strain-hardening thoracic elasticity to modulate flight motor muscular actuation [1, 2]. Micro-mechanical energy harvesters utilise nonlinear elasticity to improve harvesting efficiency [3–5]. Compliant bipedal robots utilise distributed elasticity to improve walking efficiency [6]. Among the multifaceted roles that nonlinear elasticity can play in such systems, energetic roles are often central: structural elasticity can absorb inertial loads and/or mitigate inertial power requirements, thereby increasing system efficiency. However, there is a sense in which the pursuit of efficiency can be restrictive. Energetically-optimal states tend to be discrete: located at particular states of elasticity (*e.g.*, the resonant elasticity); or at particular discrete frequencies (*e.g.*, the resonant frequencies), and particular (*e.g.*, symmetric, harmonic) waveforms. For instance: as per classical analysis, linear resonance occurs at discrete frequencies, and under simple-harmonic forcing; and in nonlinear systems, such as the Duffing oscillator, frequency response magnitude peaks are also typically discrete. In both cases, deviating from the energetically-optimal frequency-elasticity match, or resonant state, incurs a penalty in efficiency.

Here, we describe a novel technique for bypassing this efficiency penalty in some contexts. Using work-loop analysis techniques – showing several parallels with phase portrait techniques – we can illustrate and prove several key optimality results. These techniques allow us to prove how several classes of forward- and inverse-problems for energetic optimality necessarily lead to non-unique solutions; and to derive simple bounds defining this region of non-unique optimal solutions. These new theoretical results have significant implications for the use of nonlinear dynamics in engineering design. They describe ways to introduce nonlinear elasticities into a system to ensure energetic optimality, and illustrate how, for certain classes of energetic optimality, a whole space of optimal nonlinear elasticities exists. The choice of nonlinear elasticity within this space is a design tool that can be used to control other aspects of system behaviour. These results also describe methods for modulating the frequency of a resonant response, and/or breaking its symmetry, while maintaining energetic optimality. Improving the energetic optimality of these forms of response modulation is crucial to several forms of bio-inspired locomotion system: modulating the frequency of bipedal walking can govern the transition to running [7]; and modulating the wingstroke offset of a flapping-wing micro-air-vehicle (FW-MAV) can lead to body pitch control [8]. In this way, these theoretical techniques lead to new design and control principles for a range of engineering systems.

2. Energy resonance in the time-domain

In linear and nonlinear systems, the phenomenon of resonance is complex and multifaceted: representing a range of distinct, and often mutually-exclusive, states of optimality [9, 10] and interaction phenomena [11]. Energy, or global, resonance is one such resonant phenomenon that has key relevance to the design and operation of efficient resonators (biolocomotive systems, energy harvesters, *etc.*) [3–5, 9, 12]. Consider, for instance, a general nonlinear time-invariant single-degree-of-freedom (1DOF) parallel elastic actuation (PEA) system (Fig. 1):

$$D(x, \dot{x}, \ddot{x}, \dots) + F_s(x) = F(t). \quad (1)$$

[†] arion.pons@mail.huji.ac.il

[‡] tsevi.beatus@mail.huji.ac.il

Figure 1: Schematic of a general nonlinear time-invariant 1DOF PEA system

with general system (*i.e.*, plant, or load) dynamics $D(x, \dot{x}, \ddot{x}, \dots)$, linear or nonlinear elastic element $F_s(x)$, and actuator load input $G(t)$. The state of energy resonance in this system is easy to define, but hard to locate – it is the state:

$$F(t)\dot{x}(t) \geq 0, \forall t. \quad (2)$$

That is, the actuator power consumption should always be positive: power should flow from the actuator to the system, and never vice-versa. This unidirectionality of power flow represents both an intuitive state of energetic optimality, and a formal one. Intuitively, if we desire the largest possible system response, then we should seek always to use the actuator, $F(t)$, to feed energy into the system – rather than draw energy out of the system. Unidirectional power flow defines the condition that all of the actuator power consumption is directed towards increasing the total energy in the system.

Formally, energy resonant states are optimal with respect to elasticity. Consider an energy resonant state for Eq. 1 at some $F_s(x)$, and some $x(t)$ and $F(t)$ that are periodic with common period T . The overall actuator mechanical power consumption at this state can be defined in multiple ways, for instance:

$$\begin{aligned} \text{the net power:} \quad \bar{P}_{\text{net}} &= \int_0^T F(t)\dot{x}(t) dt, \\ \text{the absolute power:} \quad \bar{P}_{\text{abs}} &= \int_0^T |F(t)\dot{x}(t)| dt, \\ \text{the positive-only power:} \quad \bar{P}_{\text{pos}} &= \int_0^T F(t)\dot{x}(t)[F(t)\dot{x}(t) > 0]_I dt, \end{aligned} \quad (3)$$

where $[\cdot]_I$ is the Iverson bracket, $[\lambda]_I = 1$ for λ true, $[\lambda]_I = 0$ for λ false [13]. This difference between these metrics lies in their treatment of negative power, $F\dot{x} < 0$. The net power represents the mechanical power throughput of the system – the power dissipated to the system or plant, $D(\cdot)$. It does not represent the mechanical power consumption of the actuation except in the case where the actuator is intrinsically capable of absorbing negative power, and storing this power for future use – for instance, in certain configurations of electrical actuator with power electronics. The absolute power represents the mechanical power consumption of the actuator if the actuator itself is responsible for drawing power out of the system – for instance, a rocket or jet engine, which must consume fuel to produce thrust, irrespective of the direction this thrust is oriented (whether to produce negative or positive power). The positive-only power represents the mechanical power consumption of the actuator if an additional dissipative braking system is responsible for generating negative power – for instance, in a vehicle with a dissipative braking system. A dissipative braking system can relieve the actuator from a responsibility to generate negative power, but cannot store this energy for future use.

Note that further, more generalised, negative-power penalties can be defined, *e.g.*, to represent the behaviours of biological muscles [12, 14, 15]. However, the penalty detail matters not: it is clear that, only under the energy resonant condition, Eq. 2, will the power throughput (net power) equal the actuator power consumption (absolute, positive-only, *etc.*). In any non-energy resonant state, the actuator power consumption will be greater than the net power; the difference in power representing wasted negative power. A key corollary of this is that, at an energy resonant state, there exists no other elasticity, $F_s(x)$, that could reduce the actuator power consumption (absolute, positive-only, *etc.*) required to generate $x(t)$. This can be demonstrated in the following way. The elasticity, $F_s(x)$, cannot alter the net power required to generate a specified $x(t)$ – this can be confirmed by evaluating the net power integral:

$$\int_0^T F(t)\dot{x}(t) dt = \int_0^T D(x, \dot{x}, \ddot{x}, \dots)\dot{x}(t) dt + \int_{x(0)}^{x(T)} F_s(x) dx = \int_0^T D(x, \dot{x}, \ddot{x}, \dots)\dot{x}(t) dt. \quad (4)$$

It is also impossible for the actuator power consumption to be less than the net power – this is a property of the definitions in Eq. 3. Therefore, there exists no elasticity $F_s(x)$, that could further minimise the actuator power consumption (absolute, positive-only, *etc.*) required to generate the output, $x(t)$, of an energy resonant state. In this sense, energy resonant states are energetically-optimal.

3. Energy resonance in work-loop planes

Work loops are an analysis tool used frequently in applied contexts, but have not yet seen significant theoretical application. Their defining characteristic is that they display a metric of force against a metric displacement, and therefore have an area that is synonymous with work, *i.e.*, energy. In biomechanics, work loops are used to visualise, and characterise the behaviour of muscle groups undergoing periodic motion – *e.g.*, muscles within the insect flight motor [16–18]. In materials science, they are one of many forms of hysteresis loop, used to characterise viscoelastic and other hysteretic material behaviour [19]. Work-loop techniques can be applied to the dynamical system of Eq. 1: given some pair of $x(t)$ and $F(t)$ for Eq. 1, it is possible to visualise this pair in the plane of F against x (Fig. 2). We denote this plane x - F (abscissa-ordinate). If $x(t)$ and $F(t)$ are periodic, with common period, then this pair will trace out a closed loop in the x - F plane: a work loop. This work loop may take many shapes. For instance, any linear PEA system undergoing steady-state simple-harmonic motion shows an elliptical work loop (Fig. 2a). That is, for a system of the form:

$$\ddot{x} + 2\zeta\omega_0\dot{x} + \omega_0^2x = F(t), \quad (5)$$

with $x = \hat{x} \cos(\Omega t)$, we can establish that:

$$F^2 - 2F(\omega_0^2 - \Omega^2)x + ((\omega_0^2 - \Omega^2)^2 + 4\zeta^2\omega_0^2\Omega^2)x^2 = 4\zeta^2\omega_0^2\Omega^2\hat{x}^2, \quad (6)$$

describing an ellipse. However, categories of dynamical system do not directly translate to consistent work loop shapes. For instance, as we add additional harmonics to the motion of a linear system, the work loop rapidly becomes inexpressible in closed form.

In our analysis, we will consider a system which is simultaneously more general and more restrictive than the nonlinear PEA system of Eq. 1. We consider a work loop that is a closed simple curve (*i.e.*, no self-intersections), and is no more than bivalued at any x (Fig. 2). Other than this, the shape of the loop can be arbitrary. Such a loop could arise from systems considerably more complex than Eq. 1, including, *e.g.*, computational fluid dynamics (CFD) models. For instance, Fig. 2b illustrates a work loop arising from CFD analysis of *Drosophila melanogaster* wingbeat oscillation, derived from [20–22]. But, conversely, even the linear PEA system, Eq. 5, is capable of generating work loops which are more than bivalued at any x – for instance, very simply, in cases where the output, $x(t)$, is not composed of two monotonic half cycles.

In cases where the work loop is a closed simple curve, as specified, it is representable as an upper and lower curve: $F^+(x)$ and $F^-(x)$ (Fig. 2a). These curves represent the two monotonic half-cycles of $x(t)$, and, as such, are each associated with a particular sign of the velocity (\dot{x}). For a dissipative work loop (net power > 0), over F^+ , $\dot{x} > 0$, and over F^- , $\dot{x} < 0$. Going further, if we distinguish between the system's elastic load, $F(t)$, and inelastic load, $G(t)$, as altered by a parallel (PEA) elasticity – that is, in the particular case of Eq. 1, as:

$$\begin{aligned} \text{inelastic load, } G(t): & \quad D(x, \dot{x}, \ddot{x}, \dots) = G(t), \\ \text{elastic load, } F(t): & \quad D(x, \dot{x}, \ddot{x}, \dots) + F_s(x) = G(t) + F_s(x) = F(t), \end{aligned} \quad (7)$$

– then we can define work-loop equations of motion for this general PEA system:

$$G^\pm(x) + F_s(x) = F^\pm(x). \quad (8)$$

These work-loop equations of motion describe not only Eq. 1, but also the load-requirement dynamics of a more complex system (*e.g.*, the CFD model in Fig. 2b): elasticity, $F_s(x)$ alters the load, $F^\pm(x)$, required to generate the output response associated with the desired output, $G^\pm(x)$. In simple cases, Eq. 7-8 can be expressed entirely in closed form. For instance, the linear PEA system undergoing simple-harmonic motion (Eq. 5):

$$\begin{aligned} G^\pm(x) &= \Omega^2x \pm 2\zeta\omega_0\Omega\sqrt{\hat{x}^2 - x^2} \\ F^\pm(x) &= (\omega_0^2 - \Omega^2)x \pm 2\zeta\omega_0\Omega\sqrt{\hat{x}^2 - x^2} \\ \text{i.e., } G^\pm(x) + \omega_0^2x &= F^\pm(x). \end{aligned} \quad (9)$$

The work-loop equations of motion, Eq. 8, permit a definition of the energy resonant condition, Eq. 2, in the work-loop plane. We seek to define the condition $F\dot{x} \geq 0$ (Eq. 2), and we know that over F^+ , $\dot{x} > 0$, and over F^- , $\dot{x} < 0$, therefore, for energy resonance:

Figure 2: Schematic of work loops for (a) linear and (b) general systems, alongside (c) the conditions for energy resonance, in $F_s(x)$ and $G^\pm(x)$.

$$F^+(x) \geq 0 \text{ and } F^-(x) \leq 0. \quad (10)$$

Or, via Eq. 8, for energy resonance:

$$G^-(x) \leq -F_s(x) \leq G^+(x), \quad (11)$$

as illustrated in Fig. 2c. Eq. 11 is the elastic-bound condition for this general PEA system, describing the relationship between elasticity, $F_s(x)$, and the inelastic system work loop, $G^\pm(x)$ (a function only of the plant dynamics and desired output) that must exist in order for an energy resonant state to exist. Eq. 11 is an inequality condition, describing a continuum of states – whether in $F_s(x)$, or $G^\pm(x)$ – that are energy resonant. Notably, however, this condition contains within it a pair of equality condition. At $\max x$ and $\min x$ ($\pm \hat{x}$ for simple-harmonic motion), $G^-(x) = G^+(x)$, by virtue of the fact that the work loop is closed. Therefore, at these values, the inequality in Eq. 12 becomes an equality:

$$\begin{aligned} G^-(\max x) &= -F_s(\max x) = G^+(\max x), \\ G^-(\min x) &= -F_s(\min x) = G^+(\min x). \end{aligned} \quad (12)$$

Physically, peak inertial loads (inelastic loads at the x -extrema, where $\dot{x} = 0$) must always match peak elastic loads (elastic loads at the x -extrema). This equality condition, Eq. 12, is a useful commonality between the continuum of energy resonant states defined by Eq. 11 – we will illustrate its utility in Sections 4-5.

4. Work-loop analysis for structural optimisation

4.1. Elastic-bound optimisation principle

Practical applications of work-loop analysis arise in a range of physical and analytical contexts. One such analytical context is that of structural optimisation in nonlinear oscillators – for instance, the optimisation of oscillator structural properties so as to generate a desired forced oscillatory response at maximum efficiency. Structural optimisation problems of this form arise in a range of physically-relevant oscillatory systems: for instance, flapping-wing micro-air-vehicles, involving the design of drivetrain elastic elements to ensure maximum efficiency [23–25]; and micro-mechanical energy harvesters, involving the design of oscillators for maximum energy absorption [3–5]. The elastic-bound conditions, Eq. 11, are directly applicable in a structural optimisation context. Consider a nonlinear oscillator, of the form $D(x, \dot{x}, \ddot{x}, \dots) + F_s(x) = G(t)$ (Eq. 8), with some structural elasticity, $F_s(x)$, that we have design control over. If we specify some desired system output, a periodic $x(t)$, then, given some $F_s(x)$, we know the actuator load, a periodic $F(t)$, that is required to generate this desired output. The optimisation problem then is to select $F_s(x)$ such that this load requirement, $F(t)$, is optimal in some way. If we are interested in energy-efficiency, then a key metric to optimise is the mechanical power consumption associated

Figure 3: Work loop analysis and energy resonance in a structural optimization context. (a) The general structural optimisation principle (Section 4.2); (b) a set of energy-resonant Duffing elasticities (Section 4.2); (c) and energy-resonant one-way-drive elasticity (Section 4.3). The Duffing oscillator inelastic parameters are $\delta = 4$, $\omega = 2\pi$, $\hat{x} = 1$.

with $F(t)$: for instance, the absolute power, \bar{P}_{abs} , or positive-only power, \bar{P}_{pos} , as per Eq. 3[§]. In either case, the elastic-bound conditions provide a direct solution to this optimisation problem: it is the elasticities, $F_s(x)$, satisfying Eq. 11, that ensure that \bar{P}_{abs} and \bar{P}_{pos} take their minimum values with respect to $F_s(x)$. This is a highly-general principle, applicable to any PEA system that generates a closed, simple, bi-valued work loop, under the specified $x(t)$ (cf. Section 3). Fig. 3a illustrates this principle, alongside the two more specific cases studied below.

4.2 Structural optimisation of a Duffing oscillator

As an example of the work-loop structural optimisation process, consider the Duffing oscillator:

$$\ddot{x} + \delta\dot{x} + \alpha x + \beta x^3 = F(t) \quad (13)$$

with damping $\delta > 0$, linear stiffness α , cubic stiffness β , and input loading $F(t)$ which, in our analysis, may not necessarily be simple-harmonic. The energy-minimisation structural optimisation problem in this oscillator is to compute the elastic parameters, α and β , such that this specified output can be generated at a state of energy resonance, by some $F(t)$. As such, in a work-loop context, we can split Eq. 13 into an inelastic load, $G(t)$, and an elastic profile, $F_s(x)$:

$$\ddot{x} + \delta\dot{x} = G(t), \quad F_s(x) = \alpha x + \beta x^3 \quad (14)$$

More specifically, consider a steady-state simple-harmonic output, $x = \hat{x} \cos(\Omega t)$. In this case, the inelastic work loop is given by the elliptical profile:

$$G^\pm(x) = -\Omega^2 x \pm \delta\Omega\sqrt{\hat{x}^2 - x^2}. \quad (15)$$

The elastic-bound equality conditions (Eq. 12) translate to conditions on the stiffness parameters, α and β :

$$-F_s(\hat{x}) = G^\pm(\hat{x}) \therefore \Omega^2 \hat{x} = \alpha \hat{x} + \beta \hat{x}^3 \therefore \alpha = \Omega^2 - \beta \hat{x}^2 \quad (16)$$

which is to say, the Duffing stiffnesses, $F_s(x)$ that can generate this simple-harmonic output at a state of energy resonance are necessarily of the form

$$\frac{F_s(x)}{\Omega^2} = (1 - \beta^* \hat{x}^2)x + \beta^* x^3 \quad (17)$$

where $\beta^* = \beta/\Omega^2$ is a free parameter. Note that the equality condition, yielding Eq. 17, is necessary for the existence of an energy resonant state, but no sufficient. We anticipate, based on the full elastic-bound conditions,

[§] Note that, even if the net power, \bar{P}_{net} , were to be relevant to the actuator under consideration, \bar{P}_{net} is independent of $F_s(x)$: the structural optimisation problem associated with \bar{P}_{net} is irrelevant. This is further illustration of how \bar{P}_{abs} and \bar{P}_{pos} are more relevant metrics of actuator mechanical power consumption.

that Eq. 17 should describe an energy-resonant state only over some range of β^* . We may compute this range via the full elastic-bound conditions. Consider that, at the point at which the elastic-bound conditions fail, there exists the critical state:

$$G^+(x) = F_s(x) \text{ or } G^-(x) = F_s(x), \text{ for some } x \neq \pm\hat{x}. \quad (18)$$

That this state necessarily exists is a property of the smoothness of this system. Again, with the elliptical inelastic work loop profile, Eq. 15, we can describe x such that Eq. 18 is satisfied, as the roots of the quartic polynomial:

$$x^4 - x^2\hat{x}^2 + \frac{\delta^2}{\beta^{*2}\Omega^2} = 0. \quad (19)$$

Eq. 19 is a quadratic polynomial in x^2 , and, as such, we can determine that the critical x will exist (as a real number) if and only if the discriminant of this quadratic is positive. This leads to the condition:

$$-\beta_{\text{crit}}^* \leq \beta^* \leq \beta_{\text{crit}}^*, \quad \beta_{\text{crit}}^* = \frac{2\delta}{\hat{x}^2\Omega} \quad (20)$$

For the constrained Duffing elasticity, Eq. 19, to be capable of generating an energy-resonant simple-harmonic output, under some periodic forcing. The actual periodic forcing required is trivial to define – it is given by Eq. 13 – though note that chaotic effects may necessitate a control system to maintain a steady-state output (and may even mean that such control is impractical). Nevertheless, Eq. 17 and 20 define the Duffing stiffnesses that are required for an energetically-optimal simple-harmonic output. Other non-simple-harmonic outputs can be optimised via the same work-loop analysis process, though numerical techniques may be required to compute both the form of the optimal elasticity (Eq. 17) and the range over which it is valid (Eq. 20)

4.3 Special cases of energy-resonant structure

In Section 4.2, we considered the optimisation of an elastic element of prescribed structure: the cubic elasticity of the Duffing oscillator. However, in a broader systems-design context, there may be no particular reason to restrict oneself to prescribed structures – considering elasticities with particular energy-resonant properties, irrespective of structure, may also be worthwhile. Work-loop analysis is a tool for identifying energy-resonant elasticities with special properties. As a notable example of this, consider again the elastic-bound conditions, Eq. 11. These conditions include, as an extremal case, the elasticities lying on the upper and lower boundaries of the loop:

$$\begin{aligned} F_{s,1}(x) &= -G^+(x), \\ F_{s,2}(x) &= -G^-(x). \end{aligned} \quad (21)$$

By definition, these elasticities generate a resultant work loop, $F^\pm(x)$, that has one half-cycle at zero load (Eq. 9, Fig. 3c):

$$\begin{aligned} F_{s,1}(x) &= -G^+(x) \therefore F^-(x) = G^-(x) - G^+(x), \quad F^+(x) = 0, \\ F_{s,2}(x) &= -G^-(x) \therefore F^+(x) = G^+(x) - G^-(x), \quad F^-(x) = 0. \end{aligned} \quad (22)$$

It follows also, that the other half-cycle will be at a state of unidirectional load: $G^+(x) - G^-(x)$ can never change sign, if $G^+(x) \geq G^-(x)$ as per our condition for no self-intersection of the work loop. The result is an energy-resonant state requiring only unidirectional actuation: we term this, a one-way-drive state. An additional property of this state is that it the duty cycle of the actuator is reduced: over the region of zero load requirement, the actuator need not be activated or energised. With the proper selection of one-way-drive elasticity, the actuator duty cycle can be reduced to 50% or less, for any appropriate work loop [12]. Both these properties make one-way-drive states systems ideal for certain classes of actuator: those which are capable of generating large intermittent loads in a single direction – such as combustion cylinders, explosive actuators, and solenoid actuators [26, 27]. Combustion cylinders, in particular, are more energy-dense than many forms of electromechanical actuator: utilising combustion cylinders to generate one-way-drive energy resonant oscillations in a flapping-wing aircraft may be an avenue to increasing the range and endurance of these aircraft.

5. Work-loop analysis for optimal control

5.1. Elastic-bound optimal control principle

Another practical application of work-loop analysis arises in the context of optimal control. In contrast with structural optimisation, which deals variable system structural properties, optimal control problems typically relate to a fixed system structure, and consider variable responses within this structure – with the aim to locate output responses (and, input forces) that are optimal in some sense. Work loop analysis is particularly relevant to optimal control problems that are concerned with optimising power consumption, or energetic efficiency, as it allows an easy description, and visualisation, of the location and properties of energy-resonant states. One of the interesting properties of energy resonance is that, even in the simplest linear systems, energy resonance is a non-unique state. As per Section 4, the energy-resonant structural elasticity for a system undergoing a specified output is non-unique

– there exists a continuum of energy-resonant elasticities. So also, the energy-resonant output for a system with fixed elasticity is non-unique – there exists a continuum of energy-resonant outputs. This continuum of energy-resonant outputs is defined directly by the elastic-bound conditions: for fixed elasticity $F_s(x)$, we seek $G^\pm(x)$ such that Eq. 11 is satisfied – $G^\pm(x)$ depending only on the desired output, $x(t)$, and the inelastic dynamics of the system, $D(\cdot)^*$. We note that these different work loops may represent outputs at different amplitudes, frequencies, and symmetric or asymmetric waveforms. If then, as part of our control problem, we desire to modulate the frequency of our system output response, while maintaining a state of energy resonance (*i.e.*, optimality in mechanical power consumption), then work-loop analysis techniques provide a strategy for doing so. We refer to this energy-resonant frequency modulation as frequency-band resonance, and note that other forms of energy resonant modulation (*e.g.*, offset-band resonance, involving symmetry-breaking modulation [12]) are also available.

5.2. Optimal frequency control of a Duffing oscillator

Consider again the general Duffing oscillator, Eq. 14. As per our structural optimisation results (Eq. 16), the frequency, ω_e , at which a simple-harmonic output is energy resonant in this general system is:

$$\omega_e^2 = \alpha + \beta \hat{x}^2. \quad (23)$$

As per our optimal control analysis, the question arises: can one maintain energy resonance while deviating from this energy-resonant frequency? As one instance of a deviation from a simple-harmonic output, consider the multiharmonic output given by:

$$\begin{aligned} x(t) &= \hat{x}(1 - \rho) \cos(\Omega t) + \hat{x}\rho \cos(3\Omega t), \\ \dot{x}(t) &= -\Omega \hat{x}(1 - \rho) \sin(\Omega t) - 3\Omega \hat{x}\rho \sin(3\Omega t), \\ \ddot{x}(t) &= -\Omega^2 \hat{x}(1 - \rho) \cos(\Omega t) - 9\Omega^2 \hat{x}\rho \cos(3\Omega t), \end{aligned} \quad (24)$$

for small ρ , this multiharmonic wave is qualitatively sinusoidal. More precisely: for the window $-0.125 \leq \rho \leq 1$, computed numerically, the global displacement extrema of $x(t)$ are $\pm \hat{x}$ ($\max x = \hat{x}$ and $\min x = -\hat{x}$), and are located at $t = 0, T/2, T, \dots$, where $T = 2\pi/\Omega$. For the more restrictive window $-0.125 \leq \rho \leq 0.25$, also computed numerically, $x(t)$ is composed of two monotonic half-cycles (velocity reversal, where $\dot{x} = 0$, exists only at $t = 0, T/2, T, \dots$). We require both these conditions to be true – thus limiting ourselves to the more restrictive of these windows.

As part of a frequency-band analysis, we seek $\rho(\Omega)$ such that $x(t)$ is energy resonant at Ω . Note that, at the energy-resonant frequency, ω_e , a simple-harmonic wave is energy resonant (Section 4.2), and thus $\rho(\omega_e) = 0$. To compute the rest of $\rho(\Omega)$, note that the elastic-bound conditions necessitate:

$$G^\pm(\hat{x}) = F_s(\hat{x}), \text{ and } G^\pm(-\hat{x}) = F_s(-\hat{x}), \quad (25)$$

where we have assumed that $\max x = \hat{x}$ and $\min x = -\hat{x}$; an assumption we know to be valid over $-0.125 \leq \rho \leq 1$. Over this window we know, in addition, that these extrema will be located at $t = 0, T/2, T, \dots$, where $T = 2\pi/\Omega$. We can therefore translate Eq. 25 into a condition in the time-domain:

$$\begin{aligned} G(0) &= G(T) = F_s(\hat{x}) = \alpha \hat{x} + \beta \hat{x}^3, \\ G(T/2) &= F_s(-\hat{x}) = -\alpha \hat{x} - \beta \hat{x}^3, \end{aligned} \quad (26)$$

which, combining with load profile:

$$\begin{aligned} G(t) = \ddot{x} + \delta \dot{x} &= -\Omega^2 \hat{x}(1 - \rho) \cos(\Omega t) - 9\Omega^2 \hat{x}\rho \cos(3\Omega t) \\ &\quad - \delta \Omega \hat{x}(1 - \rho) \sin(\Omega t) - 3\delta \Omega \hat{x}\rho \sin(3\Omega t), \end{aligned} \quad (27)$$

yields the condition:

$$G(0) = G(T) = -G(T/2) = -\Omega^2 \hat{x}(1 + 8\rho) = -F_s(\hat{x}) = -\alpha \hat{x} - \beta \hat{x}^3. \quad (28)$$

From Eq. 28 we deduce that the relationship $\rho(\Omega)$ is:

$$\rho(\Omega) = \frac{1}{8} \left(\frac{\alpha + \beta \hat{x}^2}{\Omega^2} - 1 \right) = \frac{1}{8} \left(\frac{\omega_e^2}{\Omega^2} - 1 \right). \quad (29)$$

This relationship ensures that the elastic-bound equality conditions (Eq. 12) will be satisfied in the Duffing oscillator. Again, we expect that this relationship will satisfy the full elastic-bound conditions (Eq. 11) only over a certain window of ρ and Ω . The properties of this window are determined by the Duffing parameters α, β, δ ,

** Note that this is the same as saying that we seek $F^\pm(x)$ such that Eq. 10 is satisfied. This latter formulation does not necessitate that the system be split into ‘elastic’ and ‘inelastic’ components.

Figure 4: Work loop analysis and energy resonance in an optimal control context: frequency modulation of a Duffing oscillator, involving (a) decreasing and (b) increasing output frequency.

and \hat{x} , but they are difficult to define analytically. The critical states defining the boundaries of this window are given as the solution of:

$$G(t) = -F_s(x), \quad (30)$$

with $x(t)$ as per Eq. 24, and $\rho(\Omega)$ as per Eq. 29. We compute these critical states numerically. For instance, for $\alpha = 1$, $\beta = 3$, $\delta = 2$, and $\hat{x} = 1$, we estimate, conservatively, that frequency-band resonant states exist within $0.693\omega_e < \Omega < 1.163\omega_e$, for which $-0.0650 < \rho < 0.0441$. This range is illustrated in Fig. 4. This demonstration of frequency-band resonance raises the possibility of energetically-optimal frequency modulation in a range of physical systems – we refer, in particular, to insects and FW-MAVs, for which wingbeat frequency modulation can be an important form of lift and thrust control. This illustrates the phenomenon that energetically-optimal (*i.e.*, energy resonant) operation of linear and nonlinear systems is not restricted to a single resonant frequency, but is, in fact, available over a window of frequencies. Not that this effect is not a result of nonlinearity (it exists, for instance, when $\beta = 0$), but is a result of the damping in the system (δ : the width of the work loop in the elastic-bound conditions, *cf.* Eq. 15). Damping allows energy-resonant behaviour over a range of frequencies – a remarkable physical phenomenon.

7. Conclusion

In this work we present several novel techniques of work-loop analysis, and demonstrate their theoretical and practical significance. Utilising them, we prove new optimality results for a wide class of nonlinear system, with implications for optimal system design and optimal control modulation in a range of engineering systems, including FW-MAVs. These optimality results have a range of implications in structural optimisation and optimal control – defining new designs for optimal biolocomotion system, and new principles for biolocomotive optimal control. They also illustrate a remarkable phenomenon. Energy-resonant states are not discrete, *e.g.*, restricted to particular frequencies, but in fact, are available in windows of frequency. The existence of these windows is due not to system nonlinearity, but to system damping – damping allows energetically-optimal frequency modulation.

A novel lubricated friction model for describing underdamped free responses of a spring – sliding mass oscillator

Joël Perret-Liaudet^{*}, Fida Majdoub^{**}

^{**}*ECAM, LabECAM, France*

Summary. A novel friction model is introduced in order to describe lubricated sliding contact under unsteady or transient dynamic conditions. It is based on a state variable friction model consisting on a friction force equation and a state ones. Effective film thickness is introduced as the internal variable. Relaxation behaviour to reach the steady state film thickness is introduced via a first order differential equation. To obtain friction force, film thickness is interpreted as a sharing effect between solid interaction or confined lubricant and the lubricant film itself. Experimental results consisting on free dynamic responses of a sliding oscillating system under lubrication confirm the phenomenon captured by the proposed theoretical approach.

Introduction

Friction is a nonlinear phenomenon that occurs in a lot of mechanical systems including contacts. This is in particular the case of mechanisms which are often making use of contacting surfaces in relative motion (gears, cam and cam follower systems, rolling bearings, piston ring/cylinder liner contact, universal joints, etc.) for transforming input forces and motion. In order to simulate and analyze the dynamic behavior of such systems, it is necessary to choose friction law that can be able to describe and model it. A classical way to describe friction is to use the Coulomb friction or viscous friction models, or the combination of both [1]. Such friction models are very useful thanks to their simplicity. However, in many circumstances, they cannot accurately describe tribological behaviors. In the case of lubricated contacts, other models have been used to reproduce the well-known Stribeck behavior, but they usually ignore the dynamic effects [2]. In this context, the principal aim of this study is to introduce a novel approach which can describe lubrication in a relative simple way, and capture the dynamic lag effect of the film thickness settling [3]. Finally, comparisons between numerical and experimental results obtained from an original dynamic tribometer has been reported in this study.

The suggested friction model

The proposed model is based on introduction of an internal state variables in the constitutive friction law. In this approach, modelling consists on a friction force equation coupled to a state equation, which can be formally written as

$$\begin{cases} T = \mathcal{F}(v, y) \\ \dot{y} = \mathcal{G}(v, y) \end{cases} \quad (1)$$

where y is the internal state variable and $\mathcal{F}(\cdot)$ and $\mathcal{G}(\cdot)$ are two nonlinear functions to be precise. The well-known rate-and-state-variable friction law [4] which is formulated in term of an average contact lifetime as the internal state variable is a good example of this kind of formulation. In our novel model, we heuristically suggest to introduce the instantaneous film thickness as the internal state variable y . Indeed, this is the key to interpret transition between boundary and full film hydrodynamic regimes revealed by the popular Stribeck curve [5]. For the state equation, we propose a simple relaxation process governed by the following differential equation

$$\dot{y} = (Y_{ss}(v) - y)/\tau \quad (2)$$

where $Y_{ss}(v)$ represents the film thickness to be reached. In this way, it corresponds to the steady state film thickness associated to the instantaneous sliding velocity $v(t)$. In addition, τ is the relaxation time associated to the exponential decay introduced by the equation (2). Concerning the friction equation, we introduced a mixed law given by

$$T = (1 - \alpha)T_{BL} + \alpha T_{HL} \quad (3)$$

Thus, the total friction force is assumed to be sharing between friction force T_{HL} associated to the lubricant film itself and friction force T_{BL} associated to solid interaction through surface roughness. In agreement with the Stribeck curve interpretation, the weight function $\alpha = \alpha(y)$ introduces the effect of the film thickness y . Basically, it consists on a sigmoid function which increases monotonically from 0 to 1. Finally, the friction force component T_{BL} is assumed to be constant, i.e. $T_{BL} = \mu N \text{sign}(v)$, and the friction force component T_{HL} is assumed to be velocity-dependent through a power law $T_{HL} = \eta N |v|^p \text{sign}(v)$. N represents the applied normal load and μ, η are two constants.

The dynamic transient oscillating response under study

As reported in previous works [1,6,7], we have designed and built a dynamic tribometer in order to quantify general trends of friction as a function of the sliding velocity. This experimental setup, described in Figure 1, is based on the measurement of transient responses $x(t)$ of an underdamped frictional single-degree-of-freedom mass-spring oscillator. In the principle, a

Figure 1: Scheme of the dynamic oscillating tribometer

moving mass m slides in contact with the tribological system under study. The governing equation of motion can be written as follows

$$m\ddot{x} + kx = -T \quad (4)$$

where k is the spring stiffness. By considering the proposed friction model, it follows the first order equations

$$\begin{cases} \dot{x} = v \\ \dot{v} = -kx - T(v, y) \\ \dot{y} = (Y_{ss}(v) - y)/\tau \end{cases} \quad (5)$$

with the friction force $T(v, y)$ defined by equation (3). In order to integrate equations (5), we have used a Runge Kutta numerical scheme of order 4.

Results

Figure 2 (a) shows example of an experimental velocity response. We can observe that it begins with a convex envelop and finish by a concave one. As shown in Figure 2 (b), this behavior is well captured by our model. From Figure 2 (d), this particular envelope can be interpreted by a transition from a full lubricant film force contribution to a dominant solid force contribution. This interpretation is confirmed by measurement of the electrical contact resistance (ECR) presented in Figure 2 (c). At the beginning, the separation between solids is total (the ECR is very high) and at the end full electrical contact is observed (the ECR has a low value).

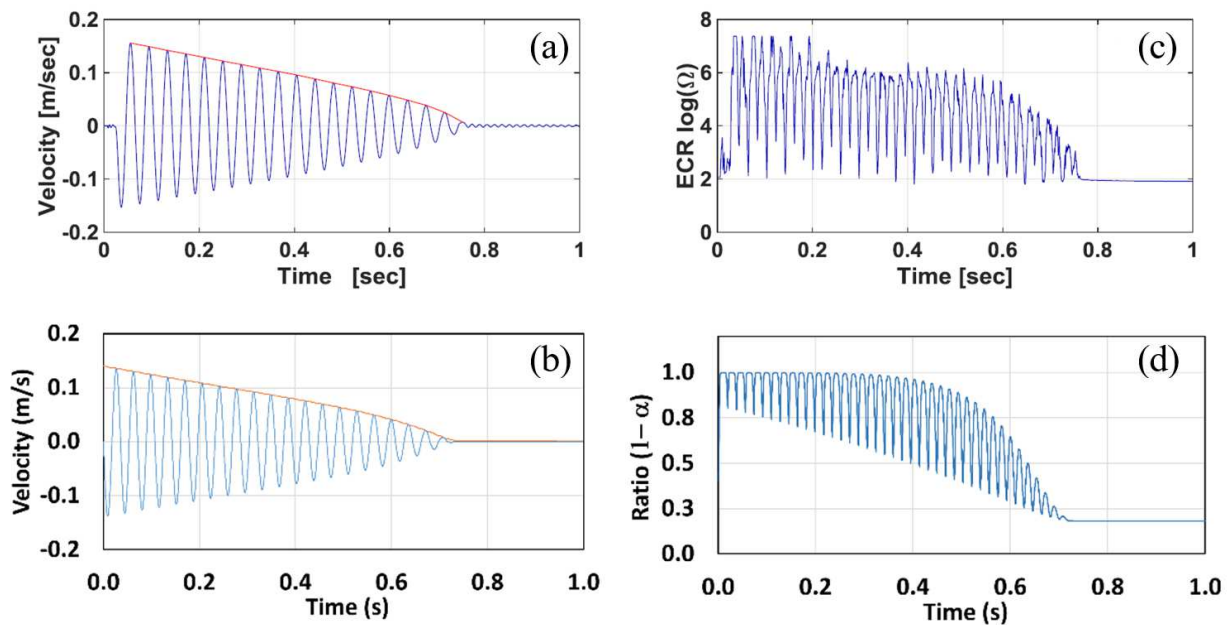

Figure 2: (a) Experimental and (b) simulated velocity responses; (c) experimental contact resistance; (d) ratio $(1 - \alpha)$ of the lubricant film force contribution.

Conclusions

The relevance of the proposed model is demonstrated in the light of comparison between numerical results and experimental ones. In particular, our new model can capture the transition related to the instantaneous film thickness which separates the two sliding surfaces, including the lag effect of the thickness dynamics. Now, ongoing work is conducted in order to relate the model parameters to the physical properties of the tribological contact.

Summary. We study the nonlinear damping of a nanomechanical graphene drum resonator. Laser interferometry is used to measure and optothermally actuate the resonator near an internal resonance condition. An unconventional nonlinear damping behavior is observed at the internal resonance frequency. A multimodal analytical model is constructed to understand the nature of this phenomenon and to relate the observed nonlinear damping to the physics of the system.

Introduction

Micro/Nano-mechanical systems are utilized in many technologies and often have been used for their sensing capabilities. An ideal framework for sensitive nanomechanical devices is 2-D materials, and especially graphene, due to its exceptional mechanical, electrical and thermal properties. By their atomically thin nature, these systems are fundamentally nonlinear. In addition to the geometric nonlinearities, graphene membranes also have nonlinear energy decay mechanisms[1]. Nonlinear damping in these devices is a fundamental limitation to their sensing capabilities yet its full understanding is an open question. Among different dissipation mechanisms, an important factor that is hypothesized to affect damping properties of graphene nanodrums is the intermodal couplings[2]. In this work, we study the nonlinear dynamics of a nanomechanical graphene resonator near its internal resonance condition to amplify the intermodal effects and uncover the physics between nonlinear damping and mode coupling.

Experimental method and observations

Experiments were conducted by optothermally actuating a graphene nanodrum while measuring its motion using laser interferometry. Optothermal actuation results in modulation of membrane tension, effectively creating a parametric excitation to the fundamental mode of the membrane that has an eigenfrequency ω_1 and direct excitation to a secondary mode of the membrane that has an eigenfrequency $\omega_2 \approx 2\omega_1$. We take advantage of this to investigate the effects of intermodal couplings and internal resonance on the nonlinear damping by exciting the membrane with an actuation frequency of $\omega_F \approx 2\omega_1$, which drives both modes resonantly. We experimentally study the membrane frequency response curves (Figure 1). By increasing the excitation level, we utilize the hardening type geometric nonlinearity of the system to match the internal resonance condition between these two modes. At the vicinity of internal resonance, we observe frequency “locking” at higher drive powers, where the increase in resonance peak with respect to the excitation amplitude is almost zero. We found that forcing the system even further breaks the “locking” barrier, causing a dramatic increase in amplitude and frequency of the parametric resonance, which we refer as “shooting”.

Figure 1: Experimentally measured frequency response curves of the membrane with increasing excitation levels, in the vicinity of internal resonance conditions.

Analytical model and results

Parametric resonance of nanomechanical systems is commonly modelled by using a single Mathieu-van der Pol-Duffing equation [3]. This model is only viable for nonlinear dynamic characterization far from the internal resonance as it will imply a varying intrinsic nonlinear damping for high driving powers in the vicinity of internal resonance, which has no physical foundations. This is clearly because of the intermodal effects, that necessitate multimodal modelling of the system. To capture the dynamics at the vicinity of internal resonance, we add to the Mathieu-van der Pol-Duffing single-mode model, a secondary linear oscillator that is directly driven by the excitation. We couple two modes by terms that arise from the nonlinear potential of 2:1 internal resonance $U_{cpl} = \alpha x_1^2 x_2$ (i.e., the coupling terms are: $-\partial U_{cpl}/\partial x_1$ for the primary mode, and $-\partial U_{cpl}/\partial x_2$ for the secondary mode):

$$\begin{aligned}\ddot{x}_1 + \omega_1^2 x_1 + \gamma x_1^3 + 2\alpha x_1 x_2 &= F_1 x_1 \cos(\omega_F t) - 2\dot{x}_1(\tau_l + \tau_{nl} x_1^2) \\ \ddot{x}_2 + \omega_2^2 x_2 + \alpha x_1^2 &= F_2 \cos(\omega_F t) - 2\tau_2 \dot{x}_2\end{aligned}$$

where γ is the Duffing coefficient, α is the intermodal coupling strength, F_1 is the parametric excitation level, F_2 is the corresponding direct forcing level and τ_l, τ_{nl} are the linear and nonlinear damping coefficients respectively. By analyzing the slow dynamics of the system, we reveal the modification of system parameters due to modal coupling, near the internal resonance condition ($2\omega_1 \approx \omega_2$). Using the intrinsic parameters of the modes for analysis, characterized by analyzing the uncoupled nonlinear response measurements, it is possible to see that the biggest effect of modal coupling is on the nonlinear damping. Additionally, the nature of the dramatic amplitude increase after the internal resonance is discovered by the bifurcation analysis of stationary solutions. The stationary (steady-state) solutions of the equations cease to exist in the vicinity of the internal resonance (see Figure 2) due to saddle-node bifurcation points. The annihilation of the bifurcation points connects two solutions branches, triggering the “shooting” phenomenon and can be used to characterize the coupling strength between the modes.

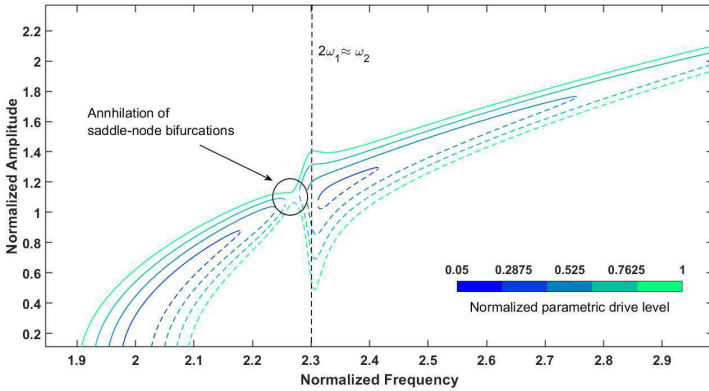

Figure 2: Steady state frequency response of the analytical model revealing the source of “shooting” behavior observed in the experiments, which is annihilation of saddle-node bifurcations.

Figure 3: Effective nonlinear damping with respect to intermodal coupling strength and excitation frequency. Nonlinear damping is maximum at the internal resonance condition.

Conclusion

We report on nonlinear damping variation via 2:1 internal resonance in graphene nanomechanical resonators. We observe a massive increase in damping in the vicinity of internal resonance that is followed by a bifurcation causing a dramatic increase of amplitude and resonance frequency. To understand this phenomenon, the resonator has been modeled by a two-modes dynamical system undergoing a 2:1 internal resonance, which successfully explained the observations. This work shows a possible nonlinear dynamics methodology to characterize the intermodal coupling of nonlinear resonators by operating them in an internal resonance condition.

Summary. In this work a clamped-guided shallow arch microbeam is considered. The actuation of the microbeam is both through a transverse and axial electrostatic forces. The considered equation of motion takes into account the initial rise of the microbeam and the sliding degree of freedom at the guided side. The static and free vibration problems are solved using the Differential Quadrature Method. The results are validated with previously published experiments found in the literature. The model is able to reproduce experimental findings regarding fundamental resonance and parametric resonance of the first mode.

Introduction

Parallel-plate based MEMS actuators are limited by the occurrence of pull-in in the static and dynamic regimes. An example of design improvement was proposed by Abu-Salih and Elata [1], where they introduced a curved microbeam obtained by buckling. Ouakad and Younis [2] proposed to analyze the nonlinear dynamics of curved microbeam using perturbation techniques. They concluded that the initial deflection of the curved beam strongly affects its behavior. Therefore, it can be used as control parameter to tune the response of the device. Recently, Ramini et al. [3] developed and experimentally tested a design in which the initial gap of the arched microbeam can be tuned using a transverse electrostatic parallel plate actuator. The design allows also the introduction of a parametric excitation through the applied axial force. Excitations at secondary resonances generate large stroke actuation generally unachievable by classical MEMS actuators. The device fabricated and tested by Alcheikh et al. [4], depicted high tunability up to 160% for the first and third mode shapes. Ouakad et al. [5] demonstrated that three-to-one and one-to-one internal resonance are achievable by controlling the initial rise of the arched microbeam. The proposed work aim to model an arched microbeam with an applied electrostatic axial force. The proposed mathematical model should reproduce the experimental finding of the previously fabricated shallow arch microbeams.

Problem Formulation

Figure 1: Clamped-guided shallow arch microbeam with transverse and axial excitations.

We consider a clamped-guided shallow arch given by Figure 1, of initial shape $w_0(x)$, width b , thickness h , length L , modulus of elasticity E , cross sectional area $A = bh$, moment of inertia I , mass density ρ and M and k are the mass and stiffness of the moving side electrode. The axial displacement is denoted by $u(x, t)$ and the transverse displacement is denoted by $w(x, t)$ and assumed to be around the initial curvature $w_0(x)$ (Figure 1). Using the Euler-Bernoulli beam theory and the von Karman nonlinear strain, the extended Hamilton's principle is used to derive the governing equations and boundary conditions. They are given as follows:

$$\rho A \ddot{w} + EI w'''' + c \dot{w} = N_L (w'' + w_0'') + \frac{\epsilon b V_1^2}{2(d + w + w_0)^2} \quad (1)$$

$$M \ddot{X}_L + k X_L = \frac{\epsilon A_{pp} (V_2 + V_{AC} \cos(2n\pi f t))^2}{2(g - X_L)^2} - N_L \quad (2)$$

$$w(0, t) = 0, \quad w'(0, t) = 0, \quad w(L, t) = 0, \quad w'(L, t) = 0 \quad (3)$$

$$N_L(t) = \frac{EA}{L} \left[X_L + \frac{1}{2} \int_0^L (w'^2 + 2w'w_0') dx \right] \quad (4)$$

where $n = 1$ or 2 for the fundamental and parametric excitations, respectively.

Equations 1 to 4 are solved using the Differential Quadrature Method (DQM) for the space derivative and then the Finite Difference Method (FDM) is used to calculate limit cycle solution [6].

Figure 2: (a) Variation of the static deflection $w(L/2)$ with respect to V_2 for $d_0 = 2.6\mu\text{m}$. (b) Variation of the first natural frequency for $d_0 = 2.6\mu\text{m}$.

Figure 3: Frequency-response curves of the midspan transverse deflection and axial displacement for $V_2 = 3\text{V}$ and $V_{AC} = 5\text{V}$ when $d_0 = 2.6\mu\text{m}$ and $f_1 = 15.27\text{kHz}$. (a) Fundamental resonance, (b) Principal parametric resonance of the first mode.

Static and free vibration of the microbeam

The static response of the microbeam is shown in Figure 2-a. Only the effect of the side voltage V_2 has been considered here. As shown, the static response of the transverse deflection at midspan $w(L/2)$ is highly constrained when the microbeam recover a straight position at $w(L/2) = d_0$. The axial displacement at $x = L$, expressed by X_L , is responding as a classical electrostatic parallel plate actuator. The dashed branches denote unstable solutions. The free vibration problem is also solved under the effect of the applied side voltage V_2 . The results shown in Figure 2-b are compared with those obtained experimentally by Alcheikh et al. [4]. As shown, very good agreement is obtained.

Fundamental resonance and parametric resonance of the first mode

The frequency-response curves for the fundamental resonance are shown in Figure 3-a for the midspan transverse deflection and axial displacement. A softening behavior is deduced from the simulations. A similar behavior is observed for the parametric resonance of the first mode in Figure 3-b. Also here, dashed branches denote unstable solutions.

Conclusions

We proposed a nonlinear dynamic analysis of a clamped-guided shallow arch microbeam. The governing equations and associated boundary conditions are derived and the solved using a combination of Differential Quadrature Method, for the space derivative, and the Finite Difference Method for the limit-cycle solutions. The static and free vibration responses have been simulated for the transverse and side displacements. The variation of the fundamental frequency with respect to the applied side voltage is compared and validated with published experimental results. The frequency-response curves showed that both fundamental and parametric resonances are possible in accordance with previously reported experimental analyses.

Summary. This study investigates the nonlinear damping in in-plane micromachined electromechanical resonators theoretically and experimentally. More specifically, precise experiments are performed on an electrically actuated micromachined bridge resonator and the response of the system in the primary resonance region is captured at various AC voltage levels. For the theoretical part, a nonlinear Euler-Bernoulli beam theory is utilised taking into account the geometric, electrostatic, and damping nonlinearities. A general cubic damping model and a Kelvin-Voigt model are considered in the theoretical model. A high-dimensional discretisation is carried out by retaining 10 modes in the Galerkin discretisation. Extensive comparisons are conducted between the experimental data and the theoretical results at different AC voltage levels. It is shown that the resonator exhibits strong nonlinear damping. Different damping models are compared to examine the performance of each model in capturing the damping nonlinearity.

Introduction

Nonlinearly driven micro-electromechanical (MEMS) resonators have drawn increasing attention in the recent decades by wide-spreading potential applications, such as frequency stabilization, filtering, and sensing [1]. Nonlinear vibration of these movable structures has been intensely investigated theoretically and experimentally, chiefly for the electrostatically driven MEMS resonators. A key property affecting the nonlinear vibration of MEMS resonators is damping, in which a variety of physical mechanisms could contribute (e.g., thermoelastic, squeeze film damping, nonlinear mode coupling, and linear viscous damping) [2,3]. As driven the system nonlinearly, the energy dissipation tends to deviate from the linear viscous dissipation and start to vary nonlinearly. Despite the deep study of the nonlinear energy dissipation (or nonlinear damping) in the recent decades [4,5], there is still no comprehensive study on nonlinear damping in MEMS resonators electrostatically driven with relatively large gaps. The present study thoroughly investigates the nonlinear damping in micromachined electromechanical resonators using carefully conducted experiments and an accurate nonlinear theoretical model.

Experimental set-up and theoretical model

In this study, a clamped-clamped in-plane microbeam made of silicon is considered, which is of length L , width b , cross-sectional area A , second moment of area I , Young's modulus E , mass density ρ , and material damping coefficient η . The microbeam is excited by a stationary electrode separated from the microbeam with a large transduction gap, Fig.1(a). To minimize the effect of squeeze film damping, the microbeam is placed in a vacuum chamber with a pressure of 950mTorr set throughout the experiments. Hence the squeeze film damping effect will be neglected in the theoretical study. The nonlinear equation of motion for the MEMS resonator under consideration is derived using the Euler-Bernoulli beam theory and utilising a Kelvin-Voigt model, resulting in a nonlinear damping mechanism. Apart from the Kelvin-Voigt damping, a general nonlinear cubic damping mechanism (for the transverse motion w) is modelled as well. The equation of motion can be derived as

$$\rho A \partial_{tt} w + c_1 \partial_t w + c_2 \partial_t w |\partial_t w| + c_3 (\partial_t w)^3 + EI \partial_{xxxx} w + \eta I \partial_{txxxx} w - \frac{EA}{2L} \partial_{xx} w \int_0^L (\partial_x w)^2 dx - \frac{\eta A}{2L} \partial_{xx} w \int_0^L 2 \partial_x w \partial_{tx} w dx - \frac{\varepsilon b [V_{DC} + V_{AC} \cos(\omega t)]^2}{2(d-w)^2} = 0, \quad (8)$$

in which c_1, c_2 , and c_3 are damping coefficients and d is the MEMS gap width.

The equation of motion is first recast into nondimensional form and then discretised into a set of nonlinearly coupled ordinary differential equations via use of Galerkin technique, considering 10 degrees of freedom. The resultant set is solved using a continuation technique.

Results and Discussion

In this section, the nonlinear resonance response of the MEMS resonator is examined in detail and thorough comparisons are conducted between the theoretical predictions and experimental data. Different linear and nonlinear damping models are examined to determine which model better predict the dissipation in the system. All models are calibrated once and then the damping coefficients are kept fixed as the AC excitation level is increased. Four cases are examined, namely the linear viscous damping model, Kelvin-Voigt damping, cubic nonlinear model (c_1 and c_3) and general quadratic-cubic model. In the results shown in Figs.1(b)-(e), ω_1 denotes the primary nondimensional natural frequency of the microbeam, Ω stands for the nondimensional frequency of excitation, and w_d indicates the nondimensional midpoint transverse oscillation amplitude (with respect to d), measured from the deflected configuration. In all the theoretical results, solid and dashed lines denote stable and unstable periodic solutions, respectively.

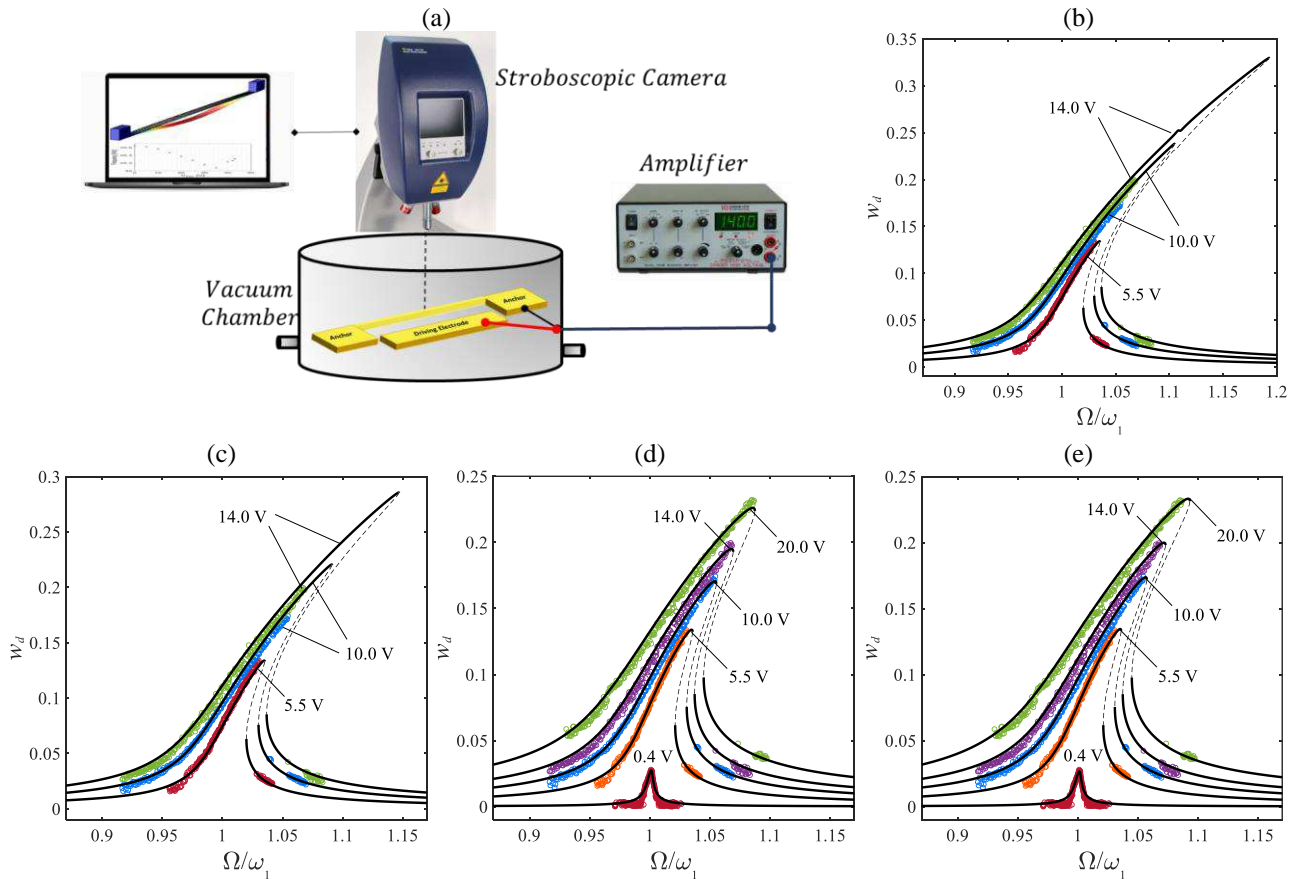

Figure 1: (a) Experimental setup with 3D schematic of the microbeam with length 800 μm , thickness 2.9 μm , width 25 μm , and transduction gap 8 μm . (b, c) Frequency responses of the MEMS resonator at $V_{\text{DC}} = 5$ V and three AC voltages (shown on the curves) based on linear and Kelvin-Voigt damping models, respectively. (d, e) Frequency responses of the MEMS resonator at $V_{\text{DC}} = 5$ V and various AC voltages (denoted on the curves), based on cubic and general quadratic-cubic models, respectively.

Figs.1(b) and (c) correspond to linear and Kelvin-Voigt damping, respectively. For both cases, the frequency response for $V_{\text{AC}} = 5.5$ V is used to calibrate the damping coefficient which is then kept fixed as the AC voltage is increased to larger magnitudes. As seen, both damping models overestimate peak oscillation amplitudes for both AC excitation levels. The results for the cubic damping model are shown in Fig.1(d); for this damping model, the coefficients c_1 and c_3 are calibrated using the two lower-amplitude frequency responses, i.e. those for 0.4 and 5.5 V. The damping coefficients are then kept fixed and the frequency responses at other AC voltages are obtained and compared to the experimental data. It is seen that the cubic model captures the nonlinear damping in the system with a good accuracy; however, it slightly underestimates the peak amplitude, and this becomes more visible at higher AC voltage levels. The final model examined is the general quadratic-cubic damping model and the result for this case is shown in Fig.1(e). This model requires three frequency responses for calibration of three damping coefficients. As seen, this model has the best accuracy in predicting the primary resonance response amplitudes at various AC voltages among all damping models examined.

Conclusions

This study conducted a theoretical-experimental investigation on the nonlinear damping in in-plane MEMS resonators. It was shown that both linear and Kelvin-Voigt models overestimate the peak amplitude at higher excitation levels. The general quadratic-cubic damping model showed excellent agreement with experimental data and worked best among different models.

Drag Forces in Non-Uniform Cantilever Beam Oscillating in Viscous fluid

Lalsingh Devsoth and Ashok Kumar Pandey

Indian Institute of Technology Hyderabad, Kandi, Sangareddy, Telangana, 502285.

Summary. Sensitiveness of the micro-mechanical cantilever beams strongly depends on the fluid damping such as damping due to drag and squeeze film. There have been many studies associated with drag force computation in uniform cantilever beam oscillating in isolation. In this work, we are presenting drag force computation in non-uniform cantilever beam with linear and quartic converging and diverging widths. Finally, we find the variation of added mass effect and quality factor based on drag force as a function of degree of non-uniformity, i.e., tapering parameter. It is found that the quality factor increases for converging beam and decreases for diverging beam. The effect is found to be more in quartic varying beam.

Introduction

Micro-Electro-Mechanical Systems (MEMS)/ Nano-Electro-Mechanical Systems (NEMS) such as biosensors, atomic force microscope, etc., generally operate in fluid. Therefore it is essential to compute drag forces due to fluid and structure interaction [1]. To compute drag forces in uniform cantilever beam, there exist formulas to compute fluid damping and added mass effect of a rigid circular cylinder oscillating with certain frequency in air [2]. To generalize the formula for arbitrary cross-section, Tuck [3] had developed formulation to compute drag forces and added mass effect. Although, generalized formula is written in terms of unknowns pressure and vorticity it appears little complex. However, he also extended it to a thin ribbon having zero thickness. To further include the effect of mode shape and rectangular section, Sader [4] modified hydrodynamic function for cantilever beam with rectangular section by modifying the hydrodynamic function of circular cylinder given in [2]. Zhang et al. [5] obtained more explicit form of drag force and add-mass effect in cantilever beam. However, all the previous study are limited to uniform cantilever section with circular or thin-rectangular sections. In this study, we compute the drag forces in non-uniform cantilever beam based on the mode-shapes and frequencies of corresponding converging and diverging beams and compare it with that of uniform beam.

Theoretical model for non-uniform beam

The oscillations of a cantilever beam in a viscous fluid is governed by a linearized unsteady Stokes equation $-i\omega\rho\nabla^2\mathbf{v} = -\nabla p + \mu\nabla^2\mathbf{v}$, $\nabla\cdot\mathbf{v} = 0$. Fourier transformed unsteady Stokes equation is solved using the stream function [3], where, ω frequency of oscillation, velocity \mathbf{v} and pressure p is obtain by transforming above equation into vorticity equation and pressure harmonic equation $\nabla^2 p = 0$ [3]. Assuming the velocity of vibrating beam in z-direction with velocity, $u = u_0 e^{i\omega t}$ [1], where, u_0 is the maximum amplitude of the vibration, the hydrodynamic function is found by integrating pressure along beam width in terms of Reynold's number ($Re = \frac{\rho\omega b^2}{\mu}$, where, b is the width of beam) [3]. Subsequently, damping coefficient at each section of the beam is found from imaginary component of hydrodynamic function and then the modal damping. To compute the force for a thin beam with converging and diverging widths, we use the corresponding frequencies and mode shapes obtained by Sajal et al.[7]. Here, the beam width is taken as $b = b_0(1 + \alpha\frac{x}{L})^n$, where, $n = 1$ (linear), $n = 4$ (quartic), α is tapering parameter varying from -0.5 to 0.5. For converging beam, it is negative and for diverging beam it is positive. The mode shape of non-uniform beam is given by $w(x) = \frac{v(x)}{\sigma(x)}$, where, $v(x)$ is the exact mode shape of the uniform beam, $\sigma(x)$ is function to capture non-uniform effect which is taken for linear variation in width as $\sigma(x) = \sqrt{1 + \alpha\frac{x}{L}}$ and for the quadratic as $\sigma(x) = (1 + \alpha\frac{x}{L})^2$ [7]. The area and area moment of inertia of the beam section also vary with width. The different modal frequencies $\omega = (\frac{\lambda}{l})^2 \sqrt{\frac{EI}{\rho_b A}}$ of the non-uniform beam are obtained by solving the characteristic equation of the beam [7, 6], where, λ for linearly tapered beam are 4.3119, 4.0978, 3.922, 3.7710, 3.6420, 3.5160, 3.4129, 3.3208, 3.2368, 3.162, 3.0958 for tapering parameter are -0.5, -0.4, -0.3, -0.2, -0.1, 0, 0.1, 0.2, 0.3, 0.4, 0.5. The corresponding λ for quartic case are 7.558, 6.2981, 5.3361, 4.5882, 3.9940, 3.516, 3.1241, 2.7989, 2.5259, 2.294, 2.0961. Finally, quality factor (i.e $Q = \frac{\text{mass} \times \omega}{C_{davg}}$) and the modal damping coefficient $C_{davg} = \frac{\int_0^L c_{dx} w^2(x) dx}{\int_0^L w^2(x) dx}$ are computed.

Results and Discussion

For a non-uniform microbeam as shown in Figure 1(a) undergoes vibration in ambient air of viscosity of $1.8 \times 10^{-5} \frac{kg}{m-s}$ which induces fluid damping and added mass. To compute these quantities, we take a microbeam of density $\rho = 2300 kg/m^3$, elastic modulus, $E = 62.5 GPa$, width at fixed end as $b_0 = 40 \mu m$, length $L = 200 \mu m$, and thickness $h_0 = 0.965 \mu m$. To compare the influence of drag forces and added mass, we plot the hydrodynamic function per velocity for free end width corresponding to tapering parameters of ($\alpha = -0.5, 0, 0.5$) as shown in Fig 1(b)-(e) for both linear and quartic converging diverging beam. Figure 1(b) and Fig 1(c) represent the added-mass and damping effect, respectively, for a linear converging diverging beam. The trend of both the curve show decrease in their value as Re increase. Similarly, for the quartic converging diverging beam, Fig 1(d) and Fig 1(e) show that the added-mass and damping effect similar trend. However the effect is more pronounced in quartic beams. For validation, we have also compared the results of uniform beam ($\alpha = 0$) results with circular cylinder case mentioned in [2]. Subsequently, for frequency variation as shown in Fig 1(f) from [7], Fig 1(g) and Fig 1(h) show variation of damping coefficient and added-mass of non-uniform beam with different tapering parameters for linear and quartic varying beams. As the tapering ratio increases,

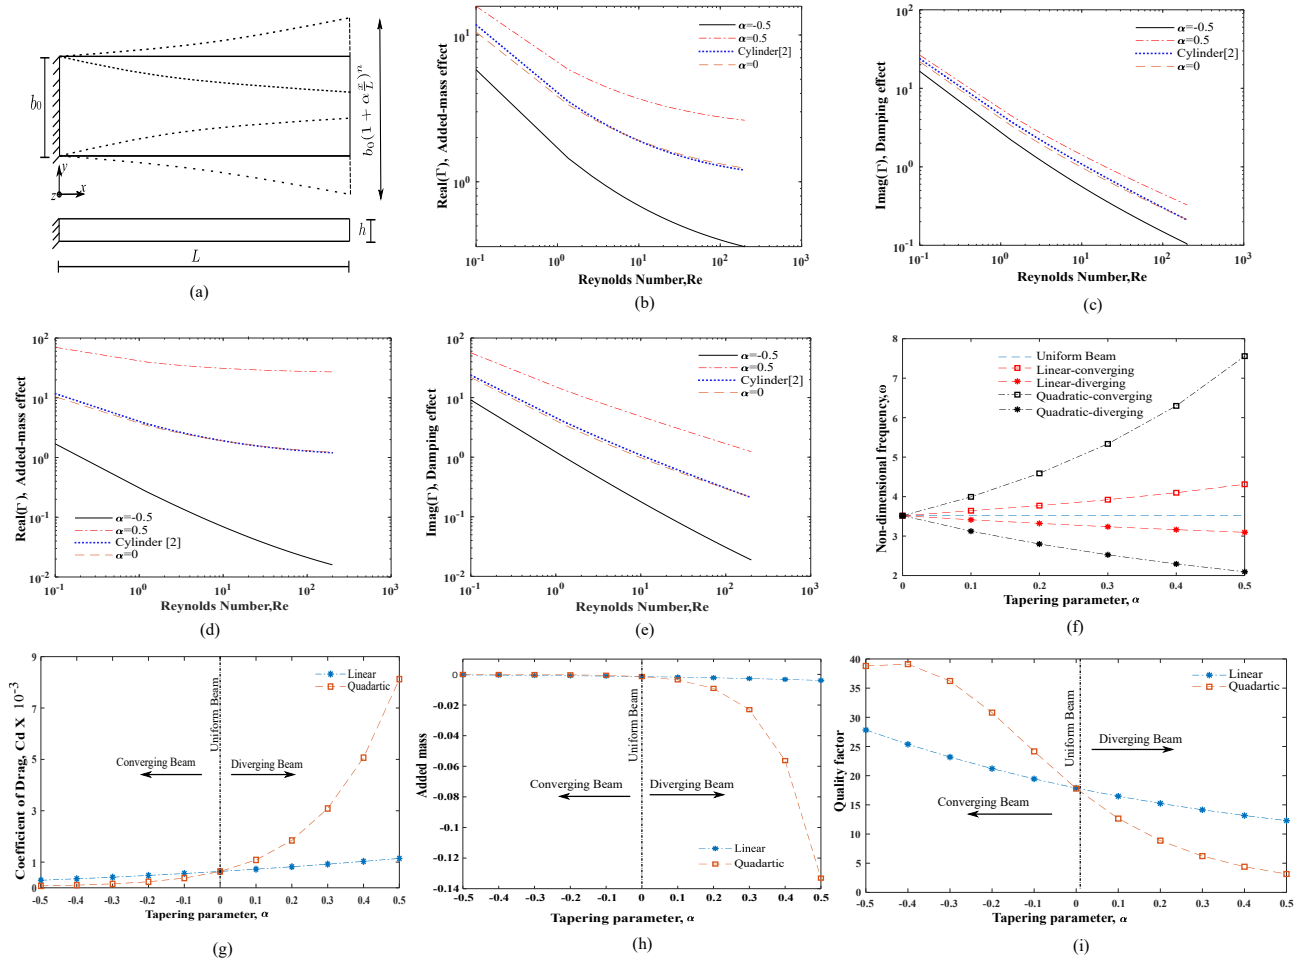

Figure 1: (a) A typical cantilever beam; Variation of hydrodynamic function with Re for $\alpha = -0.5, 0, 0.5$ to capture (b) added-mass and (c) damping coefficient of linearly varying beam, and (d) added-mass and (e) damping coefficient of quartic varying beam. Variation of (f) non-dimensional frequency, (g) coefficient of drag, (h) added mass, (i) Quality factor of converging-diverging beam with tapering ratio α .

overlapping/wet area increases which lead to increase in damping and reduction in added mass effect. Finally, the variation of quality factor for linearly and quartic beam are shown in Fig 1(i). It shows that quality factor increases for converging beam and decreases for diverging in both types non-uniform beam. The results presented here will be useful in designing non-uniform beam based mass sensors [8].

Conclusions

We have computed damping coefficient and added mass effect due to drag forces in non-uniform cantilever beam based on semi-analytical method. For free-end width of non-uniform beam corresponding to $\alpha = -0.5, 0, 0.5$, we compare the hydrodynamic functions corresponding to damping and added mass effect per unit length. Subsequently, we find modal damping coefficient and modal added mass effect linear and quartic varying beam with $\alpha = -0.5, 0, 0.5$. It is found that damping effect increases with increases in tapering parameter. The corresponding quality factor increases with decrease in tapering parameter. Such variation can be useful in optimizing the performance of non-uniform cantilever sensor.

Summary. Dynamic AFM is transitioning from a high-resolution imaging tool to a nanomechanical probe that can perform precise quantification of matter in fields as varied as microbiology, molecular metrology, and material science. To date, this has been achieved by estimating the nanoscale forces that exist between the probe and the sample, using empirical models that are merely approximations of the true probe-sample interaction physics. Here, we go beyond such approximations by making use of the recent advances in data-science and machine learning to distil nonlinear governing equations of dynamic AFM, and thus predict tip-sample forces directly from experimental raw deflection data. Our data-driven algorithm obtains physics-based models from experiments and is able to estimate time-resolved nanoscale interactions with sub-microsecond resolution.

Introduction

Dynamic atomic force microscopy (AFM) has become an indispensable tool for resolving mechanical, chemical and biological properties of samples at nanoscale. The precise quantification of materials at the nanoscale is achieved with accurate estimation of the tip-sample interaction force. However, dynamic AFM in contrast to its name does not measure directly the interaction force while imaging in any of its modalities. Instead, the interaction force is often reconstructed indirectly by combining different information channels like the frequency, amplitude and phase of the oscillating cantilever, while modulating the height of the probe above the sample surface [4]. The existing reconstruction techniques in dynamic AFM possess several drawbacks such as inability to resolve instantaneous tip-sample force, requiring a priori knowledge on the transfer function of the cantilever or large number of harmonics, which makes them cumbersome and inefficient to study the fast processes encountered in biological and chemical systems [3]. Thus a generalized approach for dynamic AFM that allows direct access to time-resolved surface forces irrespective of the chosen probe-sample configuration is currently missing.

Figure 1: Schematic of the identification process. The data (orange trajectories) from the AFM setup is used as input to the sparse identification algorithm. The algorithm determines the governing model of the system and predicts the corresponding dynamics as shown by the blue phase space trajectories.

In this regard, here we demonstrate that data-driven identification applied to dynamic AFM experiments can provide physically interpretable models and simultaneously estimate the time-resolved interaction forces. We make use of the recent advances in sparse identification [1] and machine learning [2] techniques to identify the governing equations directly from the experimental measurements. In contrast to existing methods, the data-driven approach has no inherent assumptions on the type of interactions or mathematical models but relies solely on the measurements and thus can be generalized to any cantilever-sample configuration. Furthermore, based on the identified governing equations, our method also quantifies

the tip-sample force with a sub-microsecond resolution. We showcase this experimentally by using the data-driven algorithm on the temporal data obtained from a silicon cantilever interacting with a two-component polymeric sample made up of Polystyrene (PS) and Low-Density-Polyethylene (LDPE). The results and insights obtained from the identification procedure are in excellent agreement with the expected tip-sample interaction mechanism in polymers. In particular, we showcase the variation in contact duration, peak loading forces in stiff and compliant materials as well as highlight the ability of the technique to probe transient surface forces and capture the hysteresis phenomenon. A schematic of such an identification is shown in Fig. 1.

Methods and Results

In order to characterize the tip-sample force in experimental scenario, we first begin by training the algorithm on several standard AFM models such as Derjaguin-Muller-Toporov (DMT), Johnson, Kendall and Roberts (JKR) and Lennard-Jones (LJ) among others. This step allows us to expand the library of functions which is used to reconstruct the tip-sample nonlinearities from polynomials, trigonometric terms to specific nonlinear functions that are capable of describing the nano-scale forces encountered in dynamic AFM. We present in Fig.2 the identification results on synthetic data obtained from DMT model. Here, Fig.2(a) shows the identified dynamics (Orange) and the original dynamics (blue) of the system in a 2D phase-space portrait. Whereas, Fig.2(b) shows the identified versus the original co-efficients of the dynamical system governed by DMT tip-sample interaction force. The difference in the identified co-efficients is attributed to the noise added to the synthetic data to mimic the experimental conditions. By utilizing the co-efficients of the identified system, the tip-sample force is re-constructed with sub-microsecond resolution.

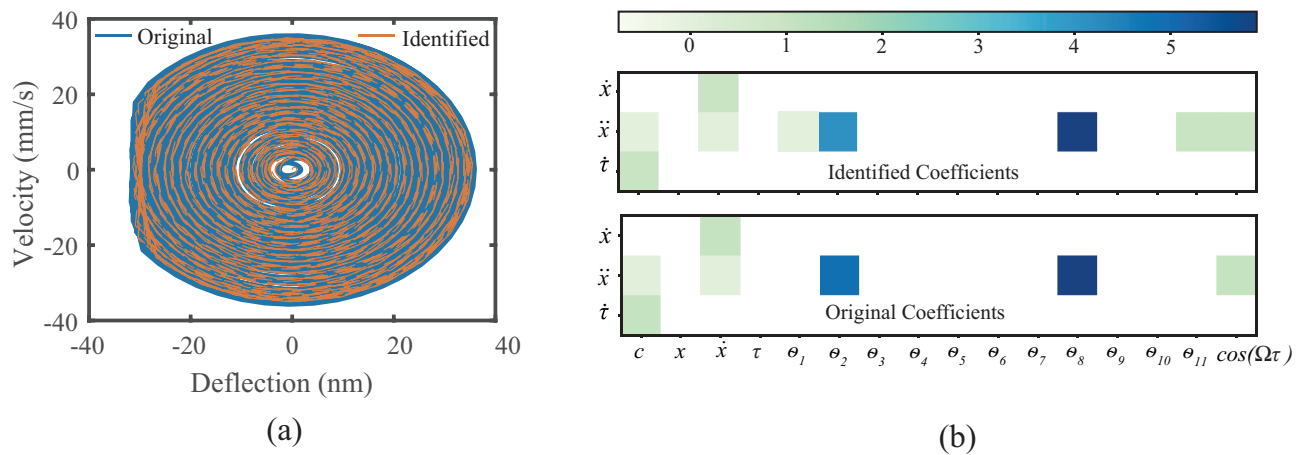

Figure 2: Identification of DMT model dynamics. (a) Identified (orange) trajectories from data driven analysis superimposed on the original trajectories (blue) obtained from simulations. (b) Map showing the strength of identified versus the original coefficient values used in the simulations.

Conclusion

We report here a novel approach at identifying the governing equations of motion and the associated tip-sample force in dynamic AFM using machine learning and data science techniques. The data driven algorithm based on sparse identification is trained on standard AFM models and a condensed library of functions capable of identifying experimental tip-sample interaction mechanics is determined. To highlight the capability of the technique, numerical simulations with noise corrupted synthetic data and experiments on polymer materials are performed. The analysis of the results show that the technique is able to obtain the dynamical trajectory of the underlying system without any prior assumption on the nature of tip-sample interaction. The method thus opens a completely new window into using machine learning algorithms in AFM nano-characterization with real-time data as well in developing novel feedback architectures and high-speed imaging.

Asymptotic solutions of singular perturbed system of transport equations with small mutual diffusion in the case of many spatial variables

Nesterov Andrey

* *PLEKHANOV Russian University of Economics, Moscow, Russia*

Summary. We construct an asymptotic expansion on a small parameter of the solution of the Cauchy problem for a singularly perturbed system of transport equations with small nonlinearity and mutual diffusion describing the transport in a multiphase medium for many spatial variables. The asymptotic expansion of the solution is constructed as a series in powers of a small parameter and contains a functions of the boundary and inner layers. The main part of the asymptotics is described by one equation, which under certain requirements on the nonlinearity and diffusion terms is a generalization of the equation Burgers -Korteweg-de Vries in the case of many spatial variables.

Statement of the problem

The asymptotic expansion (AE) of the solution of the Cauchy problem for a singularly perturbed system of transport equations with small nonlinearity and diffusion is constructed

$$\varepsilon^2(U_t + \sum_{i=1}^m D_i U_{x_i}) = AU + \varepsilon F(U) + \varepsilon^3 \sum_{i=1}^m B_{ij}(U) U_{x_i x_j}, |\bar{x}| < \infty, t > 0, \quad (1)-(2)$$

$$U(\bar{x}, 0) = H \omega\left(\frac{\bar{x}}{\varepsilon}\right).$$

Here $U = \{u_1, \dots, u_n\}$ is the solution, $0 < \varepsilon < 1$ is a small positive parameter, D_i is a diagonal constant matrix, the function $F(U)$ and the matrix $B_{ij}(U)$ are smooth enough, smooth function $\omega(x)$ is rapidly decreasing together with all derivatives. Matrix A has a single zero eigenvalue, which corresponds to the eigenvector h_0 , vector h^*_0 - eigenvector of the matrix A^T , corresponding to the zero eigenvalue, non-zero eigenvalues of the matrix A is imposed condition $\operatorname{Re} \lambda < 0$. Below, without limiting generality, we put $(h_0, h^*_0) = I$. Additionally, it is required that

$$(F(Z), h^*_0) = 0, (B_{ij}(Z))^T h^*_0 = 0 \forall Z, i, j = 1, \dots, m, \operatorname{Re} \lambda > 0 \forall \lambda \neq 0. \quad (3)$$

Such systems of equations can describe the transfer of substances in multiphase media.

The AE of the solution up to order N (determined by the smoothness of the input data) is constructed by the method of boundary functions [4] and has the form

$$U(\bar{x}, t) = \sum_{i=0}^N \varepsilon^i (s_i(\bar{\xi}, t) + \pi_i(\bar{\xi}, \tau)) + R_N = U_N + R_N, \quad (4)$$

$$\bar{\xi} = (\bar{x} - \bar{V}t) / \varepsilon, \bar{\xi} = \bar{x} / \varepsilon, \tau = t / \varepsilon^2, \bar{V} = \{(D^i h_0, h^*_0) / (h_0, h^*_0), i = 1, \dots, m\}.$$

The construction of AE members is described in detail in [1], [2], [3] and others. In accordance with the boundary layer method of A. V. Vasilyeva and V. F. Butuzov [4] we present nonlinear function $F(U)$ in the form

$$F(U) = F(\bar{U} + S + \Pi + R) = F(\bar{U}) + (F(\bar{U} + S) - F(\bar{U})) + (F(\bar{U} + \Pi) - F(\bar{U})) + (F(\bar{U} + S + \Pi + R) - F(\bar{U} + S) - F(\bar{U} + \Pi) + F(\bar{U})) = \bar{F} + SF + \Pi F + RF.$$

A similar representation is made for $B(U)$

$$B(U) = \bar{B} + SB + \Pi B + RB.$$

Construction of asymptotic expansion of the solution

Construction regular part AE

Regular part AE have the form

$$\bar{U}(\bar{x}, t) = \sum_{i=0}^N \varepsilon^i \bar{u}_i(\bar{x}, t). \quad (5)$$

The term \bar{U} plays a supporting role.

Substitute the expansion (5) in the system (6)

$$\varepsilon^2(\bar{U}_t + \sum_{i=1}^m D_i \bar{U}_{x_i}) = A\bar{U} + \varepsilon F(\bar{U}) + \varepsilon^3 \sum_{i,j=1}^m B_{ij}(\bar{U}) \bar{U}_{x_i x_j}, |x_i| < \infty, 1 \leq i \leq m, t > 0, \quad (6)$$

and we obtain the equations for the terms of the expansion [4]:

$$\left\{ \begin{array}{l} \varepsilon^0 : A\bar{u}_0 = 0, \\ \varepsilon^1 : A\bar{u}_1 = -F(\bar{u}_0), \\ \varepsilon^2 : A\bar{u}_2 = \bar{u}_{0,t} + \sum_{i=1}^m D_i \bar{u}_{0,x_i} - F'_u(\bar{u}_0) \bar{u}_1 \\ \dots \end{array} \right.$$

The equation at ε is solvable by condition (3).

Hence

$$\left\{ \begin{array}{l} \bar{u}_0(x, t) = u_0(x, t)h_0 \\ \bar{u}_1(x, t) = u_1(x, t)h_0 - GF(\bar{u}_0), \end{array} \right.$$

Here G is a pseudo-inverse to A operator, u_0 and u_1 are some scalar functions.

We write down the condition of solvability of the equation at ε^2 :

$$(\bar{u}_{0,t} + \sum_{i=1}^m D_i \bar{u}_{0,x_i} - F'_u(\bar{u}_0) \bar{u}_1, h^*_0) = 0.$$

From condition (3) follows $(F'_u(Z)\delta, h^*_0) = 0 \forall \delta$.

Therefore the solvability condition gives the equation for u_0

$$u_{0,t} + \sum_{i=1}^m V_i u_{0,x_i} = 0, V_i = (D_i h_0, h^*_0). \quad (7)$$

From the regular part of initial conditions $u_0(\bar{x}, 0) = 0$ it follows $u_0(\bar{x}, t) \equiv 0 \forall \bar{x}, t$.

Similarly, all other u_i are zero. The values V_i will be used below.

Construction S function

S function have the form

$$S(\bar{\zeta}, t) = \sum_{i=0}^N \varepsilon^i s_i(\bar{\zeta}, t), \quad \zeta_i = (x_i - V_i t) / \varepsilon, i = 1, \dots, m. \quad (8)$$

V_i defined by the formula (7).

Function S is the solution of the system

$$\varepsilon^2 (S_t + \sum_{i=1}^m D_i S_{x_i}) = AS + \varepsilon SF + \varepsilon^3 \sum_{i,j=1}^m SB_{ij} S_{x_i x_j}, |\bar{\zeta}| < \infty, t > 0. \quad (9)$$

Moving to the variables $(\bar{\zeta}, t)$ taking into account $\bar{U} = 0$, we get

$$\begin{aligned} \varepsilon^2 S_t + \varepsilon \sum_{i=1}^m \Psi_i S_{\zeta_i} &= AS + \varepsilon F(S) + \varepsilon^3 \sum_{i,j=1}^m B_{ij}(S) S_{\zeta_i \zeta_j}, \\ \Psi_i &\equiv D_i - V_i. \end{aligned} \quad (10)$$

Than we obtain the equations for the terms of the expansion [4]

$$\left\{ \begin{array}{l} \varepsilon^0 : As_0 = 0, \\ \varepsilon^1 : As_1 = \sum_{i=1}^m \Psi_i s_{0,\zeta_i} - F(s_0) - \sum_{i,j=1}^m B_{ij}(s_0) s_{0,\zeta_i \zeta_j} \equiv Q_1, \\ \varepsilon^2 : As_2 = s_{0,t} + \sum_{i=1}^m \Psi_i s_{1,\zeta_i} - F'_u(s_0) s_1 - \sum_{i,j=1}^m B_{ij}(s_0) s_{1,\zeta_i \zeta_j} \equiv Q_2, \\ \dots \end{array} \right.$$

From here, taking into account the condition (3), we get

$$\begin{aligned} s_0(\bar{\zeta}, t) &= \varphi_0(\bar{\zeta}, t)h_0, \\ s_1(\bar{\zeta}, t) &= \varphi_1(\bar{\zeta}, t)h_0 + GQ_1. \end{aligned}$$

We write down the solvability conditions of the equation at ε^2 :

$$(Q_2, h^*_0) = (s_{0,t} + \sum_{i=1}^m \Psi_i s_{1,\zeta_i} - F'_u(s_0) s_1 - \sum_{i,j=1}^m B_{ij} s_{1,\zeta_i \zeta_j}, h^*_0) = 0.$$

Substituting here the expression for s_l and taking into account the conditions (3) as well as equality $(\Psi_i h_0, h^*_0) = ((D_i - V_i)h_0, h^*_0) = 0$,

we obtain equation for determining φ_0 . Let's introduce notation

$$M_{ij} = (\Psi_i G \Psi_j h_0, h^*_0) + (\Psi_j G \Psi_i h_0, h^*_0) \forall i \neq j, M_{ii} = (\Psi_i G \Psi_i h_0, h^*_0),$$

$$F_{i,eff}(\varphi_0) = -(\Psi_i G F(\varphi_0 h_0), h^*_0),$$

$$B_{ijk,eff}(\varphi_0) = -(\Psi_k G B_{ij}(\varphi_0 h_0) h_0, h^*_0).$$

Then the equation for determining φ_0 can be rewritten as

$$\varphi_{0,t} + \sum_{i,j=1}^m M_{ij} \varphi_{0,\zeta_i \zeta_j} + \sum_{i=1}^m (F_{i,eff}(\varphi_0))'_{\zeta_i} + \sum_{i,j,k=1}^m (B_{ijk,eff}(\varphi_0) \varphi_{0,\zeta_i \zeta_j})'_{\zeta_k} = 0. \quad (11)$$

In the expanded form the equation has the form

$$\begin{aligned} \varphi_{0,t} + \sum_{i,j=1}^m M_{ij} \varphi_{0,\zeta_i \zeta_j} + \sum_{i=1}^m F'_{i,eff}(\varphi_0) \varphi_{0,\zeta_i} + \\ + \sum_{i,j,k=1}^m (B_{ijk,eff}(\varphi_0) \varphi_{0,\zeta_i \zeta_j \zeta_k} + B'_{ijk,eff}(\varphi_0) \varphi_{0,\zeta_i \zeta_j} \varphi_{0,\zeta_k}) = 0. \end{aligned} \quad (12)$$

We will impose an additional condition

$$\sum_{i,j=1}^m M_{ij} z_i z_j \leq 0 \forall \sum_{i=1}^m z_i^2 > 0.$$

To obtain the equation for s_n , $n \geq l$, we write the expansion terms of order ε^n , ε^{n+1} and ε^{n+2} :

$$\varepsilon^j : A s_j = s_{j-2,t} + Q_j, j = n, n+1, n+2,$$

where Q_l is defined above, and Q_p for $p > l$ is expressed in terms of previously found s_{p-1}

$$Q_p = \sum_{i=1}^m \Psi_i s_{p-1,\zeta_i} - F'_u(s_0) s_{p-1} - \sum_{i,j=1}^m B_{ij} s_{p-1,\zeta_i \zeta_j}, p = 2, 3, \dots$$

From the relations for $j = n, n+1$ it follows that

$$s_j = h_0 \varphi_j(\bar{\zeta}, t) + G Q_j, j = n, n+1,$$

where φ_n, φ_{n+1} are as yet unknown functions.

Writing the solvability condition $(s_{n,t} + Q_{n+2}, h^*_0) = 0$ of the equation for s_{n+2}

after exception of s_{n+1} , we obtain the equation for s_n . Adding a designation

$$F1_{i,eff} = -(\Psi_i G F'(\varphi_0 h_0) h_0, h^*_0),$$

taking into account the notations introduced earlier, the linear equation for φ_n can be rewritten as

$$\begin{aligned} \varphi_{n,t} + \sum_{i,j=1}^m M_{ij} \varphi_{n,\zeta_i \zeta_j} + \sum_{i=1}^m (F1_{i,eff} \varphi_n)'_{\zeta_i} + \sum_{i,j,k=1}^m (B_{ijk,eff}(\varphi_0) \varphi_{n,\zeta_i \zeta_j})'_{\zeta_k} + \\ + \sum_{i,j,k=1}^m ((B_{ijk,eff}(\varphi_0))' \varphi_n \varphi_{0,\zeta_i \zeta_j})_{\zeta_k} = \Phi_n(\bar{\zeta}, t), \quad n \geq 1. \end{aligned} \quad (13)$$

where Φ_n is expressed by the previously found $\varphi_j, j < n$.

Construction II function

To satisfy the initial conditions the function Π is constructed.

Π function have the form

$$\Pi(\bar{\xi}, \tau) = \sum_{i=0}^N \varepsilon^i p_i(\bar{\xi}, \tau), \quad \bar{\xi} = \bar{x} / \varepsilon, \tau = t / \varepsilon^2, \quad (14)$$

produced as standard [4]. Function Π is the solution of the system

$$\Pi_\tau + \varepsilon \sum_{i=1}^m D_i \Pi_{\zeta_i} = A \Pi + \varepsilon \Pi F + \varepsilon \sum_{i,j=1}^m B \Pi_{ij} \Pi_{\zeta_i \zeta_j}, |\bar{\xi}| < \infty, \tau > 0, \quad (15)$$

together with satisfies the initial conditions and is a boundary layer function

$$S(\bar{\zeta}, 0) + \Pi(\bar{\zeta}, 0) = H \omega\left(\frac{\bar{x}}{\varepsilon}\right), \Pi(\bar{\zeta}, \tau) \rightarrow 0, \quad \tau \rightarrow \infty$$

The main term is defined as the solution of the system

$$p_{0,\tau} = Ap_0, \left| \bar{\xi} \right| < \infty, \tau > 0. \quad (16)$$

The initial conditions for φ_0 and p_0 are defined together, with the addition of the constraint condition p_0 at $\tau \rightarrow \infty$:

$$p_0 + \varphi_0|_{t=0} = U(\bar{x}, 0) = H\omega\left(\frac{\bar{x}}{\varepsilon}\right), \left| p_0(\bar{\xi}, \infty) \right| < \infty. \quad (17)$$

From conditions (17), we obtain the initial conditions for φ_0 and p_0 . The solution of problem (16) with initial condition (17) and condition at infinity exists and satisfies the estimate

$$\left\| p_0(\bar{\xi}, \tau) \right\| < C \exp(-\kappa\tau), \kappa > 0. \quad (18)$$

The remaining p_i are defined as solutions of linear inhomogeneous ODES and satisfy similar estimates:

$$p_{i,\tau} = Ap_i + P_i, i \geq 1, \left| \bar{\xi} \right| < \infty, \tau > 0. \\ \left\| p_i(\bar{\xi}, \tau) \right\| < C \exp(-\kappa\tau), \kappa > 0. \quad (19)$$

Here P_i is expressed through previously found $p_j, j < i$.

The initial conditions for the functions φ_i and p_i are obtained together from the conditions

$$\sum_{i=1}^{\infty} \varepsilon^i (s_i(\bar{\xi}, 0) + p_i(\bar{\xi}, 0)) = 0, \sum_{i=1}^{\infty} \varepsilon^i p_i(\bar{\xi}, \tau) \rightarrow 0, \\ \tau \rightarrow \infty$$

what gives

$$s_i(\bar{\xi}, 0) + p_i(\bar{\xi}, 0) = 0, p_i(\bar{\xi}, \tau) \rightarrow 0 \quad \forall i > 0. \quad (20)$$

From conditions (21) we obtain the initial conditions for the functions φ_i and p_i .

Evaluation of the residual member

The residual term is estimated by the residual term in the problem.

The question of the existence of a solution and exponential estimates of the solution of equations (1)-(2), (11)-(17) under rapidly decreasing initial conditions for the variable $\bar{\xi}$ not considered here.

The residual term was estimated by residual.

Let the function $\omega(z)$ have derivatives up to $N+3$ rd order, the function $F(z)$ have derivatives up to $N+3$ rd order in the domain $\|U\| < C, C > 0$, and let $\|U(x, 0)\| < C\delta, \delta > 0$.

Theorem. The solution of the problem (1) - (2) is represented as

$$U(\bar{x}, t) = \sum_{i=0}^N \varepsilon^i (s_i(\bar{\xi}, t) + p_i(\bar{\xi}, \tau)) + R_N = U_N + R_N, \quad (21)$$

where $U_N = S_N + \Pi_N$ is the constructed AE, and the residual term R_N satisfies the Cauchy problem

$$\varepsilon^2 (R_t + \sum_{i=1}^m D_i R_{x_i}) = AR + \varepsilon RF + \varepsilon^3 \sum_{i,j=1}^m RB_{ij} R_{x_i x_j} + r, |\bar{x}| < \infty, t > 0, \\ R(\bar{x}, 0) = 0, r = O(\varepsilon^N).$$

Conclusion

1. The solution of the problem (1) - (2) at $t > t_0$, where $t_0 > 0$ is some fixed (independent of ε), has the form

$$U(\bar{x}, t) = \sum_{i=0}^N \varepsilon^i (s_i(\bar{\xi}, t) + p_i(\bar{\xi}, \tau)) + R_N = s_0(\bar{\xi}, t) + O(\varepsilon) = \varphi_0(\bar{\xi}, t)h_0 + O(\varepsilon),$$

where the principal term AE $\varphi_0(\bar{\xi}, t)$ is the solution of the equation

$$\varphi_{0,t} + \sum_{i,j=1}^m M_{ij} \varphi_{0,\zeta_i \zeta_j} + \sum_{i=1}^m (F_{i,eff}(\varphi_0))'_{\zeta_i} + \sum_{i,j,k=1}^m (B_{ijk,eff}(\varphi_0) \varphi_{0,\zeta_i \zeta_j})'_{\zeta_k} = 0$$

(generalized Burgers – Korteweg – de Vries equation). For a quadratic function $F(u)$ and constant matrices $B(u)$, equation (13) is a generalization of the Burgers – Korteweg – de Vries equation [5] to the multidimensional case:

$$\varphi_{0,t} + \sum_{i,j=1}^m M_{ij} \varphi_{0,\zeta_i \zeta_j} + \sum_{i=1}^m k_i \varphi_0 \varphi_{0,\zeta_i} + \sum_{i,j,k=1}^m B_{ijk,eff} \varphi_{0,\zeta_i \zeta_j \zeta_k} = 0.$$

For the case of a single spatial variable, the equation (13) differs from the BKdF equation only in the numerical values of the coefficients

$$\varphi_{0,t} + M \varphi_{0,\zeta\zeta}'' + k \varphi_0 \varphi_{0,\zeta}' + B \varphi_{0,\zeta\zeta\zeta}''' = 0.$$

2. Very interesting properties of the spatial part (the relationship between the degree of degeneracy of the parabolic part of the operator and the dimension of the system (1) are obtained in [1],[3].

3. For the dissipativity of the equation (11), the condition is sufficient

$$M(\bar{z}) = \sum_{i,j=1}^m M_{ij} z_i z_j \leq 0 \forall \sum_{i=1}^m z_i^2 > 0. \quad (22)$$

It is shown in [1] that the set of matrices A that satisfies the conditions imposed above and satisfies the condition (22) is not empty.

4. When $B(U) = 0$, the system (1) becomes a system of transfer equations, i.e. a hyperbolic type system.

In this case, the equation (11) that defines the main AE term has the form

$$\varphi_{0,t} + \sum_{i,j=1}^m M_{ij} \varphi_{0,\zeta_i \zeta_j}'' + \sum_{i=1}^m (F_{i,eff}(\varphi_0))'_{\zeta_i} = 0, \quad (23)$$

In [1], a class of matrices A is allocated for which the quadratic form $M(\bar{z})$, defining the spatial part of the equation, is sign-positive, and the equation (23) i.e. becomes a parabolic equation (such as the Burgers equation). The nature of the evolution of the principal term of the AE can be described as the movement with some "effective speed" V_{eff}

$$\bar{V}_{eff} = \{V_i = (D_i h_0, h_0^*), i = 1, \dots, n\}$$

with simultaneous pseudodiffusion, the nature of which is determined by the coefficients M_{ij} , which is influenced by nonlinearity.

The spatial part with the second derivatives is determined by the symmetric matrix M . In [1] it is obtained that the quadratic form $M(\bar{z})$ can be degenerate, and the degree of degeneration depends on the ratio of the number of equations n and the number of spatial variables m . For a class of matrices A allocated in [1], for $m=3$ (three spatial variables) and for $n=2$, the matrix M has two zero eigenvalues and one negative, for $n=3$ - one zero and two negative, for $n=4$ and more, all eigenvalues of the matrix M become negative.

Figure 1 shows the evolution of the main AE member for $m=3$ and $n=2, n=3$.

Figure 1. $n=2, n=3$.

In the case of three-dimensional space, the picture of the solution evolution of the principal term of the AE will have the following view. In a two-phase environment, pseudodiffusion processes develop along one axis (the direction of which is given by the vector $\Delta = \bar{V}_1 - \bar{V}_2$). Accordingly, the initial local perturbation will move in space with an "effective" average speed V_{eff} and simultaneously deform, diffusing into a "cloud" extended in the direction of the vector Δ . In the case of three phases (a system of three equations), the initial perturbation will move to the Pro-travel with the averaged speed and diffuse in the plane of vectors $\bar{V}_1 - \bar{V}_2, \bar{V}_1 - \bar{V}_3$, forming a flat "cloud".

In the case of four or more phases (a system of 4 or more equations), the initial perturbation will move at the effective velocity V_{ef} and diffuse over all three axes.

5. For the case of $B(U) = 0$ and a slightly different type of nonlinearity, an AE of a similar problem is constructed in [1]. When a number of additional conditions are imposed, it is possible to prove the estimate of the residual term of the constructed AE in the norm C .

6. The obtained result (11) allows us to identify non-obvious patterns of behavior of the solution of the Cauchy problem for singularly perturbed systems of type (1), as well as to identify non-obvious patterns of transfer processes in multiphase media in the case of rapid exchange between phases.

7. The numerical solution of the Cauchy problem for equation (11) requires significantly less computational resources than the solution of the original problem (1), due to the fact that equation (11) is not singularly perturbed.

Dynamic of the wind powered walking vehicle

Mikhail Garbuz^{*}, Liubov Klimina^{*} and Vitaly Samsonov^{*}

^{*} *Institute of Mechanics, Lomonosov Moscow State University, Moscow, Russia*

Summary. This paper presents the modelling of novel walking vehicle which aims to move against the wind flow using only the energy of the wind. The vehicle consist of the body, four legs, and wind propeller installed on it. When it is situated in a wind flow, propeller begins to rotate and transmits the energy to the main crank of the legs.

A mathematical model of the system is constructed. Aerodynamics of the propeller is described using a quasi-steady approach basing on available experimental data. It is shown that for certain values of parameters the apparatus can perform motion in upwind direction. Sufficient conditions of existence of periodic regimes are obtained. It is shown that the system can possess two types of periodic regimes corresponding to upwind motion. The average velocity of the body depending on the geometrical parameters is investigated. Evolution of attracting and repelling regimes of motion is analyzed. To demonstrate the possibility of motion against the wind, the plastic prototype of the vehicle is constructed and tested.

Introduction

The problem statement of a straight motion against the flow due to the energy of this flow for walking robots is unique. Nowadays Theo Jansen's mechanical devices are widely known, which are able to walk and get energy from the wind [1, 2]. Such mechanisms can perform motion in downwind direction with a help of sails, or in perpendicular to the wind direction, using a propeller.

In present work, we introduce the novel wind powered walking vehicle based on the Chebyshev plantigrade machine [3,4]. To realize the upwind motion, we upgraded mechanical scheme and supplemented a wind propeller on the body.

Description of the mechanical system

Scheme of the mechanical system is represented in Fig.1. The base of the walking mechanism consists of the body and four legs which are installed on it. This base is equipped with a wind turbine so that the shaft of the propeller is connected with the main shaft of legs by a worm gear. We suppose that this vehicle is located in the horizontal steady wind flow with the speed v_0 . The vehicle moves straight along the wind over an absolutely rough plane in the gravity field.

Figure 1: The scheme of the mechanism.

We assume that there is no slipping of the supporting legs and there is no tilting of the body. With these assumptions, the vehicle has one degree of freedom. The angle φ of rotation of the leg's crank shaft is chosen as a generalized coordinate. Equations of motion of the system are derived using the Lagrange formalism:

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{\varphi}} \right) - \left(\frac{\partial L}{\partial \varphi} \right) = n \cdot M_{aero} - \frac{v}{\dot{\varphi}} (F_{aero} + k(v + v_0)).$$

Here $L(\varphi, \dot{\varphi})$ is the Lagrange function, n is a gear ratio between propeller and cranks, v is a horizontal velocity of the body, k is the aerodynamic drag coefficient of the body. M_{aero} and F_{aero} are the aerodynamic torque and the drag force acting on the propeller, correspondently. These functions are described according a quasi-steady model and have the following form:

$$M_{aero} = \frac{1}{2} \rho_a S \cdot r_a (v + v_0)^2 C_T(\lambda), \quad F_{aero} = \frac{1}{2} \rho_a S \cdot (v + v_0)^2 C_D(\lambda),$$

where $\lambda = n r_a \dot{\varphi} (v + v_0)^{-1}$ is a tip speed ratio of the propeller, ρ_a is the air density, S and r_a are the characteristic area and the radius of the propeller. $C_T(\lambda)$ and $C_D(\lambda)$ are non-dimensional coefficients of torque and drag force, correspondingly. These coefficients are approximated using experimental data [5].

Right hand side of the system is π -periodic with respect to φ . Therefore, the phase space of the system is cylindrical. An attracting limit cycle with a positive value of $\dot{\varphi}$ enclosing the phase cylinder corresponds to desired upwind motion regime.

The following parameter is introduced: $\varepsilon =$. It is supposed to be a small value. This means that characteristic values of aerodynamic loads are significantly smaller than characteristic values of inertial forces.

Main results

We obtained sufficient conditions of existence of periodic upwind motion regimes using the Andronov-Pontryagin asymptotic method [6]. This method involves the averaging procedure. Notice that averaging is widely used in most powerful and demanded approaches of nonlinear dynamics [7, 8]. We performed analysis of limit cycles depending on parameters of the vehicle. The attraction properties of the regimes are studied.

Figure 2: Bifurcation diagram for periodical trajectories.

An example of bifurcation diagram is shown in Fig. 2 for the case $\varepsilon \rightarrow 0$ with other parameters of the system corresponding to the laboratory prototype constructed and tested in the Institute of Mechanics of Lomonosov Moscow State University. The description of the prototype and the video of its upwind motion are available [9]. In particular, the total length of the prototype is 225 mm. Fig. 2 illustrates how the average velocity the body depends on gear ratio n . Upper branch of diagram corresponds to attracting trajectories, and lower to repelling ones. Red cross corresponds to the bifurcation when a repelling periodic trajectory enclosing a phase cylinder merges with a separatrix and is destroyed as a result. Accuracy of asymptotic bifurcation diagram was checked by direct numerical integration of the system for the case $\varepsilon = 0.76$. In particular, the value of parameter n for which repelling trajectory is destroyed is determined with 6% precession.

Conclusion

The mathematical model of a wind powered walking vehicle is constructed. Results of parametrical analysis of the model are used to adjust constructive parameters of the first prototype. Experimental testing of the prototype demonstrated the possibility of motion against the wind for a walking mechanism.

The work was carried out within the framework of the research project “Development of methods for the study of controlled mechanical systems interacting with a continuous medium” (AAAA-A19-119012990123-0).

Methods of perturbation theory and their applications in nonlinear fracture mechanics and continuum damage mechanics

Larisa Stepanova*

*Department of Mathematical Modeling in Mechanics, Samara University, Samara, 443086, Russia

Summary. Perturbation theory techniques and their applications in nonlinear fracture mechanics (NFM) are discussed. This study summarizes an overview of the state of the art on the asymptotic description of fracture of nonlinear and damaged materials. The asymptotic stress, strain and damage fields near the crack tip for power-law materials and the influence of the damage accumulation processes on the stress-strain state in the vicinity of the crack tip are analyzed. The paper gives a detailed review of the fundamental results obtained in NFM by means of asymptotic methods and perturbation theory approaches. The main attention is paid to power-law materials and asymptotic stress and strain fields in the vicinity of the crack in both non-damaged materials and damaged materials under mixed mode loadings. The paper analyses the development of the asymptotic elastic-plastic crack-tip fields derived by Hutchinson, Rice and Rosengren as a singular dominant term of the asymptotic expansion for the stress and strain fields in a power-law hardening material and shows the current state of the asymptotic methods and their applications in NFM and continuum damage mechanics.

Introduction

Asymptotic methods have several essential advantages: universality, the analytical form of the solutions obtained and simplicity of further qualitative analysis. The asymptotic methods and perturbation theory are promising and effective approach of the derivation of approximate or even closed form solutions. Nowadays the perturbation theory techniques are applied to a wide variety of static and dynamic solid mechanics problems. Asymptotic methods have also been used with success in various nonlinear problems of fracture mechanics. The asymptotic analysis of the stress and strain distributions in the vicinity of the wedge-shaped domain is one of the most fundamental problems both in linear fracture mechanics and NFM. Thus, in linear fracture mechanics very important results have been obtained by use of the methods of asymptotic analysis. An excellent review of the most considerable contributions in this field is provided by A. Carpinteri and M. Paggi in their work [1]. The present study is aimed at analysis of the results recently obtained in NFM and continuum damage mechanics for power-law constitutive equations and the power-law damage evolution equation by means of asymptotic methods and perturbation theory.

Asymptotic solutions to problems of NFM

Crack-tip stress and strain singularities for pure power law material response $\varepsilon / \varepsilon_0 = \alpha (\sigma / \sigma_0)^n$, where α is a material constant, σ_0 is the reference yield strength, n is the strain hardening exponent, $\varepsilon_0 = \sigma_0 / E$ is the reference yield strain, are investigated in [2-4]. The crack tip fields can be derived in the separable form [2-4]

$$\sigma_{ij}(r, \theta) = \sigma_0 \left(\frac{J}{k_n r} \right)^{1/(n+1)} \tilde{\sigma}_{ij}(\theta, n), \quad \varepsilon_{ij}(r, \theta) = \alpha \varepsilon_0 \left(\frac{J}{k_n r} \right)^{n/(n+1)} \tilde{\varepsilon}_{ij}(\theta, n), \quad u_i(r, \theta) = \alpha \varepsilon_0 \left(\frac{J}{k_n r} \right)^{n/(n+1)} r^{1/(n+1)} \tilde{u}_i(\theta, n), \quad (1)$$

where J is the path-independent integral, I_n is the dimensionless J -integral (an integration constant depending on n), $k_n = \alpha \sigma_0 \varepsilon_0 I_n$. The asymptotic fields (1) are referred to as the Hutchinson-Rice-Rosengren (HRR) fields in the vicinity of the crack tip in power-law materials. The asymptotic solution (1) was sought in the separable form $\chi(r, \theta) = r^{\lambda+1} f(\theta)$.

where $\chi(r, \theta)$ is the Airy stress function: $\sigma_{\theta\theta} = \chi_{,rr}$, $\sigma_{rr} = \Delta\chi - \sigma_{\theta\theta}$, $\sigma_{r\theta} = -r^{-1} (r^{-1} \chi_{,\theta})_{,r}$. The resulting nonlinear ordinary differential equation following from the compatibility equation is homogeneous in $f(\theta)$:

$$\begin{aligned} & f_e^2 f'''' \left\{ (n-1) \left[(1-\lambda^2) f + f'' \right]^2 + f_e^2 \right\} + (n-1)(n-3) \left\{ \left[(1-\lambda^2) f + f'' \right] \left[(1-\lambda^2) f' + f''' \right] + 4\lambda^2 f f'' \right\} \left[(1-\lambda^2) f + f'' \right] + \\ & + (n-1) f_e^2 \left\{ \left[(1-\lambda^2) f' + f''' \right]^2 + \left[(1-\lambda^2) f + f'' \right] (1-\lambda^2) f'' + 4\lambda^2 (f''^2 + f f''') \right\} \left[(1-\lambda^2) f + f'' \right] + 2(n-1) f_e^2 \times \\ & \times \left\{ \left[(1-\lambda^2) f + f'' \right] \left[(1-\lambda^2) f' + f''' \right] + 4\lambda^2 f f'' \right\} \left[(1-\lambda^2) f' + f''' \right] - C_2 f_e^4 \left[(1-\lambda^2) f + f'' \right] + f_e^4 (1-\lambda^2) f'' + \\ & + C_1 (n-1) f_e^2 \left\{ \left[(1-\lambda^2) f + f'' \right] \left[(1-\lambda^2) f' + f''' \right] + 4\lambda^2 f f'' \right\} f' + C_1 f_e^4 f'' = 0, \quad f_e^2 = \left[(1-\lambda^2) f + f'' \right]^2 + 4\lambda^2 f'^2 \end{aligned} \quad (2)$$

where the following notations are adopted: $C_1 = 4\lambda[(\lambda-1)n+1]$, $C_2 = (\lambda-1)n[(\lambda-1)n+2]$.

The fourth order nonlinear differential equation (2) with traction-free boundary conditions

$$f(\theta = \pm\pi) = 0, \quad f'(\theta = \pm\pi) = 0 \quad (3)$$

defines a nonlinear eigenvalue problem in which λ is the eigenvalue and $f(\theta)$ is the corresponding eigenfunction. Thus, the eigenfunction expansion method results in the nonlinear eigenvalue problem: it is necessary to find eigenvalues leading to nontrivial solutions of Eq. (2) satisfying the boundary conditions (3). The eigenvalue corresponding to the HRR problem (1) is well known $\lambda = n/(n+1)$. The further development of NFM required analysis of eigenspectra and orders of singularity at a crack tip for power-law materials [5 – 8]. In [6] the necessity of introducing higher or lower order

singular terms to more correctly describe the asymptotic fields of crack tip is shown. The coordinate perturbation technique is employed to study the eigenspectra of creeping body. To attain eigensolutions a numerical scheme is worked out and the results obtained provide the information including the number of singularities, and their orders, as well as the angular distributions of stresses. The present study discusses different approaches to solve nonlinear eigenvalue problems arising in NFM for power-law materials. The main attention is paid to perturbation techniques to solve nonlinear eigenvalue problems (2), (3). Eqs. (2) and (3) form a nonlinear eigenvalue problem, where the unknown eigenvalue λ and the eigenfunction $f(\theta)$ depend on the boundary conditions and the hardening exponent. An analytical expression for the eigenvalues of the nonlinear equation can be derived by applying the perturbation method. For this purpose, the eigenvalue is split into $\lambda = \lambda_0 + \varepsilon$, where λ_0 refers to the “undisturbed” linear problem and ε is the deviation on account of the nonlinearity. The hardening exponent n and the stress function $f(\theta)$ are represented as power series

$$n = n_0 + \varepsilon n_1 + \varepsilon^2 n_2 + \varepsilon^3 n_3 + \dots = \sum_{j=0}^{\infty} \varepsilon^j n_j, \quad f(\theta) = f_0(\theta) + \varepsilon f_1(\theta) + \varepsilon^2 f_2(\theta) + \varepsilon^3 f_3(\theta) + \dots = \sum_{j=0}^{\infty} \varepsilon^j f_j(\theta),$$

where $n_0 = 1$ and $f_0(\theta)$ are referred to the linear solution. This method allows us to find the closed form solution.

Conclusions

Recent activity is surveyed in the analysis of crack-tip stress and strain fields for stationary and growing cracks in power-law materials. Some of the main subjects to further progress are discussed. In the study the detailed review of solutions for crack problems obtained for power law constitutive equations is presented. In NFM, one often needs to solve nonlinear differential equations about eigenfunction and eigenvalue. Many nonlinear eigenvalue equations have multiple solutions. Boundary value problems of these problems are not easy to gain by means of numerical techniques such as the shooting method. The perturbation and asymptotic approximations of nonlinear problems often break down as nonlinearity becomes strong [9, 10]. Therefore, they are only valid for weakly nonlinear ordinary differential equations and partial differential equations in general. The homotopy analysis method (HAM) is an analytic approximation method for highly nonlinear problems. Unlike perturbation techniques, the HAM is independent of any small/large physical parameters at all. The HAM provides us a convenient way to guarantee the convergence of solution series so that it is valid even if nonlinearity becomes rather strong. Thus, in fracture mechanics HAM may play a significant role in solving nonlinear eigenvalue problems. The book [9] shows the great potential and validity of the for highly nonlinear eigenvalue equations with multiple solutions and singularity. The HAM will provide us one of the promising approaches for nonlinear eigenvalue problem arising in fracture mechanics. The present review shows that asymptotic solutions of fracture mechanics problem will be connected with derivation of multi-term asymptotic series expansions for the crack-tip fields using effective computer algorithms and procedures [7,8]. The further development of NFM and continuum damage mechanics will evidently be connected with experimental determination of active damage accumulation zone in the vicinity of the crack tip via interference-optic methods [11], tomographic scanning techniques [12], acoustic emission methods [13] and, undoubtedly, with using highly accurate current perturbation theory and homotopy techniques [14].

Energy model of free vibrations and resonance in elastic bodies

Yuriy Alyushin

National University of Science and Technology MISIS, Moscow, 119991, Russia

Mechanics based on the concepts of space, time, and energy with a single elastic modulus and a new average stress scale that takes into account the energy of particles in the initial state is used to analyze the energy features of free vibrations and resonance. When describing motion in the Lagrange form, the elastic energy is determined by the quadratic invariant of the tensor, whose components are partial derivatives of Euler variables with respect to Lagrange variables. The increment of the invariant due to elastic deformation is represented as the sum of two scalars, one of which depends on the average value of the relative lengths of the edges of particles in the form of an infinitesimal parallelepiped, the second is equal to the standard deviation of these lengths from the average value. It is shown that each of the scalars can be represented as two dimensionless kinematic analogs of elastic energy that participate in the implementation of the law of conservation of energy in different ways. One part of the elastic energy passes into kinetic energy and participates in the implementation of the law of conservation of energy for the body as a whole, taking into account external forces. The second part is not converted to kinetic energy, leads to a change in the deformed state of the particles in accordance with the equations of motion, while maintaining the same level of the elastic energy of the particles used for this purpose. Kinematic analogues differ from the corresponding types of energy by a multiplier equal to the elastic modulus, which is directly proportional to the density and heat capacity of the material and inversely proportional to the volume compression coefficient. Transverse, torsional, and longitudinal vibrations are considered in free and resonant conditions. A mechanism for converting forced vibrations into their own after the termination of external influences is proposed. Resonance occurs due to the superposition of free and forced vibrations with the same or similar frequency with the formation of a new free wave on each cycle with an increase in the amplitude and energy involved in the vibrations, which occurs mainly due to internal sources, and not external forces.

Non-stationary dynamics of the sine-lattice consisting of three pendulums (trimer)

Margarita Kovaleva*, Leonid Manevitch*

*N.N. Semenov Federal Research Center for Chemical Physics, Russian Academy of Sciences,
Moscow, Russia

Summary. We present an analysis of both low- and high-amplitude oscillations of nonlinearly coupled trimer, even when the quasi-linear approximation cannot be applied. The described models are fundamental for many areas of Mechanics and Physics (paraffin crystals, DNA molecules etc.). We obtained the conditions of stability of basic stationary solutions corresponding to nonlinear normal modes (NNMs). Supposing the NNMs resonant interaction we introduce a “slow” time-scale which determines a characteristic time of the energy exchange between the pendulums. Introducing the angle variables, we reduce the considered phase space.

Introduction

Dynamics of coupled nonlinear oscillators attracts the growing interest of scientific community because of its fundamental meaning and various applications.

We will focus on the large-amplitude oscillations but not rotations of the pendulums. In current paper, in contrast to many works devoted to interacting nonlinear oscillators, non-linearity of both the pendulums and the coupling between them are not assumed to be small. Thus, research methods that involve quasi-linearity and the presence of a small parameter characterizing nonlinearity and/or coupling are not applicable. To overcome this difficulty a semi-inverse method was proposed [1]. Using this method and LPT concept the system of two identical linearly and strongly nonlinearly coupled pendulums was examined under different oscillation amplitudes [2]. Stationary and non-stationary transitions leading to a qualitative change in the dynamic behavior of the system were analytically described. This work continues the previous investigations for the more complex case, when the coupling between the pendulums cannot be assumed, and the number of degrees of freedom is equal three.

The model and asymptotic procedure

Hamiltonian of the system of three identic pendula coupled via cosine potential in the dimensionless form can be represented in the following form:

$$H = \sum_{j=1,2,3} \left(\frac{1}{2} \left(\frac{dq_j}{dt} \right)^2 + (1 - \cos(q_j)) \right) + \beta(1 - \cos(q_2 - q_3)) + \beta(1 - \cos(q_2 - q_1)) \quad (1)$$

We suppose that NNMs frequencies are close to each other, and the motion of the system happens with the frequency which is also close to those of Nonlinear Normal Modes (NNMs) of the system. The assumption of the closeness of the motion to the resonance with single frequency allows application of the semi-inverse approach, which was already used in our earlier works. Closeness to resonance allows us to introduce a small parameter and further apply a multi-scale procedure. In the slow time-scale we obtain a system of equations with new form of non-linearity:

$$\begin{aligned} i \frac{d}{d\tau_1} \varphi_1 + \mu \left(-\frac{\omega}{2} \varphi_1 + \frac{1}{\sqrt{2\omega}} J_1 \left(\sqrt{\frac{2}{\omega}} |\varphi_1| \right) \frac{\varphi_1}{|\varphi_1|} \right) + \frac{\beta_0}{\sqrt{2\omega}} J_1 \left(\sqrt{\frac{2}{\omega}} |\varphi_1 - \varphi_2| \right) \frac{\varphi_1 - \varphi_2}{|\varphi_1 - \varphi_2|} &= 0, \\ i \frac{d}{d\tau_1} \varphi_2 + \mu \left(-\frac{\omega}{2} \varphi_2 + \frac{1}{\sqrt{2\omega}} J_1 \left(\sqrt{\frac{2}{\omega}} |\varphi_2| \right) \frac{\varphi_2}{|\varphi_2|} \right) + \frac{\beta_0}{\sqrt{2\omega}} J_1 \left(\sqrt{\frac{2}{\omega}} |\varphi_2 - \varphi_1| \right) \frac{\varphi_2 - \varphi_1}{|\varphi_2 - \varphi_1|} + \frac{\beta_0}{\sqrt{2\omega}} J_1 \left(\sqrt{\frac{2}{\omega}} |\varphi_2 - \varphi_3| \right) \frac{\varphi_2 - \varphi_3}{|\varphi_2 - \varphi_3|} &= 0, \\ i \frac{d}{d\tau_1} \varphi_3 + \mu \left(-\frac{\omega}{2} \varphi_3 + \frac{1}{\sqrt{2\omega}} J_1 \left(\sqrt{\frac{2}{\omega}} |\varphi_3| \right) \frac{\varphi_3}{|\varphi_3|} \right) + \frac{\beta_0}{\sqrt{2\omega}} J_1 \left(\sqrt{\frac{2}{\omega}} |\varphi_3 - \varphi_2| \right) \frac{\varphi_3 - \varphi_2}{|\varphi_3 - \varphi_2|} &= 0, \end{aligned} \quad (2)$$

where J_1 is Bessel function of the first kind. Using such representation we can obtain analytical description of the NNMs' frequencies in the system. We see a very good agreement for the initial excitation up to $Q=9/10\pi$. As we expected the frequency of the oscillations decreases with the increase of the initial excitation (due to the ‘soft’ nonlinearity effect). We should also emphasize that our assumption on the closeness of the NNMs frequencies appears to be valid for a wide range of the parameters and initial conditions.

Non-stationary dynamics: Poincaré maps study

To proceed with the study of the phase space we intend to reduce the dimensionality of the model. Similarly to the system of two pendula [2] asymptotic system (2) possesses an additional integral of motion

$$X = \sum_{k=1}^3 |\varphi_k|^2$$

It allows us to introduce spherical coordinates

$$\begin{cases} \varphi_1 = \sqrt{X} \cos \theta \cos \varphi e^{i\delta_1} \\ \varphi_2 = \sqrt{X} \sin \theta e^{i\delta_2} \\ \varphi_3 = \sqrt{X} \cos \theta \sin \varphi e^{i\delta_3} \end{cases} \quad (3)$$

and using the fact that only the relative phases have physical meaning we reduce the system's dimensionality: $\Delta_{12} = \delta_1 - \delta_2$, $\Delta_{23} = \delta_2 - \delta_3$. The systems Hamiltonian:

$$H_{4D} = \mu \left(\frac{1}{4} Q^2 \omega^2 - J_0 (Q \sin \theta) - J_0 (Q \cos \theta \cos \varphi) - J_0 (Q \cos \theta \sin \varphi) \right) - \beta_0 J_0 (Q \sqrt{S_1}) - \beta_0 J_0 (Q \sqrt{S_2}). \quad (4)$$

System (8) is four-dimensional, and its dimensionality can be reduced using Hamiltonian (9), but the system remains non-integrable even in the slow time scale. However, the Poincaré sections analysis of the reduced system can be provided. The section plane was defined as $\theta = 1.53$, Δ_{23} was defined from (4) as $H = h(\beta_0)$.

Figure 1: NNMs of the asymptotic system (solid lines) and comparison with the numerical results of the full system (dotted lines)

We have constructed Poincaré maps for different values of the coupling parameter β . For low values of coupling the dynamics is regular; there are two stationary points on the map C_1 and C_2 , which correspond to quasiperiodic dynamical regimes with energy localization on one of the side-oscillators (see Fig 2a). If the coupling increases the chaotic regimes occupy the most of the phase space, then a new periodic regime C_3 of regular energy transport from one side-element to another appears in the chaotic region (see Fig 2b). We remind that this regime is called LPT, which is a phase trajectory that shows the possibility of the intensive regular energy exchange between the two edges of the short chain.

Figure 2: Time-evolutions of different regimes of system (4): $\theta=1.53$, $\epsilon=0.1$, $\mu=10$, a) $\beta_0 = 0.5$, initial conditions correspond to C_1 ; b) $\beta_0 = 2$, initial conditions correspond to C_3

Conclusions

We report the study of the non-stationary dynamics in the system of three pendulums coupled by cosine potential. In the earlier works the intensive beatings were reported in the systems with more than two degrees of freedom with the periodic boundary conditions but they characterize the energy exchange not between the coherent domains. Present work extends the phenomenon of the intensive periodic energy exchange between the two ends of the short oscillatory chains with more than two degrees of freedom. The physical meaning of the regime with excitation mostly localized on the side-element is similar to that of the discrete breather in the long chain of nonlinear oscillators

Period approximation for nonlinear oscillators with Carleman linearization

Csanád Árpád Hubay and Tamás Kalmár-Nagy

Department of Fluid Mechanics, Faculty of Mechanical Engineering, Budapest University of Technology and Economics, Budapest, Hungary

Summary. A method for period approximation of nonlinear oscillators using Carleman linearization is presented. The approximation of the amplitude-dependent period of a given nonlinear oscillator is calculated and compared to exact period values.

Introduction

Calculation of the period of a nonlinear oscillator is an important engineering problem. In this paper, a versatile tool, the so-called Carleman linearization [1] is used to obtain the solutions of nonlinear oscillator $\ddot{x} + f(x, \dot{x}) = 0$ and its exact amplitude-dependent period is approximated. An example of such nonlinear oscillator is

$$\ddot{x} + (1 + \dot{x}^2)x = 0, \quad x(0) = A, \quad \dot{x}(0) = 0. \quad (1)$$

Mickens et al. [2] derived the formula of the exact period of the oscillator (1):

$$T_{exact}(A) = 4A \int_0^1 \frac{dz}{\sqrt{\exp(A^2(1 - z^2)) - 1}}. \quad (2)$$

An approximation of the exact period in case of small values of A is given in [3] as

$$T_{approx}(A) \approx 2\pi \left(1 - \frac{1}{8}A^2 + \frac{1}{256}A^4 + \frac{5}{6144}A^6 - \frac{7}{262144}A^8 + \dots \right). \quad (3)$$

Small and large amplitude periodic orbits of Eq. (1) were investigated by Kalmár-Nagy and Erneux in [4].

Carleman linearization and period approximation

Eq. (1) can be written as

$$\begin{aligned} \dot{x}_1 &= x_2, \\ \dot{x}_2 &= -(1 + x_2^2)x_1. \end{aligned} \quad (4)$$

By introducing the notation

$$\mathbf{x}^{[j]} = (x_1^j, x_1^{j-1}x_2, x_1^{j-2}x_2^2, \dots, x_1^2x_2^{j-2}, x_1x_2^{j-1}, x_2^j)^T, \quad j = 1, \dots, n, \quad (5)$$

and applying Carleman linearization [1] Eq. (4) is recast as

$$\underbrace{\frac{d}{dt} \begin{pmatrix} \mathbf{x}^{[1]} \\ \mathbf{x}^{[2]} \\ \mathbf{x}^{[3]} \\ \vdots \\ \mathbf{x}^{[n-2]} \\ \mathbf{x}^{[n-1]} \\ \mathbf{x}^{[n]} \end{pmatrix}}_{\dot{\mathbf{y}}_n} = \underbrace{\begin{pmatrix} \mathbf{B}_{1,1} & \mathbf{0} & \mathbf{B}_{1,3} & \dots & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{B}_{2,2} & \mathbf{0} & \ddots & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \dots & \mathbf{B}_{n-2,n-2} & \mathbf{0} & \mathbf{B}_{n-2,n} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & \mathbf{B}_{n-1,n-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & \mathbf{0} & \mathbf{B}_{n,n} \end{pmatrix}}_{\mathbf{C}_n} \underbrace{\begin{pmatrix} \mathbf{x}^{[1]} \\ \mathbf{x}^{[2]} \\ \mathbf{x}^{[3]} \\ \vdots \\ \mathbf{x}^{[n-2]} \\ \mathbf{x}^{[n-1]} \\ \mathbf{x}^{[n]} \end{pmatrix}}_{\mathbf{y}_n}, \quad (6)$$

$$\mathbf{y}_0(A) = (A, 0, A^2, 0, 0, A^3, 0, 0, 0, \dots, A^n, \dots, 0)^T,$$

where \mathbf{C}_n denotes the Carleman matrix of order n and \mathbf{y}_0 is the vector of initial conditions. The matrices $\mathbf{B}_{j,j}$, $j = 1, \dots, n$ and $\mathbf{B}_{k,k+2}$, $k = 1, \dots, n-2$ are constructed as follows

$$\mathbf{B}_{j,j} = \begin{pmatrix} 0 & -j & & & \\ 1 & 0 & -j+1 & & \mathbf{0} \\ & 2 & 0 & \dots & \\ & & \dots & 0 & -2 \\ \mathbf{0} & & & j-1 & 0 & -1 \\ & & & & j & 0 \end{pmatrix}, \quad \mathbf{B}_{k,k+2} = \begin{pmatrix} 0 & 0 & 0 & 0 & \dots & 0 & 0 \\ 0 & 0 & -1 & 0 & \dots & 0 & 0 \\ 0 & 0 & 0 & -2 & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \dots & -k & 0 \end{pmatrix}. \quad (7)$$

The approximation of the solution of Eq. (4) is written as

$$\hat{x}_1(t) = \mathbf{e}_1^T e^{\mathbf{C}_n t} \mathbf{y}_0(A), \quad \hat{x}_2(t) = \mathbf{e}_2^T e^{\mathbf{C}_n t} \mathbf{y}_0(A), \quad (8)$$

where e_1 and e_2 are standard basis vectors. The approximate solution $\hat{x}_2(t)$ can be written as power series of A , i.e.,

$$\hat{x}_2(t) = \sum_{k=1}^n \tilde{x}_{2,k}(t) \frac{A^k}{k!}. \quad (9)$$

The period $T(A)$ of system (4) is approximated based on [5] as

$$T(A) = 2\pi + \Delta T(A) = 2\pi + \sum_{k=1}^n A^k \tilde{T}_k. \quad (10)$$

The coefficients $\tilde{x}_{2,k}(t)$ in Eq. (9) at the period $T(A)$ are expressed as

$$\tilde{x}_{2,k}(T(A)) = \tilde{x}_{2,k}(2\pi + \Delta T(A)) = \tilde{x}_{2,k}(2\pi) + \sum_{m=1}^n \tilde{x}_{2,k}^{(m)}(2\pi) \frac{\Delta T(A)^m}{m!}, \quad (11)$$

where $\tilde{x}_{2,k}^{(m)}$ denotes the m th derivative. Since Eq. (4) is a conservative system [4], $\hat{x}_2(T(A)) = 0$ must hold. Balancing the terms

$$\begin{aligned} A : 0 &= \tilde{x}_{2,1}(2\pi), \\ A^2 : 0 &= \tilde{x}_{2,2}(2\pi) + \tilde{x}_{2,1}'(2\pi) \tilde{T}_1, \\ A^3 : 0 &= \tilde{x}_{2,3}(2\pi) + \tilde{x}_{2,2}'(2\pi) \tilde{T}_1 + \tilde{x}_{2,1}''(2\pi) \tilde{T}_2 + \tilde{x}_{2,1}'(2\pi) \frac{\tilde{T}_1^2}{2!}, \\ &\vdots \end{aligned} \quad (12)$$

where the primes mean derivation. System (12) is solved for the unknown \tilde{T}_k 's.

Using the Carleman linearization of order $n = 9$ of system (4) the approximation of the period reads as

$$T(A) \approx 2\pi \left(1 - \frac{1}{8}A^2 + \frac{1}{256}A^4 + \frac{5}{6144}A^6 - \frac{7}{262144}A^8 \right), \quad (13)$$

the same as in Eq. (3). The following table shows some numerical results in case of $n = 5, 7, 9$ order Carleman matrices.

A	$T_{exact}(A)$	$n = 5$		$n = 7$		$n = 9$	
		$T(A)$	Rel. error [%]	$T(A)$	Rel. error [%]	$T(A)$	Rel. error [%]
0.01	6.2831	6.2831		6.2831		6.2831	
0.1	6.2753	6.2753		6.2753		6.2753	
1	5.5272	5.5223	0.088	5.5274	0.004	5.5273	0.001
1.5	4.6903	4.6403	1.065	4.6985	0.176	4.6942	0.085
2	3.7613	3.5343	6.036	3.8615	2.644	3.8186	1.522
2.2	3.4131	3.0568	10.44	3.6366	6.547	3.5445	3.850

Conclusions

A new way of calculation for the period of a nonlinear oscillator was introduced. Approximate period values of a given oscillator were calculated and compared to exact ones. We conclude, in the case of small amplitudes, Carleman linearization can be used for approximation of the period of a nonlinear oscillator.

Time integration based stability calculation for delayed periodic system with linear time complexity

Daniel Bachrathy*, Kristof Nagy*

* *MTA-BME Lendület Machine Tool Research Group, Department of Applied Mechanics, Budapest University of Technology and Economics*

Summary. In this work, the implicit subspace iteration method is combined with direct time integration of linear periodic delay differential equations. The linear time complexity of the proposed method is shown for different DDE solvers with higher order convergence. The proposed method is really efficient for dynamical system with large time period.

Semi-Discretization Method

There have been many algorithms [1, 5, 6, 7] developed during the last 20 years for systems where the time-delay effect is coupled with parametric excitation. The semi-discretization method (SDM) is one of the efficient ways to analyze stability [1, 2]. The basic idea of the SDM is the numerical discretization of the delayed terms only above the delay-time interval. Consequently, the governing DDE becomes an ordinary differential equation (ODE) that can be solved in closed form in linear cases for each time step within these discrete delay-intervals, and a linear discrete map is constructed that describes the connection of the discretized state as a large vector over the discrete time instants within the delay interval. The size of this mapping depends on the resolution of the delay discretization.

If explicit time-periodicity also appears due to the parametric excitation, the time-periodic coefficients (or even the delays) should also be discretized in time over the time period, and the above procedure leads to different linear mappings at each sampled instant of the time period:

$$\mathbf{z}_{i+1} = \mathbf{G}_i \mathbf{z}_i \quad i = 0, 1, \dots, n-1 \quad (1)$$

Here, \mathbf{G}_i denotes the coefficient matrix connecting states \mathbf{z}_i and \mathbf{z}_{i+1} , which are the vectors of the discretized states sampled at the discrete time intervals at subsequent time instants. A discrete map can be defined between the initial delay-discrete state \mathbf{z}_0 and the one \mathbf{z}_m a principal period later:

$$\mathbf{z}_m = \mathbf{G}_{m-1} \dots \mathbf{G}_2 \mathbf{G}_1 \mathbf{G}_0 \mathbf{z}_0 = \mathbf{\Phi} \mathbf{z}_0, \quad (2)$$

where the transition matrix $\mathbf{\Phi}$ is a finite-dimensional approximation of the infinite-dimensional monodromy operator. Thus, the stability analysis is reduced to the problem whether the absolute values of all the eigenvalues of $\mathbf{\Phi}$ are less than one: $|\mu_i| < 1$. In order to improve numerical accuracy, the delay resolution, the order of semi-discretization, and the time periodicity resolution can be increased.

Implicit Subspace Iteration

Consider the general eigenvalue problem [4] $\mathbf{\Phi} \mathbf{S} = \mathbf{S} \mathbf{\mu}$, where $\mathbf{\Phi}$ is an $\mathbb{R}^{n \times n}$ square matrix, $\mathbf{\mu}$ is a diagonal matrix of size $\mathbb{R}^{n \times n}$ containing the eigenvalues of $\mathbf{\Phi}$ on its main diagonal, and matrix \mathbf{S} of size $\mathbb{R}^{n \times n}$ consists of the eigenvectors of $\mathbf{\Phi}$ in its columns. A set of $N_s < n$ dominant eigenvectors corresponding to the first N_s eigenvalues of the largest absolute values can be approximated in an iterative way. Let \mathbf{S}_j of size $\mathbb{R}^{n \times N_s}$ denote the matrix of the N_s dominant eigenvectors after the j th iteration step. Starting from a random set of initial conditions \mathbf{S}_0 and taking an iteration, a new set \mathbf{V}_j of size $\mathbb{R}^{n \times N_s}$ can be calculated according to the following iteration [4]

$$\mathbf{V}_j = \mathbf{\Phi} \mathbf{S}_j \quad (3)$$

$$\mathbf{V}_j \approx \mathbf{S}_j \mathbf{H}_j \rightarrow \mathbf{H}_j = (\mathbf{S}_j^H \mathbf{S}_j)^{-1} \mathbf{S}_j^H \mathbf{V}_j \quad (4)$$

$$\mathbf{H}_j = \mathbf{G}_j \mathbf{\lambda}_j \mathbf{G}_j^{-1} \quad (5)$$

$$\mathbf{S}_{j+1} = \mathbf{V}_j \mathbf{G}_j \quad (6)$$

where \mathbf{G}_j is the matrix formed by the eigenvectors of \mathbf{H}_j and $\mathbf{\lambda}_j$ is a diagonal matrix of eigenvalues of \mathbf{H}_j . Note, that in a numerical implementation, the approximated eigenvectors should be normalized after each iteration steps.

If \mathbf{S}_j is obtained after a sufficient number of iteration steps, it will converge to the dominant eigenvectors, and the basis formed by the column vectors in both \mathbf{S}_j and \mathbf{V}_j span approximately the same space. Therefore, an approximate matrix \mathbf{H}_j of size $\mathbb{R}^{N_s \times N_s}$ connecting \mathbf{S}_j and \mathbf{V}_j can be obtained using a pseudo-inverse calculation from the relation. After several iteration steps, the eigenvalues of \mathbf{H}_j provide a good approximation for the dominant eigenvalues of $\mathbf{\Phi}$. This way, it is enough to compute the eigenvalues of a significantly reduced N_s -sized matrix \mathbf{H}_j instead of the large n -sized matrix $\mathbf{\Phi}$. The details of this iteration process can be found in [3, 4].

In this form, the Implicit Subspace Iteration iteration is just an iterative method to find the eigenvalues of a known matrix $\mathbf{\Phi}$, however, the calculation of this matrix itself is the most time consuming operation if the time period is long $m \gg n$.

Figure 1: Convergence of the spectral radius for the traditional SDM and for Implicit Sub Space Iteration combined with time integration with Explicit Euler (EE) method and higher-order Runge-Kutta methods

Due to the m number of matrix multiplication in Eq.(2), the time complexity is proportional to $\mathcal{O}(mn^3)$, if a sparse representation of \mathbf{G}_i is used then it can tend to $\mathcal{O}(mn^2)$ [8, 9]. To decrease the computational need one can reduce the stepsize (m and n together) and increase the order of semi-discretization, however, it is complicated to increase it above 2 [2].

Direct time integration

It is also possible to determine the mapping in Eq.(3) without calculating the whole matrix Φ . The vector \mathbf{V}_j can be calculated directly by means of the time integration of the equations of motion of the given system with $\mathcal{O}(m)$ time complexity. Thus, the advantage of implementing the ISIM is that the transition matrix Φ does not have to be calculated. During the time integration process, one can use the same approximation as in the SDM (constant coefficients within the time step), then the final results for the eigenvalues will be identical.

However, if we apply time integration, then any advanced higher-order fixed-time-step computation scheme can be used to increase the rate of convergence of the eigenvalues, while the time complexity will be the same. This is presented for the well-known delayed Mathieu equation:

$$\ddot{x}(t) + \kappa \dot{x}(t) + (\delta + \epsilon \cos(\omega t))x = bx(t - \tau). \quad (7)$$

In Fig.1 the error of the largest multiplier is shown for parameters $\kappa = 0.01, \delta = 5, \epsilon = 1, b = 1, \tau = 2\pi, \omega = 0.01$ (note, that $m = 100n$). The reference values for the eigenvalues is computed of $n = 2^{15}$.

Conclusions

The combination of the IISI with fixed-step-time-integration have only a linear time complexity and the convergence rate of the eigenvalues is the same as the order of the integration scheme. The next research goal is to implement integrators with variable step size, which will have a great advantage in the case when the change of the coefficients of the governing equation are not smooth, however, the non-uniform steps size leads to a difficulty in the computation of \mathbf{H}_j in Eq.(4).

Summary. In this work, we investigate the uni-directional wave propagation in elastic locally resonant mechanical metamaterials with inerter elements, where mass and stiffness properties are simultaneously modulated as periodic functions of time. Time-modulated properties of inerter elements are adopted in order to highlight the effect of time-dependent inertia amplification on mass properties. By considering the Bloch theorem and Fourier expansion, the system of Hill equations is reduced to the eigenvalue problem that gives dispersion relations with asymmetric frequency band structures.

Formulation of the problem

Let us consider the mass-spring-inerter systems representing the locally resonant mechanical metamaterial (LRMM) lattice as shown in Figure 1. The model consists of the periodically repeated mass-spring-inerter blocks connected into an infinite chain. The local resonators are represented by small inner masses inside the host outer masses. The local resonators are introduced into the lattice due to the well know properties of generating low-frequency band gaps in the metamaterial structures. Bloch wave propagation analysis is performed for the corresponding unit cell by applying the proper periodic boundary conditions. Figure 1 illustrates the n -th unit cell of the LRMM lattice, which is bounded by red dashed rectangle and it consists of three identical mass-in-mass subsystems connected through time-modulated springs and inerters. Moreover, each mass-in-mass subsystem is connected to the ground through pairs of time-modulated springs and inerters. Note that internal resonators are also connected to the host mass through a time-modulated spring.

Figure 1: The unit cell of the inerter-based LRMM lattice.

Mathematical model

The governing equations of the locally resonant lattice with time varying stiffness and inerter properties for the n -th unit cell (Figure 1) can be expressed, in a general case, as a system of ordinary differential equations with time dependent coefficients, known as Hill equations [1], as follows

$$M\ddot{u}_r^n + k_{r-1}(t)(u_r^n - u_{r-1}^n) + k_r(t)(u_r^n - u_{r+1}^n) + k_{gr}(t)u_r^n + k_{Rr}(t)(u_r^n - v_r^n) + B_{r-1}(t)(\ddot{u}_r^n - \ddot{u}_{r-1}^n) + \quad (1)$$

$$B_r(t)(\ddot{u}_r^n - \ddot{u}_{r+1}^n) + B_{gr}(t)\ddot{u}_r^n + \dot{B}_{r-1}(t)(\dot{u}_r^n - \dot{u}_{r-1}^n) + \dot{B}_r(t)(\dot{u}_r^n - \dot{u}_{r+1}^n) + \dot{B}_{gr}(t)\dot{u}_r^n = 0, \quad (2)$$

$$m\ddot{v}_r^n + k_{Rr}(t)(v_r^n - u_r^n) = 0,$$

where $r = 1, \dots, R$, R is the number of masses in the n -th unit cell.

In order to study the uni-directional wave propagation in the time-modulated one-dimensional lattice structure we limit our analysis to the case when $R = 3$. The differential equation (1) describes the motion of the r -th point mass in the n -th unit cell, and differential equation (2) describes the motion of the internal resonator.

Solution procedures

Plane wave method is applied by considering the Fourier series expansion of displacement vector and time-dependent mass and stiffness matrices. We assume that mass and stiffness matrices are modulated with the velocity $v_m = \frac{\lambda_m}{T_m}$. The terms λ_m and T_m are related to the spatial wave length and temporal period of modulation, respectively. By considering the inverse method explained in [2], the plane wave solution of the time-varying lattice model presented in equations (1) and (2) can be assumed in Bloch-Fourier form [3] as

$$\mathbf{u}_n(t) = e^{i(-n\mu + \omega t)} \sum_{p=-\infty}^{\infty} \mathbf{a}_p e^{ip\omega_m t}, \quad (3)$$

where $\mathbf{a}(t) = \mathbf{a}(t + T_m)$ is the vector of periodic amplitude function in time and $\mu = \lambda_m \kappa$ is the non-dimensional wavenumber. Considering the truncated expansion from equation (3), the system of differential equations is reduced to

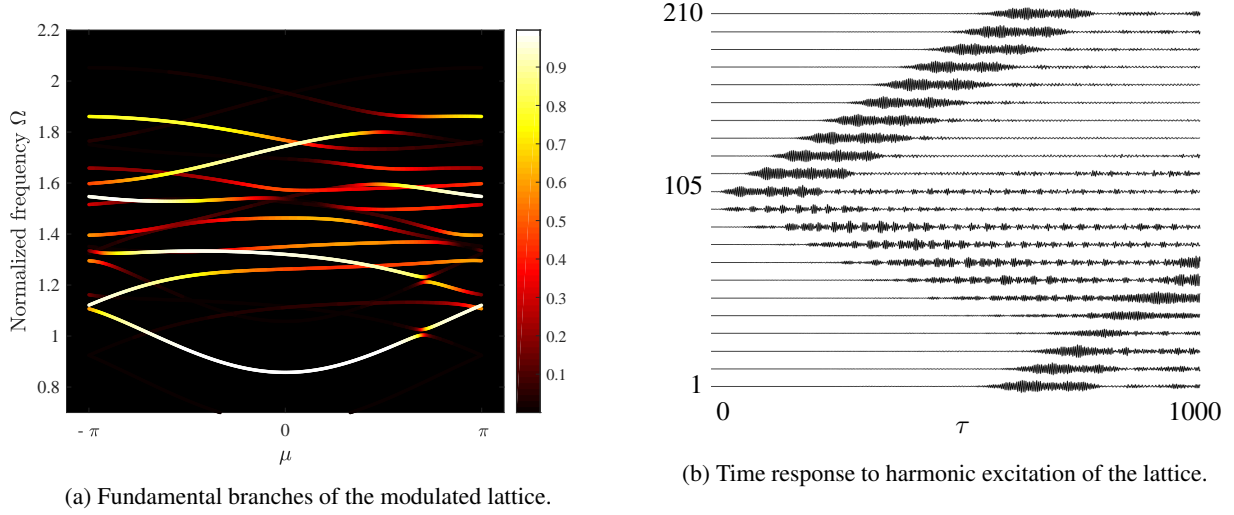

Figure 2: The local resonant structure with time varying inerter and stiffness properties.

the system of $(R + N_r)(2P + 1)$ algebraic equations. Therefore, by taking the values of $P = 1$ and $Q = 2$ in equation (3) the system (1) is reduced to the following quadratic eigenvalue problem

$$(\Omega^2 \mathbf{A}_1 + \Omega \mathbf{A}_2 + \mathbf{A}_3) \mathbf{a} = \mathbf{0}, \quad (4)$$

where $\Omega = \omega/\omega_0$ and \mathbf{a} are eigenvalues and eigenvectors of the system, respectively.

Numerical results

The aim of the numerical study is to verify the applicability of the above proposed method based on the Bloch-Fourier expansion and to perform the dispersion analysis of the time-modulated periodic elastic lattice with local resonators given in the form of one-dimensional chain with inerters (Figure 2a). Moreover, the uni-directional wave propagation is observed based on the solution of the system of equations using the finite difference method for a specified excitation frequency (Figure 2b).

By considering the simultaneous time-modulation of stiffness and inertia properties, the dispersion characteristic of the lattice is presented in Figure 2a. The diagrams show many crossings and folding of dispersion branches within, and at the edges of the first Brillouin zone. The fundamental branches are obtained by using the weighting and threshold process. Moreover, the asymmetric band gaps can be observed for the presented configuration, from which we can find specter of frequencies which can lead to asymmetric or uni-directional wave propagation. Finally, to demonstrate the uni-directional wave propagation we apply the harmonic excitation on the center mass of the finite chain with the picked frequency $\Omega = 1.7$. The finite chain has 70 unit cells and Born-von Karman boundary conditions are applied at the ends of the chain. We observe only the displacement amplitudes of outer masses of the chain. The spatial profile in Figure 2b indicates one way traveling of the primary wave in the positive direction $+x$. However, it can be noticed that a small portion of wave energy is traveling in the opposite direction, which can be attributed to the fact that the corresponding asymmetric band gap is influenced by internal resonators of the LRMM lattice.

Conclusions

In this study, we numerically demonstrate how uni-directional wave propagation can occur in time-modulated elastic and locally resonant metamaterial lattices with inerters. We successfully included inerter elements in the lattice structure demonstrating the shift of dispersion frequencies to lower values due to the inertia amplification effect. The Bloch-Fourier based procedure is suggested to analyze the dispersion characteristics of systems with simultaneous time-modulation of stiffness and mass properties. Dispersion characteristic is used to confirm the existence of asymmetric band gaps and then applied as a basis for transient analysis and demonstration of uni-directional wave propagation.

Energy flow characteristics of periodical orbits of nonlinear dynamical systems

Jing Tang Xing

Maritime Engineering, Faculty of Engineering & Physical Sciences, Boldrewood Campus,
University of Southampton, Southampton SO16 7QF, UK

Summary. Based on energy flow theory, it is revealed that a necessary sufficient condition for nonlinear dynamical systems (NDS) $\dot{\mathbf{y}} = \mathbf{f}(\mathbf{y}, t)$ to have periodical orbits is that there exist a non-zero spin matrix and one closed orbit with a corresponding period T , along which the time averaged flows of generalised potential energy (GPE) and generalised kinetic energy (GKE) vanish. For autonomous systems, a necessary condition to have periodical orbits is the energy flow characteristic factors (EFCFs) must not be semi-positive or semi-negative. Three examples are given to support the above revealed characteristics.

Keywords: Nonlinear dynamics, Periodical orbits, Energy flow matrices, Spin matrices, Generalised potential / kinetic energies.

Introduction

NDS investigated herein are generally sufficient to regard a second order differential equation with its initial conditions in a non-dimensional form, as discussed by [1-5], which can be transformed into the first order differential equation

$$d\mathbf{y}/dt \equiv \dot{\mathbf{y}} = \mathbf{f}(t, \mathbf{y}), \quad \mathbf{y}(0) = \mathbf{y}_0. \quad (1)$$

We consider that $\mathbf{y} = \mathbf{y}(t) \in R^n$ is a vector valued function of an independent variable $t \in I = (t_1, t_2) \subseteq R$ and $\mathbf{f}: U \rightarrow R^n$ is a smooth function of variable t and vector \mathbf{y} defined on some subset $U \subseteq R^n$, an n -dimensional phase space, and we seek a solution $\boldsymbol{\varphi}(\mathbf{y}_0, t)$ such that

$$\boldsymbol{\varphi}(\mathbf{y}_0, 0) = \mathbf{y}_0. \quad (2)$$

The solution $\boldsymbol{\varphi}(\mathbf{y}_0, \cdot): I \rightarrow R^n$ defines a solution curve, trajectory or orbit of Eq.1 based at \mathbf{y}_0 as shown by Fig. 1(a). According to the basic local existence and uniqueness theorem [6], there exist no intersections of the trajectories of Eq.1 in the solution space except at its fixed points. The solution curves $\boldsymbol{\varphi}_t(U)$ generate the flow shown by Fig. 1(b). To investigate the behaviors of NDS, Xing [5] developed an energy flow theory, which has discovered that i) GPE automatically plays a role of Lyapunov function for stability at fixed points of NDS, ii) generalised energy conservation law of chaotic motions [5,7], iii) behaviors of friction-induced vibrations [8]. This paper aims to tackle the periodical solutions of NDS to reveal its energy flow characteristics.

Figure 1: (a) a solution curve $\boldsymbol{\varphi}_t(\mathbf{y}_0)$ with its energy flow curve $E_t(\mathbf{y}_0)$, of which their tangent vectors at a point \mathbf{y} are $\dot{\mathbf{y}} = \mathbf{f}$ and \dot{E} , respectively; (b) the flow $\boldsymbol{\varphi}_t(U)$ and the energy flow $E_t(U)$ in R^n (Xing [5, 7]).

Fundamentals of energy flow analysis

Energy flow variables, matrices, and equations

In the energy flow theory, the following energy flow variables based on Eq.1 in phase space are defined,

$$\text{GPE: } E = 0.5\mathbf{y}^T \mathbf{y}; \quad \text{GKE: } K = 0.5\dot{\mathbf{y}}^T \dot{\mathbf{y}}; \quad \text{Force power: } P = \mathbf{y}^T \mathbf{f}, \quad (3)$$

of which the time averaged GPE and GKE as well as the time averaged GPE-flow (GPEF) and the time averaged GKE-flow (GKEF) during a period $(0, T)$ are respectively defined by

$$\begin{aligned} \langle E \rangle &= \int_0^T 0.5\mathbf{y}^T \mathbf{y} dt / T, & \langle K \rangle &= \int_0^T 0.5\dot{\mathbf{y}}^T \dot{\mathbf{y}} dt / T, & \langle P \rangle &= \int_0^T \mathbf{y}^T \mathbf{f} dt / T, \\ \langle \dot{E} \rangle &= \int_0^T \dot{E} dt / T = [E(T) - E(0)] / T = \int_0^T P dt / T = \langle P \rangle, \end{aligned} \quad (4)$$

$$\langle \dot{K} \rangle = \int_0^T \dot{K} dt / T = [K(T) - K(0)] / T = \int_0^T \dot{\mathbf{y}}^T \dot{\mathbf{f}} dt / T.$$

The corresponding energy flow equilibrium equations take the forms

$$\begin{aligned} \dot{E} &= P, \quad E_0 = 0.5 \mathbf{y}_0^T \mathbf{y}_0, \quad \mathbf{J} = \partial \mathbf{f} / \partial \mathbf{y}^T, \quad \mathbf{E} = 0.5(\mathbf{J} + \mathbf{J}^T), \quad \mathbf{U} = 0.5(\mathbf{J} - \mathbf{J}^T), \\ \dot{K} &= \dot{\mathbf{y}}^T \dot{\mathbf{y}} = \dot{\mathbf{y}}^T \dot{\mathbf{f}} = \dot{\mathbf{y}}^T (\partial \mathbf{f} / \partial t + \mathbf{J} \dot{\mathbf{y}}) = \dot{\mathbf{y}}^T \partial \mathbf{f} / \partial t + \dot{\mathbf{y}}^T \mathbf{E} \dot{\mathbf{y}} = \partial K / \partial t + \dot{\mathbf{y}}^T \mathbf{E} \dot{\mathbf{y}}, \end{aligned} \quad (5)$$

where \mathbf{J} is *Jacobian* matrix, the partial derivative of vector \mathbf{f} with respect to vector \mathbf{y}^T [5]. For autonomous NDS from Eq. 5 we have

$$\dot{\mathbf{y}} = \mathbf{f}(\mathbf{y}), \quad \dot{K} = \dot{\mathbf{y}}^T \mathbf{E} \dot{\mathbf{y}}, \quad \langle \dot{K} \rangle = \frac{1}{T} \int_0^T \dot{\mathbf{y}}^T \mathbf{E} \dot{\mathbf{y}} dt, \quad (6)$$

since $\partial K / \partial t = 0$. Here \mathbf{E} is a real symmetrical *energy flow matrix* while \mathbf{U} is a real skew-symmetrical *spin matrix*, so that $\mathbf{y}^T \mathbf{U} \mathbf{y} = \mathbf{0} = \dot{\mathbf{y}}^T \mathbf{U} \dot{\mathbf{y}}$. Geometrically, GPE relates the position \mathbf{y} of a point in phase space, while GKE involves the velocity or tangent vector $\dot{\mathbf{y}}$ of solution curve, and the generalised force power P gives the energy flow, the time change rate of GPE.

Energy flow characteristic factors

The energy flow matrix \mathbf{E} is a real symmetrical matrix, of which the eigenvalues and the corresponding eigenvectors are real, and its characteristic equation

$$\mathbf{E} \boldsymbol{\varepsilon} = \lambda \boldsymbol{\varepsilon}, \quad |\mathbf{E} - \lambda \mathbf{I}| = 0, \quad (7)$$

can give the eigenvalue λ_l and its corresponding eigenvector $\boldsymbol{\Psi}_l$ satisfying the orthogonal relationships

$$\boldsymbol{\Psi}^T \mathbf{E} \boldsymbol{\Psi} = \boldsymbol{\Lambda} = \text{diag}(\lambda_l), \quad \boldsymbol{\Psi}^T \boldsymbol{\Psi} = \mathbf{I}, \quad \boldsymbol{\Psi} = [\boldsymbol{\Psi}_1 \quad \boldsymbol{\Psi}_2 \quad \cdots \quad \boldsymbol{\Psi}_n]. \quad (8)$$

Normally, the eigenvectors with different eigenvalues span a complete subspace in the neighbor of the point where the matrix \mathbf{E} defined, so that the vector $\boldsymbol{\varepsilon}$ can be represented as

$$\boldsymbol{\varepsilon} = \boldsymbol{\Psi} \boldsymbol{\zeta}, \quad (9)$$

which, when substituted into the term $\boldsymbol{\varepsilon}^T \mathbf{E} \boldsymbol{\varepsilon}$ and by using the orthogonal relationships in Eq.8, gives

$$\boldsymbol{\varepsilon}^T \mathbf{E} \boldsymbol{\varepsilon} = \boldsymbol{\zeta}^T \boldsymbol{\Psi}^T \mathbf{E} \boldsymbol{\Psi} \boldsymbol{\zeta} = \boldsymbol{\zeta}^T \boldsymbol{\Lambda} \boldsymbol{\zeta} = \sum_{l=1}^n \lambda_l \zeta_l^2. \quad (10)$$

This result implies that the value of $\boldsymbol{\varepsilon}^T \mathbf{E} \boldsymbol{\varepsilon}$ about a point is totally determined by the eigenvalues and eigenvectors of energy flow matrix. We respectively call λ_l and $\boldsymbol{\Psi}_l$ as the energy flow characteristic factors (EFCFs) and the energy flow characteristic vectors (EFCVs) of NDS.

Spin matrix

The spin matrix \mathbf{U} is a real skew-symmetric matrix and therefore its non-zero eigenvalues κ_l must be conjugate purely imaginaries with the complex eigenvector matrix \mathbf{Y} satisfying the following orthogonal relationships

$$\mathbf{Y}^{*T} \mathbf{U} \mathbf{Y} = \text{diag}(\kappa_l), \quad \mathbf{Y}^{*T} \mathbf{Y} = \mathbf{I}, \quad (11)$$

Here $*$ denotes a conjugate of complex number.

Curl of a vector field

The curl of a vector field \mathbf{f} , denoted by $\text{curl} \mathbf{f}$, or $\nabla \times \mathbf{f}$, at a point O is defined in terms of its projection onto various lines through the point. As shown in Fig.2, if \mathbf{v} is a unit vector, the projection of the $\text{curl} \mathbf{f}$ onto \mathbf{v} is defined as a limited value of a closed-curve integral in a plane orthogonal to \mathbf{v} , divided by the area A enclosed by the closed curve. Here, the path C of integration is constructed around the point O , so that, when Eqs. 1 and 3 are introduced, we have

$$(\nabla \times \mathbf{f})_{\mathbf{v}} = \lim_{A \rightarrow 0} \left\{ \oint_C \mathbf{f} \cdot d\mathbf{y} / A \right\} = \lim_{A \rightarrow 0} \left\{ \oint_C \dot{\mathbf{y}} \cdot \dot{\mathbf{y}} / A \right\} = \lim_{A \rightarrow 0} \left\{ \oint_C 2K dt / A \right\}. \quad (12)$$

Figure 2: Circulation integration of path C with its positive direction obeying the right-hand rule to define the curl of vector field \mathbf{f} .

For 3-dimensional space, the curl \mathbf{f} can be denoted in a tensor form

$$(\nabla \times \mathbf{f})_i = e_{ijk} f_{k,j}, \quad (13)$$

where e_{ijk} is the permutation tensor [9,10]. The curl \mathbf{f} is a dual vector of a skew-symmetrical matrix \mathbf{U} , spin matrix, satisfying the following relationship

$$(\mathbf{U})_{ij} = U_{ij} = -0.5 e_{ijk} (\nabla \times \mathbf{f})_k = -0.5 e_{ijk} e_{krs} f_{s,r} = -0.5 (\delta_{ir} \delta_{js} - \delta_{is} \delta_{jr}) f_{s,r} = 0.5 (f_{i,j} - f_{j,i}) = 0.5 (\mathbf{J} - \mathbf{J}^T)_{ij}. \quad (14)$$

Periodical orbits

For NDS, a periodical orbit is defined as a closed path governed by Eq. 1 in phase space, along which the phase point $\mathbf{y}(t)$ with its velocity $\dot{\mathbf{y}}(t)$, starting from a position $\mathbf{y}(\hat{t})$ at time \hat{t} , moves to the same position $\mathbf{y}(\hat{t} + T) = \mathbf{y}(\hat{t})$ with the same velocity $\dot{\mathbf{y}}(\hat{t} + T) = \dot{\mathbf{y}}(\hat{t})$ after a period T , and the motion repeats again, such as $\hat{t} = 0$ shown in Fig.3. If we assume that dS denotes a differential line element with its unit outside normal vector \mathbf{v}_i and unit tangent vector τ_i at a point on the closed curve in Fig.3, so that

$$\tau dS = \dot{\mathbf{y}} |d\mathbf{y}| / |\dot{\mathbf{y}}| = \dot{\mathbf{y}} |\dot{\mathbf{y}} dt| / |\dot{\mathbf{y}}| = \dot{\mathbf{y}} dt, \quad (15)$$

based on which the integrals along the curve in the next section hold.

Figure 3: The periodical orbit and the unit normal / tangent vectors of line element dS on orbit.

This definition implies that for a periodical orbit, its position vector should be a periodical function of time. Generally, this periodical function can be represented by a Fourier series of period T . For simplifying mathematic formulations but not losing generality, as an example, we consider this function is a sinusoidal function

$$\mathbf{y}(t) = \hat{\mathbf{y}} \sin(\omega t + \hat{\phi}), \quad \dot{\mathbf{y}}(t) = \hat{\mathbf{y}} \omega \cos(\omega t + \hat{\phi}), \quad \omega = \frac{2\pi}{T}, \quad (16)$$

where $\hat{\mathbf{y}}$ and $\hat{\phi}$ denote the amplitude and phase angle, ω is a frequency corresponding to the period. From Eq. 16, it follows that GPE and GKE respectively are

$$\begin{aligned} E &= \frac{1}{2} \sin^2(\omega t + \hat{\phi}) \hat{\mathbf{y}}^T \hat{\mathbf{y}} = 2\hat{E} \sin^2(\omega t + \hat{\phi}), & \hat{E} &= \frac{\hat{\mathbf{y}}^T \hat{\mathbf{y}}}{4}, \\ K &= \frac{1}{2} \cos^2(\omega t + \hat{\phi}) \hat{\mathbf{y}}^T \hat{\mathbf{y}} \omega^2 = 2\hat{K} \sin^2(\omega t + \hat{\phi}), & \hat{K} &= \frac{\hat{\mathbf{y}}^T \hat{\mathbf{y}}}{4} \omega^2 = \omega^2 \hat{E}. \end{aligned} \quad (17)$$

Energy flow characteristics of periodical orbits of NDS

Based on the definition of periodical orbits governed by Eq. 1, if there exists a periodical orbit, the following energy flow characteristics must hold.

Time averaged GPE

$$\langle E \rangle = \frac{1}{T} \oint_S E dt = \hat{E}, \quad (18)$$

where \hat{E} is a positive constant representing the averaged distance of phase points on the orbit to the origin since E is positive and the motion repeats along the closed orbit.

Time averaged GPEF

$$\langle \dot{E} \rangle = \frac{1}{T} \int_{\hat{t}}^{\hat{t}+T} \dot{E} dt = \frac{E(\hat{t}+T) - E(\hat{t})}{T} = 0 = \frac{1}{T} \int_{\hat{t}}^{\hat{t}+T} \mathbf{y}^T \mathbf{f} dt, \quad (19-1)$$

since for the periodical orbit S , $\mathbf{y}(\hat{t} + T) = \mathbf{y}(\hat{t})$. If the vector field \mathbf{f} takes a form

$$\mathbf{f} = \mathbf{B}(\mathbf{y})\mathbf{y} = (\bar{\mathbf{E}} + \bar{\mathbf{U}})\mathbf{y}, \quad \bar{\mathbf{E}} = (\mathbf{B} + \mathbf{B}^T)/2, \quad \bar{\mathbf{U}} = (\mathbf{B} - \mathbf{B}^T)/2, \quad (19-2)$$

Eq. 19-1 requires the EFCFs of matrix $\bar{\mathbf{E}}$ not always being semi-positive or semi-negative in the period T .

Time averaged GKE

$$\langle K \rangle = \frac{1}{T} \oint_S K dt = \bar{K} = \frac{1}{2T} \oint_S \dot{\mathbf{y}} \cdot \dot{\mathbf{y}} dt = \frac{1}{2T} \oint_S \dot{\mathbf{y}} \cdot \boldsymbol{\tau} dt, \quad (20)$$

where \bar{K} is a positive constant, since GKE is not negative. From this result, when Eq.12 noticed, it follows that $\text{curl} \mathbf{f}$ must not vanish, so that Eq. 14 implies

$$\mathbf{U} \neq 0. \quad (21)$$

In a reverse case if Eq.21 holds, then Eq. 20 holds. Therefore, Eq. 21 is a necessary and sufficient condition for Eq. 20.

Time averaged GKEF

$$\langle \dot{K} \rangle = \frac{1}{T} \int_t^{T+t} \dot{K} dt = \frac{K(T+t) - K(t)}{T} = 0 = \frac{1}{T} \int_t^{T+t} \left(\frac{\partial K}{\partial t} + \dot{\mathbf{y}}^T \mathbf{E} \dot{\mathbf{y}} \right) dt, \quad (22-1)$$

For autonomous NDS, $\partial K / \partial t = 0$, from Eq. 10, it follows

$$\langle \dot{K} \rangle = \frac{1}{T} \int_t^{T+t} (\dot{\mathbf{y}}^T \mathbf{E} \dot{\mathbf{y}}) dt = \frac{1}{T} \int_t^{T+t} (\boldsymbol{\zeta}^T \boldsymbol{\Lambda} \boldsymbol{\zeta}) dt = \frac{1}{T} \int_t^{T+t} (\sum_{l=1}^n \lambda_l \zeta_l^2) dt = 0, \quad (22-2)$$

holds, implying that the EFCFs of NDS must not always be semi-positive or semi-negative in the period T .

Above equations are valid if existing periodical orbits of NDS, so that they are necessary conditions. Considering GPEF geometrically involves the distance of a phase point to the origin, we can confirm that for a periodical orbit curve, of which each point has its positive distance to the origin, so that Eq. 18 always is valid. Moreover, as discussed above, the condition in Eq. 21 can replace the Eq. 20, which implies that non-zero spin matrix of NDS is a necessary condition for its periodical orbits.

Theorem A necessary sufficient condition for NDS, governed by Eq. 1, having periodical orbits is that its spin matrix $\mathbf{U} \neq 0$ and there exists at least one closed curve with a corresponding period T , along which the time averaged GPEF and GKEF vanish. For autonomous NDS, the condition of time averaged GKEF can be replaced by that its EFCFs of energy flow matrix \mathbf{E} are always not semi-positive or semi-negative in the period T .

Examples

A linear system

As an example, we consider a system with one degree of freedom governed by equation

$$\ddot{x} + \alpha \dot{x} + x = f \cos t, \quad (23-1)$$

which can be rewritten in the form of phase space

$$\begin{bmatrix} \dot{x} \\ \dot{y} \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -1 & -\alpha \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} + \begin{bmatrix} 0 \\ f \cos t \end{bmatrix}, \quad (23-2)$$

with its Jacobian, energy flow, spin matrices and energy flow equation respectively as follows

$$\mathbf{J} = \begin{bmatrix} 0 & 1 \\ -1 & -\alpha \end{bmatrix} = \mathbf{B}, \bar{\mathbf{E}} = \begin{bmatrix} 0 & 0 \\ 0 & -\alpha \end{bmatrix}, \bar{\mathbf{U}} = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}, \dot{E} = -\alpha y^2 + y f \cos t, \dot{K} = \frac{\partial K}{\partial t} - \alpha y^2 = -\alpha y^2 - \dot{y} f \sin t. \quad (23-3)$$

The time averaged GPEF and GKEF of the system are respectively given by

$$\langle \dot{E} \rangle = \frac{1}{2\pi} \int_0^{2\pi} (-\alpha y^2 + y f \cos t) dt, \quad \langle \dot{K} \rangle = \frac{1}{2\pi} \int_0^{2\pi} (-\alpha y^2 - \dot{y} f \sin t) dt. \quad (23-4)$$

It is not difficult to obtain the EFCFs of the system

$$\bar{\lambda}_1 = -\alpha, \quad \bar{\lambda}_2 = 0, \quad (23-5)$$

implying they are semi-positive for $\alpha < 0$, semi-negative for $\alpha > 0$, and vanish when $\alpha = 0$. Based on the above results, we discuss its two cases as follows.

Non-forced case $f = 0$

For this case, the time averaged GPEF and GKEF have the values

$$\langle \dot{E} \rangle = \langle \dot{K} \rangle = \begin{cases} > 0, & \alpha < 0, \\ < 0, & \alpha > 0, \\ = 0, & \alpha = 0. \end{cases} \quad (23-6)$$

As shown in Fig. 4, from this result it follows that the system is a divergence one when $\alpha < 0$, due to time averaged GPEF and GKEF are always increasing and the orbit tends to infinite; while it is a converged one when $\alpha > 0$, the orbit tends to the origin of phase space. There are no periodical orbits for non-zero values of parameter α although the spin matrix of the system is not zero. Also, EFCFs are semi-positive or semi-negative which do not satisfy the conditions in

Theorem. When $\alpha = 0$ the system has its periodical orbit of radius $\rho = \sqrt{x_0^2 + y_0^2}$ depending on the initial condition (x_0, y_0) shown in Fig.4.

Figure 4: The orbits of 1-DOF system affected by the damping parameter α and external force f .

Forced case $f \neq 0, \alpha > 0$

For this case, since the system is linear, we know the solution of system is

$$x = \rho \sin t, \quad y = \rho \cos t, \quad (23-7)$$

so that its time averaged GPEF and GKEF calculated by using Eq. 23-4 are

$$\langle \dot{E} \rangle = \frac{1}{2\pi} \int_0^{2\pi} (-\alpha \rho^2 \cos^2 t + \rho f \cos^2 t) dt = \frac{-\alpha \rho^2 + \rho f}{2} = \langle \dot{K} \rangle = \frac{1}{2\pi} \int_0^{2\pi} (-\alpha \rho^2 \cos^2 t + \rho f \sin^2 t) dt. \quad (23-8)$$

Therefore, both GPEF and GKEF vanish when $\rho = f/\alpha$, in which the work done by the external force is dissipated by the damping of the system and the system undergoes a periodical motion with radius $\rho = f/\alpha$ shown in Fig. 4.

Van der Pol's equation

Van der Pol's equation provides an example of an oscillation with nonlinear damping, its energy dissipated at large amplitude but generated at low amplitude. The governing equation of Van der Pol's system is given by

$$\begin{bmatrix} \dot{x} \\ \dot{y} \end{bmatrix} = \mathbf{B} \begin{bmatrix} x \\ y \end{bmatrix}, \quad \mathbf{J} = \begin{bmatrix} 0 & 1 \\ -1 - 2xy & -(x^2 - 1) \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} 0 & 1 \\ -1 & -(x^2 - 1) \end{bmatrix}, \quad (24-1)$$

from which, when Eq. 5 used, it follows

$$\mathbf{E} = \begin{bmatrix} 0 & -xy \\ -xy & -(x^2 - 1) \end{bmatrix}, \quad \mathbf{U} = \begin{bmatrix} 0 & 1 + xy \\ -1 - xy & 0 \end{bmatrix}, \quad \dot{E} = -(x^2 - 1)y^2, \quad \dot{K} = \dot{\mathbf{y}}^T \mathbf{E} \dot{\mathbf{y}} = -2xy\dot{x}\dot{y} - \dot{y}^2(x^2 - 1). \quad (24-2)$$

Figure 5: the periodical orbit of Van der Pol's equation.

To check if the time averaged GPEF and GKEF vanish in a possible closed orbit, we assume that

$$x = \rho \sin t, \quad y = \rho \cos t, \quad (24-3)$$

so that we obtain

$$\langle \dot{E} \rangle = \frac{1}{2\pi} \int_0^{2\pi} [-(\rho^2 \cos^2 t - 1)\rho^2 \sin^2 t] dt = -\frac{\rho^2}{2} \left(\frac{\rho^2}{4} - 1 \right), \quad (24-4)$$

$$\langle \dot{K} \rangle = \frac{1}{2\pi} \int_0^{2\pi} [2\rho^4 \sin^2 t \cos^2 t - \rho^2 \sin^2 t (\rho^2 \sin^2 t - 1)] dt = -\frac{\rho^2}{2} \left(\frac{\rho^2}{4} - 1 \right).$$

Therefore, when $\rho = 2$, the GPEF and GKEF vanish, which gives a periodical orbit. For matrix \mathbf{E} , its EFCFs are

$$\lambda_{1,2} = \{-(x^2 - 1) \pm \sqrt{(x^2 - 1) + 4x^2 y^2}\}/2, \quad (24-5)$$

of which one positive and another negative. These results satisfy the conditions in theorem. As shown in Fig. 5, the periodical orbit is a circle of radius $\rho = 2$, along which on the domain with $|x| > 1$, the energy flow $\dot{E} < 0$, while on the domain with $|x| < 1$, the energy flow $\dot{E} > 0$, and on the full circle the averaged energy flow vanishes.

A planar system

We investigate a planar system governed by

$$\dot{x} = xy, \quad \dot{y} = -y + x^2/2, \quad (25-1)$$

of which its Jacobian, energy flow and spin matrices respectively as

$$\mathbf{J} = \begin{bmatrix} y & x \\ x & -1 \end{bmatrix} = \mathbf{E}, \quad \mathbf{U} = 0, \quad (25-2)$$

so that there are no periodical orbits due to spin matrix vanishes. We can calculate the energy flow of the system, i.e.

$$\dot{E} = 3yx^2/2 - y^2, \quad (25-3)$$

of which its zero energy flow curves are

$$y = 0, \quad y = 3x^2/2, \quad (25-4)$$

as shown in Fig.6. Using the Eq. 24-3, the time averaged GPEF is calculated as follows

$$\langle \dot{E} \rangle = \frac{\rho^2}{2\pi} \int_0^{2\pi} \left(\frac{3\rho}{2} \cos^2 t \sin t - \sin^2 t \right) dt = -\frac{\rho^2}{2} \neq 0, \quad (25-5)$$

which indicates periodical orbits are impossible.

Figure 6: The zero energy flow curves of system shown by Eq. 25-1.

Conclusions

Energy flow theory with two scalars, GPE and GKE as well as the real symmetrical energy flow matrix \mathbf{E} and the real skew-symmetrical spin matrix \mathbf{U} is effectively used to investigate NDS in phase space. It is revealed that a necessary sufficient condition for NDS $\dot{\mathbf{y}} = \mathbf{f}(t, \mathbf{y})$ having periodical orbits is that there exist a non-zero spin matrix and a closed orbit with a corresponding period T , along which the time averaged GPEF and GKEF vanish. For autonomous systems with energy flow matrix \mathbf{E} the necessary condition for periodical orbits is its EFCFs not being semi-positive or semi-negative. Three examples, a damping / forced linear system, the Van der Pol's system, and a planar one, are presented to illustrate the revealed characteristics. The developed energy flow theory provides an important means to explore dynamic characteristics of various NDS.

New simple oscillator model describing ice-induced vibrations of an offshore structure

A. K. Abramian*, S. A. Vakulenko†

**Institute for Problems in Mechanical Engineering RAS, Saint Petersburg, Russia*

†*Institute for Problems in Mechanical Engineering RAS, Saint Petersburg, Russia*

Summary. In this paper a new simple oscillator model is considered describing ice induced vibrations of upstanding, water surrounded, and bottom-founded offshore structures. Existing models are extended by taking into account deformations of an ice floe, and a moving contact interaction between an ice rod, which is cut out from the floe, and the oscillator which represents the offshore structure. Special attention is paid to a type of ice-induced vibrations (IIV) of structures, known as frequency lock-in, and characterized by having the dominant frequency of the ice forces near a natural frequency of the structure. The instability onset, induced by resonance for the oscillator and generated by the ice rod structure interaction, is studied in detail.

Statement of the problem

Vertically-sided, bottom-founded offshore structures occasionally experience sustained vibrations due to drifting ice sheets crushing against them. Usually, three regimes of interaction are distinguished: intermittent crushing, frequency lock in, and continuous brittle crushing. In this paper, we introduce a mathematical model for a special type of ice-induced vibrations (IIV) of structures, known as frequency lock-in, and characterized by having the dominant frequency of the ice forces near a natural frequency of the structure. In this paper, we propose a model extending the previous ones, in particular, those suggested in [1, 2, 3, 4]. A novelty with respect to the previous investigations is that we study the ice deformations in more detail including nonlinear deformation. We describe deformations of the ice rod taking into account possible viscous ice behaviour, and a moving contact between the structure and the ice. Following [1, 2, 3, 4] we consider an offshore structure as a one-degree-of-freedom oscillator and the ice floe as a system of ice rods, whose properties include local failure. In particular, we consider a simple oscillator, which interacts with one of such rods. Considering only one rod we take into account the connections of this rod with the others following the approach suggested in [5]. In order to simulate the behavior of the structure during the frequency lock-in regime the condition was set that the ice should always be in contact with the structure. On the basis of this requirement the equation describing the simple oscillator dynamics is given by:

$$q_{tt} + \Omega^2 q + \alpha q_t = \mu, \quad (1)$$

where $q = q(t)$ is the oscillator displacement, $\Omega^2 = \frac{G}{M}$, where Ω is the oscillator frequency, and M and G are the mass and rigidity of the oscillator respectively, and $\alpha > 0$ is a positive damping coefficient. For (1) the following initial conditions are used:

$$q(0) = 0, \quad q_t(0) = 0. \quad (2)$$

The term μ in (1) defines a force which is acting on the oscillator due to the ice rod, and has the form

$$\mu = \frac{EF}{M} \left(u_x + \frac{\delta_0}{E} u_{xt} + u_x^2 \right) |_{x=q(t)}, \quad (3)$$

where $u = u(x, t)$ is the longitudinal ice rod displacement, E is an ice Young's modulus, F is the ice rod cross sectional area, and δ_0 is the ice internal, structural damping coefficient. The term u_x in the right hand side of (3) defines the contribution of linear deformations, and the term u_{xt} is the ice viscosity. The following equation describes the dynamics of the ice rod, which is defined on the semi-infinite domain $I_q = \{x : q < x < \infty\}$.

$$ru_{xx} - mu_{tt} + \delta_0 u_{xt} = Q, \quad (4)$$

$$Q = -\beta(s_t - u_t) - k_0(s - u), \quad (5)$$

where $u(x, t)$ is the unknown ice rod displacement, m is the ice rod mass per unit length, Q is a force occurring in the rod due to its side-surface contact with others ice rods in the space around the rod in the ice floe that is considered in (4). The ice floe is drifting along the x -axis. The parameters β, r, δ_0 , and k_0 are positive. The coefficient β is the ice friction coefficient during its side-surface contact, the coefficient r is the coefficient relating the shearing stress and the strain in the ice floe, and thus defines "the load spreading capacity of the foundation" according to [5]. The parameter k_0 characterizes the rod compression which is caused by stresses due to the ice rod compression in the transverse direction by other ice rods. In other words, the ice floe behavior can be modelled by a generalized spring and a generalized dashpot. The function $s(t)$ describes the shift of the ice rod, and $s(t)$ is defined by $s(t) = -vt + \rho(t)$, where $v > 0$ is the relative ice velocity, and $\rho(t) = \sum_{n=1}^{\infty} d_n H(t - t_n)$.

Here t_n are time moments when the ice rod crushes at $x = q(t)$; d_n are the lengths of ice blocks that split off, and $H(z)$ stands for the Heaviside step function. The time moments t_n are defined by the condition

$$p(t_n) = p_c, \quad (6)$$

that is, the pressure p in the ice periodically attains a critical level p_c . We introduce the following boundary conditions

$$u(q(t), t) = q(t), \quad u(x, t) \rightarrow 0, \quad \text{for } x \rightarrow +\infty. \quad (7)$$

The first one is a contact relation between the ice rod and the oscillator, and the second one is a radiation condition at infinity. The initial conditions are given by

$$u(x, 0) = \phi_0(x), \quad u_t(x, 0) = \phi_1(x), \quad x \in (q(0), \infty), \quad (8)$$

where $\phi_j(x)$ are fast decreasing functions in x for $x \rightarrow \infty$.

Figure 1: The dependence of the equilibrium amplitude A on the ice rod speed v for the dimensionless parameters $k_0 = 25$, $d = 1$, $\beta = 0.2$, $\bar{\alpha} = 4$, and $\delta_0 = 0.1$.

Conclusions

In this paper, a new model is proposed to describe the interaction between an ice-rod and an oscillator. This model takes into account deformations of the ice floe. The model is analytically investigated by asymptotic methods. It is shown that the contact interaction between the oscillator and the ice rod leads to resonances. The main resonance between the oscillator and the external load occurs when the natural frequency Ω of the oscillator is close to the external load frequency ω . We also find a new mechanism for the oscillator's behavior which can be described by a resonance between the external load, the oscillator, and the part of the ice rod (boundary layer) inducing an oscillator-ice rod interaction during the rod's motion with speed v . We show that ice rod deformation patterns arise which are generated by an interaction between the oscillator and the rod. This ice rod deformation is exponentially decreasing along the ice rod length. We obtain a plot describing how the oscillator's amplitude A depends on the ice velocity v . For some parameter choices this plot shows a significant peak for the amplitude A . For small rod-speeds v we have a small oscillation amplitude A , as well as for large v . The height and width of the peak depend on the system parameters.

Summary. Vortex-induced vibrations of a flexible pipe, with pinned-pinned ends and straight initial configuration, are considered in this work in a number of linear and nonlinear velocity profiles, varying along the length of structure. Krenk-Nielsen [1] and Van der Pol wake oscillators are employed in order to simulate fluctuations of the fluid forces, while the structure is modelled using the Euler-Bernoulli beam. Trajectories, time histories, multi-mode lock-in are studied using the case parameters, previously investigated by [2].

Introduction

Vibrations of flexible structures remain a vital problem for the safety of oil and gas subsea production systems. Application of fluid oscillators is one of the modern ways to improve the current prediction capabilities and study the complex multi-mode vibration mechanism. The focus of this work is on the near-resonant velocity profiles and resulting behaviour of the vertical flexible structure.

Flexible riser model

The structure with pinned-pinned ends, previously studied in uniform flow in 2D in [3], is subjected to sheared flow, and the approximate solution is obtained using the method described in [4]. Approximation for sheared flow is developed using integration of the velocity profile along the length of the riser. The reduced order non-dimensional model for i th mode is as follows:

$$\begin{aligned}
 \ddot{X}_i + 2a \sum_{n=1}^N \dot{X}_n \Theta_{ni} + \omega_{rn}^2 X_i &= \frac{W_w}{Lm_*\omega_0^2} \sum_{n=1}^N X_n \Phi_{ni} + \frac{a}{2\pi St} \Lambda_i + \frac{b}{4\pi St} \sum_{n=1}^N w_n \Gamma_{ni} - b \sum_{n=1}^N \sum_{m=1}^N w_n \dot{X}_m \Delta_{nmi} + \\
 &+ \frac{c}{2} \sum_{n=1}^N \sum_{m=1}^N q_n \dot{Y}_m \Delta_{nmi} + 2\pi Sta \sum_{n=1}^N \sum_{m=1}^N \dot{X}_n \dot{X}_m \Pi_{nmi} + \pi Sta \sum_{n=1}^N \sum_{m=1}^N \dot{Y}_n \dot{Y}_m \Pi_{nmi}; \\
 \ddot{Y}_i + a \sum_{n=1}^N \dot{Y}_n \Theta_{ni} + \omega_{rn}^2 Y_i &= \frac{W_w}{Lm_*\omega_0^2} \sum_{n=1}^N Y_n \Phi_{ni} - \frac{b}{2} \sum_{n=1}^N \sum_{m=1}^N w_n \dot{Y}_m \Delta_{nmi} + \frac{c}{4\pi St} \sum_{n=1}^N q_n \Gamma_{ni} - \\
 &- c \sum_{n=1}^N \sum_{m=1}^N q_n \dot{X}_m \Delta_{nmi} + 2\pi Sta \sum_{n=1}^N \sum_{m=1}^N \dot{X}_n \dot{Y}_m \Pi_{nmi}; \\
 \ddot{w}_i - 2\varepsilon_{x1} \sum_{n=1}^N \dot{w}_n \Theta_{ni} + 2\varepsilon_{x2} \sum_{n=1}^N \sum_{m=1}^N \sum_{l=1}^N \dot{w}_n w_m w_l \Xi_{nml} + 2\varepsilon_{x3} \sum_{n=1}^N \sum_{m=1}^N \sum_{l=1}^N \dot{w}_n \dot{w}_m \dot{w}_l B_{nml} + 4 \sum_{n=1}^N w_n \Gamma_{ni} &= A_x \ddot{X}_i; \\
 \ddot{q}_i - \varepsilon_y \sum_{n=1}^N \dot{q}_n \Theta_{ni} + \varepsilon_y \sum_{n=1}^N \sum_{m=1}^N \sum_{l=1}^N \dot{q}_n q_m q_l \Xi_{nml} + \sum_{n=1}^N q_n \Gamma_{ni} &= A_y \ddot{Y}_i,
 \end{aligned} \tag{1}$$

where

$$X(\zeta, \tau) = \sum_{n=1}^N X_n(\tau) \tilde{X}_n(\zeta); \quad Y(\zeta, \tau) = \sum_{n=1}^N Y_n(\tau) \tilde{Y}_n(\zeta); \quad w(\zeta, \tau) = \sum_{n=1}^N w_n(\tau) \tilde{w}_n(\zeta); \quad q(\zeta, \tau) = \sum_{n=1}^N q_n(\tau) \tilde{q}_n(\zeta).$$

Here, τ is non-dimensional time, $\zeta = \frac{z}{L}$ is location of considered cross-section of the beam (where z represents the axial coordinate), $\tilde{X}_n(\zeta)$, $\tilde{Y}_n(\zeta)$, $\tilde{w}_n(\zeta)$, $\tilde{q}_n(\zeta)$ are sinusoidal functions, X_i and Y_i constitute in-line and cross-flow displacements multipliers, w_i and q_i are wake coefficients multipliers, Ω_R is vortex shedding frequency, St is Strouhal number, ε_{x1} , ε_{x2} , ε_{x3} , ε_y are dimensionless wake oscillator damping coefficients, A_x , A_y are empirical coupling coefficients, a , b , c are dimensionless coefficients depending on the initial drag, fluctuating drag and lift coefficients respectively, N is total number of modes considered, ω_{ni} is the i th natural frequency, ω_0 is reference frequency, m_* is mass per unit length (including structural mass and fluid added mass), W_w is weight of structure per unit length. Dimensionless coefficients Λ_i , Θ_{ni} , Φ_{ni} , Γ_{ni} , Δ_{nmi} , Π_{nmi} , B_{nml} , Ξ_{nml} represent interaction of modes with numbers n, m, l . Among them, Λ_i , Θ_{ni} , Γ_{ni} , Δ_{nmi} , B_{nml} , Ξ_{nml} constitute the difference with the uniform flow model [3] and account for the velocity/vortex shedding frequency profile integrated along ζ , e.g. $\Theta_{ni} = 2 \int_0^1 [\sin(n\pi\zeta) \sin(i\pi\zeta) St U_R(\zeta)] d\zeta$. In this work, the dynamics of the vertical flexible structure is studied using 5 mode approximation, where reduced velocity is defined based on the first natural frequency measured in [2].

Results

Five sheared flow velocity profiles were considered in the current study where the flow velocities lie in the proximity of the first few natural frequencies of the flexible structure, including reduced velocities $U_R = 5.0$ and $U_R = 10.0$, as shown in Fig. 1a. In this example, constant velocity profile with $U_R = 5.0$ results in the highest in-line and cross-flow displacement amplitudes observed in the bottom part of the structure, as illustrated in Figs 1c and 1d. Structural motion under this constant uniform velocity and under the parabolic profile with the maximum reduced velocity $U_R = 5.0$ show response of 4 modes. The parabolic profile with the maximum reduced velocity $U_R = 10.0$ leads to the most symmetric displacement amplitudes, relatively $\zeta = 0.50$ with three more significant medium peaks. Linearly varying profiles result in the increased displacements in the cross-sections subjected to the increased flow velocity, however, the profile with the velocity growing towards the top of structure leads to higher maximum amplitudes in both in-line and cross-flow directions. Fig. 1b provides two samples of multi-frequency cross-flow displacement signals at the cross-section of $\zeta = 0.33$ with the largest amplitudes demonstrated under the flow of constant velocity.

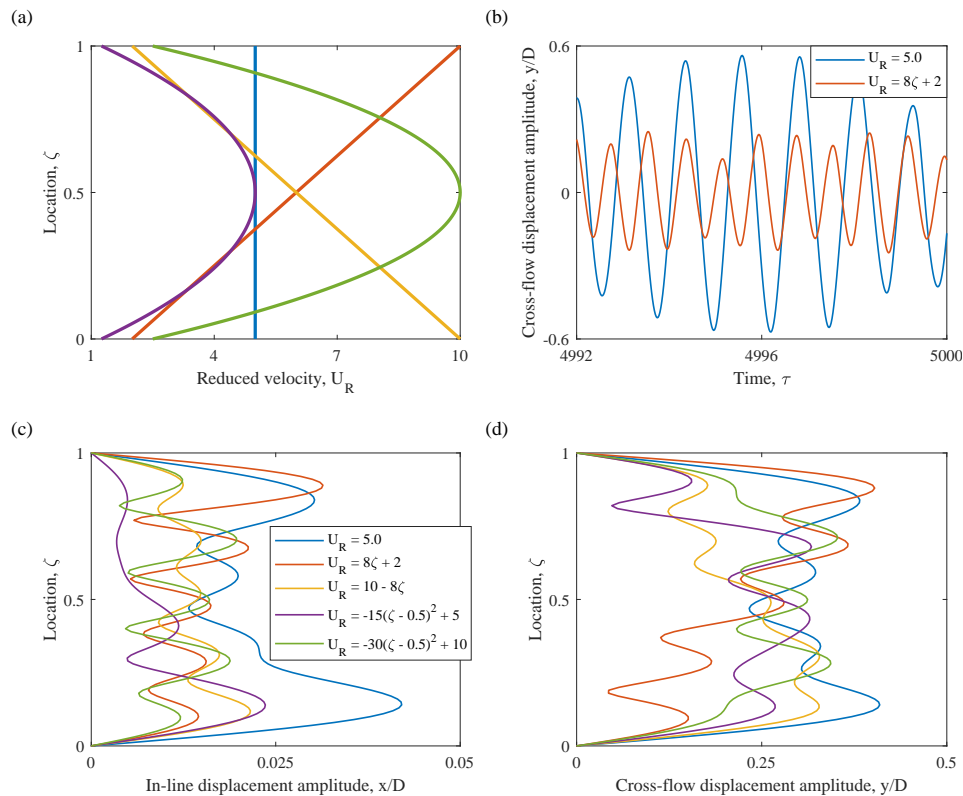

Figure 1: Dynamics of a vertical flexible structure predicted by the 5 mode approximation: (a) five considered velocity profiles shown in terms of the reduced velocity and the length of structure; (b) time histories of the largest and smallest cross-flow displacement amplitudes at $\zeta = 0.33$; (c) in-line and (d) cross-flow displacement amplitude variation along the length of structure.

Conclusions

Results of the flexible structure dynamics simulations for a number of linear and nonlinear sheared flow profiles are presented in this work, using 5 mode approximation obtained in a similar way as was done in the previous studies for uniform flows [3, 4]. The novelty of this model formulation is in the coefficients representing mode interaction and the integrated velocity profile. Multi-mode lock-in is considered in details, and the highest displacement amplitudes are predicted to occur under the influence of linear velocity profiles including the limited cases of uniform flows.

Summary. In this work, we numerically explore the stochastic dynamics of inclined marine risers subjected to pulsating internal fluid flow. The presence of geometric nonlinearities with static deflection makes the response of the inclined riser different from conventional top tension risers when subjected to pulsating flows. At first, the riser model is solved via Galerkin method and validated using perturbation approaches. Then, we study the propagation of uncertainties i.e. amplitude and frequency of pulsations in the stochastic model revealing rich and complex dynamics features.

Introduction

Pulsating flow is a phenomenon that affects the oil and gas industries. It occurs due to abrupt perturbations and fluctuations in the internal fluid flow of the riser pipe which in return can affect and influence the vibrational motion of the structure. It occurs due to several reasons such as the nature of the multi-phase flow and sudden geometric changes [1]. Because the value of the excitation amplitude and frequency of fluctuation of the flow are uncertain i.e. stochastic, the influence of the flow can be sever especially if the frequency of these flows are near structural resonances of the riser making them prone to failure by fatigue.

Problem Formulation

The inclined riser to be analyzed in this work is under mid-plane stretching and subjected to static deflection [2] and pulsating internal fluid flow. Then, the equation that describes the motion of the riser in dimensionless form can be written as

$$\begin{aligned} & \frac{\partial^2 y_d}{\partial t^2} + \frac{\partial^4 y_d}{\partial x^4} + 2\sqrt{\beta}v \frac{\partial^2 y_d}{\partial x \partial t} + \sqrt{\beta} \frac{\partial v}{\partial t} (1-x) \frac{\partial^2 y_d}{\partial x^2} + c \frac{\partial y_d}{\partial t} + c_d \frac{\partial y_d}{\partial t} \left| \frac{\partial y_d}{\partial t} \right| + (v^2 - T + \sigma(1-x)) \left(\frac{\partial^2 y_d}{\partial x^2} \right) - \sigma \left(\frac{\partial y_d}{\partial x} \right) \\ & - \left(\eta \left(\int_0^1 \left(\frac{dy_s}{dx} \right)^2 dx + \int_0^1 \left(\frac{\partial y_d}{\partial x} \right)^2 dx + \int_0^1 2 \frac{dy_s}{dx} \frac{\partial y_d}{\partial x} dx \right) \right) \left(\frac{\partial^2 y_d}{\partial x^2} \right) - \eta \left(\int_0^1 2 \frac{dy_s}{dx} \frac{\partial y_d}{\partial x} dx + \int_0^1 \left(\frac{\partial y_d}{\partial x} \right)^2 dx \right) \left(\frac{d^2 y_s}{dx^2} \right) = 0 \end{aligned} \quad (1)$$

where y_d is the deflection of the riser along position x and time t , β is fluid mass parameter, σ is self-weight parameter, v is internal fluid flow velocity, η is nonlinear geometric parameter, c is structural damping, c_d is external fluid damping and T is the applied top tension. Due to flow fluctuations, the internal velocity is assumed to have the form $v = V(1 + \gamma \cos(\Omega t))$ where V is the magnitude of the internal velocity, γ is a detuning parameter between 0 and 1 and Ω is the excitation frequency. Equation (1) is solved via Galerkin method utilizing the procedures prescribed in [3] and [4] and validated using perturbation method defined in [5-7]. Next, we consider a probabilistic frame of work in which the amplitude γ and the excitation frequency Ω are random variables. Then, we study the influence of type of different probability distributions (PDF) on the dynamic response of the structure using Monte Carlo (MC) simulations with 2^{13} samples.

Numerical Results

At first, the deterministic model is analyzed. Due to the quadratic nature of the internal fluid flow, the excitation frequency is expected to occur at Ω and 2Ω because of the nature of the parametric excitation. The dynamic response of the lowest three modes is depicted in Fig.1

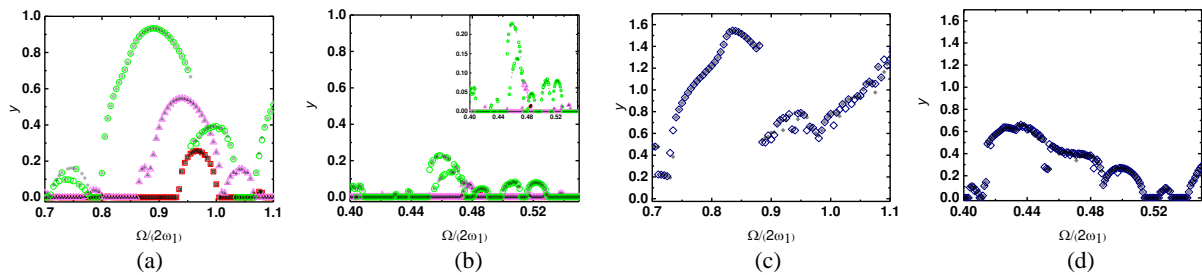

Figure 1: Multi-modal Frequency response curves around the first mode of vibrations for $V = \sqrt{\sigma}$, $c_d = 0.416$ at $x=0.48$. (a,b) Backward Sweep (\square) $\gamma = 0.25$, (\triangle) $\gamma = 0.50$, (\circ) $\gamma = 0.75$. The inset is magnified results for case (b). (c,d) (\diamond) $\gamma = 1$. Filled shapes denotes forward sweep.

We observe, in Fig. 1, the influence of the different components that exists in the system as a result of the interaction. The influence of the softening nonlinearity is less apparent due to the competing effects between the first mode and contributions from other modes that exist in the response. This is observed very well in Fig. 1b in comparison to other cases. In addition, the interaction of other resonances with the response of the solution near Ω and 2Ω become more visible at higher fluctuating velocity as the solution demonstrate chaotic behavior.

Next, we consider the stochastic response of the riser. The results from the MC method are divided into ten categories considering the two excitation frequency ranges and the combination of the distributions for the amplitude utilizing Beta and uniform distributions where they are applicable. As an example, we demonstrate the response of the riser under Beta distribution for excitation at a frequency of $\Omega/2\omega_1 = 0.464$ in Fig.2

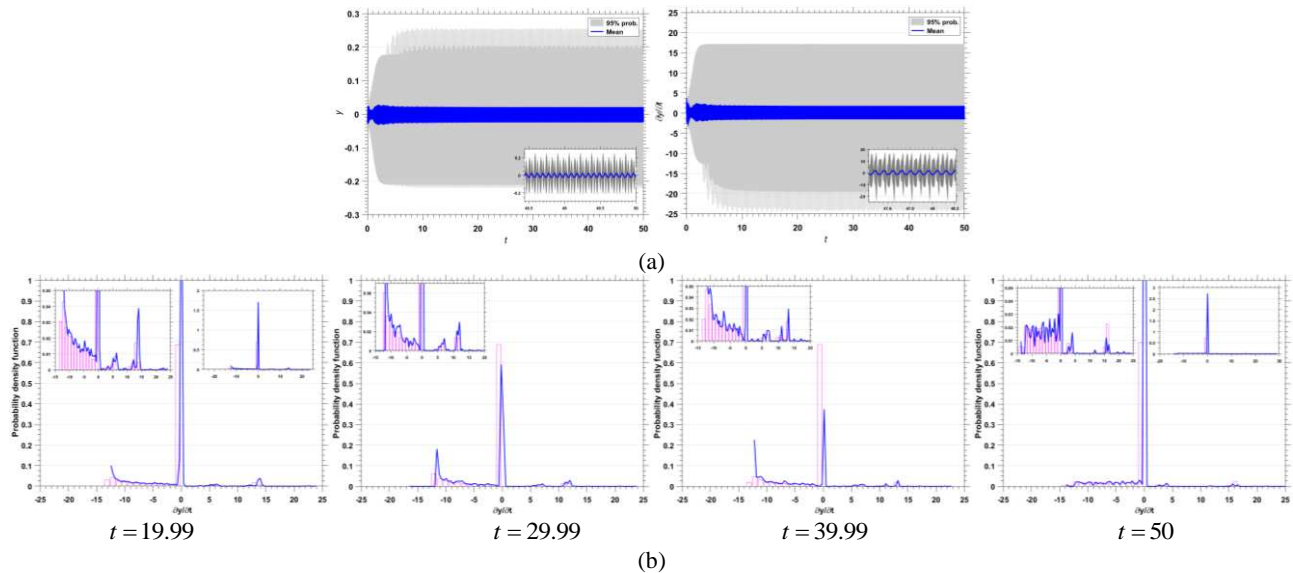

Figure 2: $\Omega/2\omega_1 = 0.464$ (a) Illustration of the nominal value (Blue line) and the 95 % envelop (grey shadow) of the displacement (left) and the velocity (right) of the riser. The box in each figure is a magnified response of the riser. (b) Evolution of the normalized probability density function as a function of the rise velocity at different times. The box in each figure is a magnified distribution of the probability density function.

The response of the riser displacement is exhibited on the left Fig. 2a and we plot the velocity in order to have a better representation of the riser response. The distribution influences type of response because at this frequency the riser excite not only secondary terms due to quadratic nonlinearity but also primary due the squaring of terms. Due to this fact, the mean value is observed to be superseded by different excitation amplitudes constituting the envelope. The propagation of the probability density function at different time interval demonstrate that it is stationary. The main feature is attributed to the primary excitation of the riser structure.

Conclusions

In this work, the stochastic dynamics of inclined risers is studied considering the influence of pulsating internal fluid flow. The presence of static deflection under the influence of geometric nonlinearity causes multiple resonances to exist. This influences the stochastic response of the riser examined under different distributions. As a result, the response of the riser in the Monte Carlo simulations revealed interesting complex and rich dynamic features

Solitary wave-like solutions in hyperelastic tubes conveying inviscid and viscous fluid

Vasily Vedeneev*

**Lomonosov Moscow State University, Moscow, Russia*

Summary. We study possible steady states of an infinitely long tube made of a hyperelastic membrane and conveying either an inviscid, or a viscous fluid with power-law rheology. The tube model is geometrically and physically nonlinear; the fluid model is limited to smooth changes in the tube's radius. For the inviscid case, we analyse the tube's stretch and flow velocity range at which standing solitary waves of both the swelling and the necking type exist. For the viscous case, we show that a steady-state solution exists only for sufficiently small flow speeds and that it has a form of a kink wave; solitary waves do not exist. For the case of a semi-infinite tube (infinite either upstream or downstream), there exist both kink and solitary wave solutions. For finite-length tubes, there exist solutions of any kind, i.e. in the form of pieces of kink waves, solitary waves, and periodic waves.

Introduction

Nonlinear waves in fluid-filled elastic tubes play an important role in problems of the cardiovascular system [1,7]. Solitary wave solutions are used for the analysis of pulse waves as well as for the study of the formation of aneurysms [3,4]. As a rule, such solutions are theoretically analysed without consideration of the fluid viscosity [2,5]. The goal of this study is to include the viscosity into account and to study its effect on solitary-wave-like solutions.

Figure 1: Cylindrical membrane tube in the initial and the deformed state.

Problem formulation and results

Governing equations

We consider a cylindrical membrane tube with a circular cross-section with a thickness of h and a radius of R , made of incompressible hyperelastic Gent material (Fig. 1). The ratio h/R is sufficiently small for the bending stresses to be neglected compared to the membrane stresses. The tube conveys a non-Newtonian viscous fluid whose rheology obeys a power law. We restrict ourselves to axisymmetric motion. In [2], a self-contained derivation of the exact equations of motion for the case of an inviscid fluid was given. We re-derive these equations and upgrade it by the viscous fluid forces taken into account. The fluid equations are considered in the formulation [9, 10]. With these assumptions, closed system of four differential equations is derived.

Analysis: inviscid fluid

If the fluid viscosity is neglected and the velocity is constant at each cross-section, the system of equation has four first integrals, as shown in [2]. We prove that the existence of these integrals retains if the velocity distribution is non-constant, but the viscosity is still neglected. The system of first integrals is reduced to a two-dimensional dynamic system, which is analysed by its phase plane (Fig. 2).

It is known [6] that for a quiescent fluid (or, equivalently, if a constant pressure is set in the tube) in a tube that is axially unstretched at infinity (axial stretch $\lambda_{10} = 1$), a standing solitary wave in the form of a localised swelling exists for a range of far-field circumferential stretches $1.18 < \lambda_{20} < 1.69$. We show that in the case of a moving fluid, there is a range of velocities ($0.063 \leq v_{f0} \leq 0.58$ for far-field radial stretch $\lambda_{20} = 1.5$), in which there exists, simultaneously with

Figure 2: Vector field and separatrices of the stationary saddle points for $\lambda_{10} = 1$, $\lambda_{20} = 1.5$, and $v_{f0} = 0.4$. General view (a), enlarged view in the area of the separatrix loops (b).

Figure 3: Swelling (a) and necking (b) solitary waves $\lambda_2(x)$ for $\lambda_{10} = 1$, $\lambda_{20} = 1.5$, and $v_{f0} = 0.4$.

Figure 4: Kink-like solution $\lambda_2(x)$ for infinite-length tube conveying viscous fluid.

the standing swelling solitary wave, a standing necking solitary wave. At a lower fluid velocity, there is only a swelling solitary wave; for larger velocities, no solitary waves exist. Note that in a model of a geometrically and physically linear tube, in which only the nonlinearity of the flow was taken into account [8], there always exists, for any nonzero flow velocity, only a standing necking solitary wave. Thus, both the existence of a standing swelling solitary wave and the limited range of fluid velocities for which a standing necking solitary wave exists are consequences of the physical and geometrical nonlinearities of the tube model.

Analysis: viscous fluid

When a viscous fluid moves, only two of the four first integrals exist, and the motion of the trajectory on the phase plane is accompanied by a simultaneous change of the vector field. First, we prove that there are limit stretch states of the tube as $x \rightarrow -\infty$ and $x \rightarrow +\infty$, with the stretches λ_1 and λ_2 tending to constants but the stresses tending to infinities to compensate for the fluid pressure and the longitudinal stress caused by the fluid viscosity, which are infinitely growing upstream and infinitely decreasing downstream. The transition between these limit states occurs in the central section of the tube and exists only if the fluid velocity is sufficiently small. In this case there is a unique solution linking the states at infinity in the form of a monotonic decrease in the radius downstream, i.e. a kink-like solution. Localised swelling or necking solutions for a tube that is infinitely long in both directions do not exist. However, such solutions exist if the tube is infinitely long in only one direction, either downstream or upstream. But solutions in which a semi-infinite tube has multiple neckings or swellings do not exist. For finite-length tubes, there exist ‘pieces’ of both swelling and necking solitary waves, as well as close-to-solitary-wave solutions with a finite number of successive swellings or neckings.
